## 1.0 Site Geology

### 1.1 General

The study area is underlain with unconsolidated and partly consolidated Atlantic Coastal Plain sediments. These sediments generally consist of unconsolidated to semi-consolidated layers of sand and clay; and semi-consolidated to very dense limestone and dolomite and can achieve thicknesses of about 5,500 feet. They range in age from late Cretaceous (approximately 100 million years old) to recent, or Holocene. The Atlantic Coastal Plain sediments overlie sedimentary strata and volcanics of Triassic age to early Jurassic age (approximately 230 million years old to about 170 million years old, respectively). These rocks overlie crystalline basement rocks of Paleozoic age (from 680 to 230 million years old) consisting of igneous intrusives and low-grade metamorphic rocks. The rock record is not continuous and time gaps exist where either no sediment deposition occurred or where erosional forces removed the rock record. In the project area, the post-Cretaceous sediments (those deposited within the last 65 million years) are estimated to be about 1,800 to 2,500 feet thick. These strata intersect a horizontal plane in a northeast to southwest trend and dip and thicken to the southeast. A discussion of the post-Cretaceous Atlantic Coastal Plain sediments follows, in descending order of occurrence. For the purpose of this discussion, the strata will be referred to based on time-rock units (i.e., rocks deposited during the same geologic time division).

### 1.2 Post-Miocene Units

The post-Miocene units consist of sediments deposited during the Pliocene, Pleistocene, and Holocene (recent) geologic ages (12 million years old and younger). These sediments are comprised of interbedded floodplain deposits of reworked alluvial and beach material and reworked Miocene sediments. Typically, these floodplain sediments are tan, gray, or greenish gray in color.

The post-Miocene unit sediments are found at the surface throughout the area. They consist of phosphatic, micaceous, and clayey sands of Pliocene age; feldspathic sands and gravels with clay beds of Pleistocene age; and varying mixes of clays, silts, sands, and gravels of Holocene age. There is very little fossil material in these sediments. In some areas, Pliocene and Pleistocene sediments may be missing from the geologic record. It is uncertain if these sediments exist within the project area.

The Holocene (recent) sediments generally consist of varying mixtures of clays, silts, sands, and, occasionally, gravels. Within the project area, these sediments are represented by low and high liquid-limit clays with varying amounts of sand and organic matter (CL and CH); inorganic, low and high liquid-limit silts (ML and MH); silty sands containing up to 40 percent silts, some clay and mica (SM); and cleaner, poorly graded sands containing less than 12 percent silts and clays (SP, SP-SM). The consistency of the fine-grained soils (silts and clays) can be described as very soft to soft. The coarse-grained soils (sands) can be described as very loose to dense, with the majority being

medium. The materials are somewhat cohesive when small amounts of silt or clay are present; however, they tend to slough below the water table when there is little fine material.

The Holocene materials are often associated with beaches and dunes. They were carried from topographically high areas from the Piedmont and upstream Coastal Plains and deposited during the formation of the floodplain of the Savannah River. The sediments are mixed by hydraulic action of the waters in the river and by erosion and redeposition of the riverbank and river shoals as the river meanders. There is no active method for sediment accumulation beyond the banks of the river. Consequently, with the exception of accumulations of organic material, there are no materials being deposited there.

Immediately below the Holocene Unit is the Pleistocene series of sediments. These sediments generally consist of arkosic sands and gravels with discontinuous lignitic and fossiliferous clay beds and overlying micaceous sands. These are underlain by the Pliocene sediments, which consist of phosphatic, micaceous, and clayey sands with limestone and dolomite beds. These sediment beds are thin and have not been regularly identified in the project area.

### **1.3 Miocene Units**

According to Clarke and others (1990), the Miocene units (20 to 12 million years old) can be subdivided into three sub-units (Miocene unit A, B, and C), each consisting of three geologically similar beds. The lowest bed of each sub-unit consists of a basal carbonate layer of sandy, phosphatic limestone or dolomite. A layer of interlaminated silty clay and clayey silt overlies the basal carbonate layer. The upper beds consist of sand layers of poorly sorted, very fine to granule-sized quartz sand with some phosphatic and dolomitic grains. Each three-bed unit is separated from the beds above and below it by an erosional surface, or unconformity. These layers are of importance because they form the primary confining layer for the principal artesian aquifer in the area.

