ARE "SUPERWEEDS" AN OUTGROWTH OF USDA BIOTECH POLICY? (PART II)

THURSDAY, SEPTEMBER 30, 2010

HOUSE OF REPRESENTATIVES,
SUBCOMMITTEE ON DOMESTIC POLICY,
COMMITTEE ON OVERSIGHT AND GOVERNMENT REFORM,
Washington, DC.

The subcommittee met, pursuant to notice, at 2:04 p.m., in room 2203, Rayburn House Office Building, Hon. Dennis J. Kucinich (chairman of the subcommittee) presiding.

Present: Representatives Kucinich, Watson, and Towns.

Staff present: Jaron R. Bourke, staff director; and Justin Baker, clerk/policy analyst.

Mr. KUCINICH. Good afternoon. The subcommittee will come to order. I want to note that usually we're joined by many Members of Congress, but late last night they had a get-out-of-dodge moment. And most Members are now back in their home constituency, a place that I intend to be in a few hours. But I am very pleased that all of you are here for this important hearing. The Subcommittee on Domestic Policy on the Committee on Oversight and Government Reform is now in order.

Today's hearing is the second day of the first hearing held by Congress to examine the environmental impact of the evolution of herbicide-resistant weeds in fields growing genetically engineered herbicide resistant crops. But for years, farmers have struggled with the impact. Across the Midwest and south, farmers growing Roundup Ready soy, corn and cotton have been encountering more and more kinds of weeds that Roundup herbicide cannot control.

That weed resistance costs farmers money and causes them to resort to more and more toxic pesticides. Please look at the monitors for an excerpt from an ABC News segment that ran last year. Staff, play that segment.

[Video shown.]

Mr. KUCINICH. Thank you. What responsibility for preventing and lessening the environmental impact of Roundup-resistant weeds and the consequent impact on farmers does the Federal Government have? Today we will hear from government regulators and others on that question. Now without objection, I'm going to continue with an opening statement of 5 minutes, any Member or witness who wishes to submit a written statement or extraneous materials for the record will have 5 legislative days to do so, without objection.

And in our previous hearing in July, we heard from weed scientists that Roundup-resistant weeds have infested between 4 and 11 million acres of prime farmland in the southeast and Midwest.

Mr. Chairman, welcome. This is the chairman of the full committee, Mr. Towns. Thank you for being here.

While a phenomenon of natural selection for herbicide resistant—resistance is not new, the acceleration in a number of resistant weed species, and especially the infested acreage, is new. And it's been caused by the commercialization of multiple Roundup-resistant crop systems. In only the last decade, eight or nine species of weeds have rapidly evolved resistance to Roundup in herbicide resistant crop fields. Indeed, Roundup resistance in weeds has been known since the year 2000 when Roundup-resistant horseweed, a weed species that had not been previously resistant to Roundup, was discovered in Roundup-Ready crop fields in Delaware.

While scientists have validated what farmers were discovering in their fields, the Nation's lead regulator of genetically engineered crops, the U.S. Department of Agriculture, has been looking the other way. Every time a pesticide company petitioned the USDA to deregulate a new herbicide-tolerant variety of crop, USDA determined that the introduction of the new crop would have "No significant impact" on the farming environment. But recently the Department's indifference to the indirect consequences of their deregulation of Roundup-resistant crops has caught the attention of two Federal District Court judges. They independently struck down the USDA's deregulation of Roundup-Ready alfalfa, and Roundup-Ready sugar beets.

They found USDA to have unreasonably and arbitrarily dismiss the environmental consequences of deregulating genetically engineered crops. In one instance, the judge found that USDA could produce no written record that it had ever considered the impact on farmers. Nevertheless, Roundup-resistant weeds are hurting farmers. They are imposing $1 billion in additional weed control costs. They threaten cotton growing so profoundly that they've been compared to the boll weevil.

And the solution may be worse than the problem. To combat Roundup-resistant weed proliferation, the pesticide industry recommends to farmers that they use more and more toxic pesticides on newly engineered crops that will be tolerant of those more toxic pesticides. That will surely lead to more environmental pollution, and, as we shall see, the collateral damage of crop destruction, and even more costs to farmers.

In today's hearing, we will show that the USDA's passivity lies in stark contrast to the EPA's active approach in preventing pest resistance to genetically engineered crops it regulates. We will show that the USDA's legal authority is no less broad than EPA's legal authority. However, USDA views its broad authority much too narrowly, while EPA used its broad authority appropriately.

Which approach has the better track record? Passive and self-constrained, USDA's approach has plainly allowed the proliferation of herbicide-resistant weeds. In contrast, EPA's record of prevention is a relative success.