The Miocene units at the project extend to a depth of about 220 feet in the upper reaches of the project area. They can achieve a thickness of about 470 feet along the coastal area, but range from about 60 to 175 feet thick under the project area. Miocene Unit C, the lowest unit, appears to be missing in the project area.

The beds of the Miocene were deposited during transgressions and regressions (rising and lowering) of the sea. The basal carbonates were deposited in open marine water during full transgressions. During this time, the land surface was at its greatest depth below the water surface. As the sea regressed, the interlayered silts and clays were deposited in a shallower, nearshore environment that allowed for the settling of the fine silts and clays. In this environment, coarser materials were already removed from the sediment and calcareous materials were not a major contributor. The upper sand beds were deposited in a shallow water, nearshore environment. At this time, the

water was at its shallowest. Materials deposited during the period the sea transgressed inland were, apparently, removed during some erosional event. As the next sea regression occurred, the next sequence of beds was deposited until the final sequence, Miocene Unit A, was deposited.

#### **1.4 Oligocene Unit**

Sediments of the Oligocene units were deposited between 35 and 20 million years ago. This unit can be as thick as 120 feet, and in some areas it is missing. The unit is estimated at approximately 60 thick under the project area, based on geophysical data.

The Oligocene unit sediments are typically tan colored limestones with varying amounts of micrite (dense, non-porous limestone), fine fossil foraminifera shells, and silt and clay-sized phosphate. The sediments were deposited in an offshore mounded carbonate bank environment, with some sand material being deposited where the bank nears the shore.

#### **1.5 Eocene Units**

Immediately below the Oligocene Unit are the Eocene Units. The Eocene sediments, deposited between 55 and 35 million years ago, are subdivided into three sub-units: the upper, middle, and lower Eocene Units. It is the source of the principal artesian aquifer in the Savannah area, the Floridan Aquifer.

##### **1.5.1 Upper Eocene Unit**

The upper Eocene Unit throughout most of the coastal area of Georgia consists of the massive, fossiliferous, Ocala Limestone. There is some glauconite at the base of the unit and an increase in clastic material in the northern coastal areas, including the project area. This unit is more than 200 feet thick throughout the coastal area, and achieves a thickness of 400 feet in some areas. These sediments were deposited in a warm, shallow water, nearshore carbonate bank environment, similar to the other Eocene units.

##### **1.5.2 Middle Eocene Unit**

The middle Eocene Unit is separated from the lower and upper units by erosional surfaces, or unconformities. It is lithologically similar to the lower unit, and can be distinguished based on the abundance of microfossils. The upper beds of this unit are more dolomitic than the upper beds of the lower unit and contrast with the lower limestone beds of the upper Eocene Unit. This unit can be up to 1,000 feet thick in some areas. At Hutchinson Island and Fort Pulaski, near Savannah, Georgia, the unit is 700 and 540 feet thick, respectively. This unit is most likely more than 700 feet thick in the study area. These sediments were deposited in an environment similar to that of the lower Eocene Unit.

### **1.5.3 Lower Eocene Unit**

This unit unconformably overlies the Paleocene unit below it. It consists of carbonate sediments, predominantly glauconitic limestones and dolomites, with sand beds in the upper part. These beds attain a thickness of up to 800 feet in the southern coastal area of Georgia but are only 120 to 180 feet thick in the project area. This unit was deposited in a nearshore warm, shallow, open marine environment.

### **1.6 Paleocene Unit**

Sediments of the Paleocene Unit were deposited between 65 and 55 million years ago. The Paleocene Unit in the northern coastal Georgia area consists of glauconitic sand, argillaceous sand, and medium to dark gray clays. The uppermost beds of the unit consist of a hard, sandy, glauconitic, fossiliferous limestone. The Paleocene Unit can be over 425 feet thick, but there is little data in the coastal area to develop accurate estimates in the project area. The Paleocene time marked the beginning of a regional sea transgression that lasted through the Eocene. The sediments represent marine to marginal marine, nearshore depositional environments. This unit unconformably overlies late Cretaceous age sediments.

## **2.0 Subsurface Investigations**

### **2.1 Background**

The Geology/Hydrogeology and HTRW Design Section, U.S. Army Corps of Engineers, Savannah District, has performed a number of subsurface investigations within the project area over the last 35 years. Several hundred borings have been drilled within and adjacent to the Savannah Harbor. The majority of these borings were along the north side of the channel and were drilled for the Savannah Harbor Widening and the Savannah Harbor Deepening projects, both completed at the end of the last century. These borings were constructed for the purpose of evaluating the in-situ materials within specific areas of the channel for harbor modification projects. The majority of the borings were water-borne; however, land-based borings have been completed to identify soil materials within the channel side slopes for the purpose of determining the most probable channel side slopes resulting for each proposed harbor modification. The investigations have used a variety of methods to obtain subsurface data, including Vibracore, splitspooning, coring, and sub-bottom sonic profiling. Standard penetration sampling using a split-barrel sampler was the method most often used. Using this method, a 1-3/8 inch inner diameter standard split barrel sampler was driven through the material using a 140-pound hammer with a 30-inch fall. The sampler was retrieved and the material was described in accordance with the Unified Soil Classification System. Selected samples were submitted for a variety of mechanical analyses, including grain size analysis, Atterberg limits, natural moisture content, and specific gravity calculations.

## 2.2 Procedures

The majority of the borings constructed within the channel were drilled from a floating barge using a variety of core drills to recover the samples. The barges were somewhat stabilized using steel spuds or anchors. They raised and lowered with the tide cycle. Drilling was very difficult off these platforms and often had to be terminated due to strong tides that would not allow the drill crew to maneuver the barge to a boring location. Wakes caused by high winds and ship traffic also greatly hampered the ability to drill from such a platform.

This drilling platform was also used to construct the Vibracore borings. This method involved vibrating a plastic tube through the subsurface soils to collect a sample that provided a more representative indication of the in-situ nature of the soils. This method could recover soft muds and loose sands that were often lost using standard penetration methods with a split-barrel sampler. However, this method generally did not penetrate stiff silts and clays or medium dense sands, or other materials exhibiting some degree of cementation, induration, or other characteristic of lithification. Also, this method did not provide adequate data that could be easily related to the relative strengths of the soils penetrated using other drilling methods.

During the mid 1980's, drilling was conducted using the U.S. Army Corps of Engineers self-elevating barge Explorer. This barge was a powered vessel that could maneuver on its own using twin diesel motors. It also had the ability to elevate itself above the water on three legs to eliminate the actions of the tide cycles and wave action. Drilling from this platform proved to be much more efficient and allowed the employment of more consistent drilling techniques. In addition, the Explorer allowed drilling in areas that were inaccessible to the standard barge due to rapid tide currents, deep water, and extreme distances from land.

## 3.0 Material Summary

### 3.1 General

The sediments underlying the project area are largely a result of varying depositional environments. As such, the sediments are discontinuous both vertically and horizontally and numerous variations occur over short distances. Boring logs completed for these investigations are included in Appendix A of this document. Analytical results of the mechanical analyses of the samples collected during these investigations are provided in Appendix B. The plans showing the locations of the borings are provided as Appendix D.

### 3.2 Soils

The uppermost sediments consist of varying mixtures of poorly-graded sands (SP), silty sands (SM), poorly-graded gravels (GP), organic silts (OH), low liquid-limit and high liquid-limit silts (ML and MH), clayey sands (SC), and low liquid-limit and high liquid-limit clays (CL and CH). Standard penetration tests from borings indicate the consistency of the fine-grained soils (silts and clays) range from very soft (0 to 4 blows per foot) to very dense (50 or greater blows per foot), while the coarse-grained soils (sands and gravels) range in consistency from dense (30 to 50 blows per foot) to very dense (50 or greater blows per foot). Typically, these soils vary in color from tan, gray, brown, light brown, and greenish to bluish gray. Generally, soils at the river bottom exhibit lower consistency than the deeper soils. The bottom soils are often very loose and semi-liquid and can extend from the bottom of the river channel to only a few inches to several feet deep.

The underlying soils consist of silty sands (SM), clayey sands (SC), high liquid-limit silts (MH), and low liquid-limit and high liquid-limit clays (CL and CH). Standard penetration tests indicate the consistencies of the fine-grained soils range from stiff (8 to 15 blows per foot) to hard (30 or greater blows per foot), while the coarse-grained soils range in density from dense (30 to 50 blows per foot) to very dense (50 or greater blows per foot). In general, these soils are characterized by a significant increase in blow counts, consistency, and cohesiveness. These soils are often described as gray, grayish green, green, and olive green.

### 3.3 Rock

Lenses of moderately hard to hard limestone have been encountered in borings constructed around the project area; however, its occurrence has been below the depths of concern for this project. In addition, borings drilled in 1969 identified compaction shale in the northern end of the channel, near Kings Island turning basin. This lithology has not been identified in any of the more recent borings and this material may be analogous to the greenish-gray to olive green, stiff to hard, fat silts and dense to very dense silty sands that have been described in later borings.

A high resolution, sub-bottom acoustic survey was performed in the channel during the early 1990's as part of the investigation program for the recently completed harbor deepening. This survey showed an area of high acoustic impedance within the middle channel (stations 70+000 to 24+000). Borings drilled in this area and subsequent dredging indicated this material was similar to the greenish-gray to olive green, stiff to hard, fat clays and dense to very dense silty sands described above.

Thin layers of rock were identified in a boring constructed in 2002 at the interface between the post-Miocene sediments and the top of the Miocene. The layer was no more than a few centimeters thick and was a green, fine-grained, sandstone. These more recent borings also describe black gravels and oblong rock fragments within the Miocene sediments, consistent with the geological descriptions of the phosphatic materials within the Miocene sediments provided above in Section 1.3. These materials were encountered both within and below the project depth.

## **4.0 Radiological Screening**

### **4.1 Purpose**

The Savannah Harbor Deepening project area is located downstream from the Savannah River Site, where radioactive materials are processed. Releases of radioactive materials from the site have been documented over the years, raising concern as to whether such releases could cause accumulation of these materials within the sediments that are to be removed from within the project area. The likelihood of this occurring has been considered improbable; nevertheless, a decision was made to screen selected sediment samples that were collected during the 2002 investigations for gross radioactivity.

### **4.2 Procedures**

All samples collected during the 2002 subsurface investigations were placed in sample jars, labeled, inventoried, boxed, and shipped to the Savannah District Army Corps of Engineers' Environmental and Materials Unit located in Marietta, Georgia. Initially, the entire stack of sample boxes was screened, and then selected individual samples. Prior to performing the analyses described in Section 2.1, above, randomly selected jar samples from every boring hole was screened for gross radioactivity. This process involved using a Bicron Geiger Mueller gauge equipped with a pancake probe. The probe was placed approximately 1 centimeter above the soil samples, and the highest reading was recorded. Readings were also collected from around the facility to determine ambient background levels.

### **4.3 Results**

All results were measured in milli-Rems per hour (mRem/hr). Background values varied between 0.01 and 0.03 mRem/hr. Values from the sediment samples ranged from 0.02 to 0.04 mRem/hr. These results are consistent with the background values, with only a few samples exhibiting an increase of 0.01 mRem/hr over the background range. This should be anticipated, since these soils contain phosphatic and glauconitic minerals, along with other clays, that exhibit naturally-occurring levels above background levels. These results are two magnitudes below acceptable action levels approved by OSHA and the EPA that range between 1 mRem/hr and 5mRem/hr. Based on these results, it is believed that the levels of gross radioactivity measured in the samples is naturally occurring and poses no hazards to the environment.

## **5.0 Possible Effects of the Project on Ground Water**

In the past, any proposed deepening of Savannah Harbor has raised questions about the possible effects this action would have on the confining layer of the principal artesian aquifer, known as the Floridan aquifer, and, ultimately, on the aquifer itself.

In light of some of the seemingly conflicting data, additional information was needed to adequately assess the possible effects of a deepened channel on the Upper Brunswick aquifer (as described by Clarke and others, 1990) and the Upper Floridan (principal artesian) aquifer that underlies the entire project area. It was decided that further studies should be conducted to verify the generalized data available from previous studies (mentioned above) of these aquifers. These studies would look at the potential impacts to the confining layer due to removing some confining and relict stream channel material. The results of these additional studies completed to date are provided in a separate document. Additional studies have yet to be completed. They are planned for completion in 2004.

## **6.0 Additional Geotechnical Requirements**

Changes in channel geometry due to deepening, widening, realignment, slope stability, or feature avoidance require re-evaluation of existing data. As channel geometry continues to change, older geotechnical data is no longer adequate to evaluate these changes for a number of reasons. One concern is that there may be an insufficient number of borings located in areas that were naturally deeper than proposed project depths but no longer are. Another concern is that older borings, drilled for a much shallower project, were completed at depths that are shallower than proposed project depths. Also, as channels become deeper to accommodate larger vessels bend widenings are often added in areas that have not been previously investigated. These concerns were considered prior to the performance of the investigations conducted for the re-evaluation of this project. However, as additional changes in channel geometry are identified these concerns will be re-evaluated and additional subsurface investigations will be required.