Perhaps we are at a crossroads for USDA's policy of passivity toward superweeds, having been reversed by two Federal judges with

scores of farmers needing relief from the cost and consequences of superweeds. And with a new administration determining policy at the Department, it may finally be the time there for the Department of Agriculture to reexamine its approach to the deregulation of the genetically engineered crops, and to make a change in policy.

It should be a change that would help prevent the proliferation of herbicide resistant weeds. It should be a change that would preserve efficacy of a relatively benign herbicide. It should be a change that would deescalate the trend to more and more toxic pesticides. It should be a change that would pass muster with Federal courts. It should be a change that would protect the long-term interest of farmers, consumers and the natural environment.

The chair recognizes the distinguished chair of the full committee, Mr. Towns of New York. I appreciate your being here, Mr. Towns, and I appreciate the leadership that you provide on the full committee.

[The prepared statement of Hon. Dennis J. Kucinich follows:]

Opening Statement of

Dennis J. Kucinich
Chairman
Domestic Policy Subcommittee
Oversight and Government Reform Committee

Hearing on

"Are 'Superweeds' an Outgrowth of USDA Biotech Policy? (Part II)"

September 30, 2010

In our previous hearing in July, we heard from weed scientists that Roundup resistant weeds have infested between 4 and 11 million acres of prime farmland in the Southeast and Midwest. While the phenomenon of natural selection for herbicide resistance is not new, the acceleration in the number of resistant weed species and especially the infested acreage is new, and it has been caused by the commercialization of multiple Roundup resistant crop systems. In only the last decade, eight or nine species of weeds have rapidly evolved resistance to Roundup in herbicide-resistant crop fields. Indeed, Roundup resistance in weeds has been known since 2000, when Roundup resistant horseweed, a weed species that had not been previously resistant to Roundup, was discovered in Roundup Ready crop fields in Delaware.

While scientists have validated what farmers were discovering in their fields, the nation's lead regulator of genetically engineered crops, the U.S. Department of Agriculture, has been looking the other way. Every time a pesticide company petitioned USDA to deregulate a new herbicide tolerant variety of crop, USDA determined that the introduction of the new crop would have "no significant impact" on the farming environment. But recently, the Department's indifference to the indirect consequences of their deregulation of Roundup resistant crops has caught the attention of two federal district court judges. They independently struck down USDA's deregulation of Roundup Ready Alfalfa and Roundup Ready Sugar beets. They found USDA to have unreasonably and arbitrarily dismissed the environmental consequences of deregulating genetically engineered crops. In one instance, the judge found that USDA could produce no written record that it had ever even considered the impact on farmers.

Nevertheless, Roundup resistant weeds are hurting farmers. They are imposing a billion dollars in additional weed control costs. They threaten cotton growing so profoundly that they have been compared to the boll weevil. And the solution may be worse than the problem. To combat Roundup resistant weed proliferation, the pesticide industry recommends to farmers that they use more and more toxic pesticides, on newly engineered crops that will be tolerant of those more toxic pesticides. That will surely

lead to more pollution and, as we shall see, the collateral damage of crop destruction and even more costs on farmers.

In today's hearing, we will show that USDA's passivity lies in stark contrast to EPA's active approach in preventing pest resistance to genetically engineered crops it regulates. We will show that USDA's legal authority is no less broad than EPA's legal authority. However, USDA views its broad authority much too narrowly, while EPA views its broad authority appropriately.

Which approach has a better track record? Passive and self-constrained, USDA's approach has plainly allowed the proliferation of herbicide resistant weeds. In contrast, EPA's record of prevention is a relative success.

Perhaps we are at a crossroads for USDA's policy of passivity toward superweeds. Having been reversed by two federal courts, with scores of farmers needing relief from the costs and consequences of superweeds, and with a new administration determining policy at the Department, it may finally be time for the Department of Agriculture to reexamine its approach to the regulation of genetically engineered crops and to make a change in policy.

It should be a change that would help prevent the proliferation of herbicide resistant weeds.

It should be a change that would preserve efficacy of a relatively benign herbicide.

It should be a change that would de-escalate the trend to more and more toxic pesticides.

It should be a change that would pass muster with federal courts.

It should be a change that would protect the long term interests of farmers, consumers and the natural environment.

Mr. TOWNS. I want to thank you, first of all, for holding this hearing. I want to thank the witnesses for being here. And I know that you realize the importance of it because the Congress is not even in session, and of course this hearing is still taking place because of the importance of it. And of course, I want to just thank my colleague for moving forward with it because, let's face it, this is a very, very important hearing and I think that sometimes we forget all about it in terms of how important it is in terms of farming and something that we sort of pushed aside.

I think it was Mr. Louis Perry, a cotton grower in Georgia whose family has been farming since 1830, told a reporter that herbicide resistant pigweed posed a lethal threat to cotton farming in Georgia. I mean, it talks about in terms of how important it is, so if we don't whip this thing, it's going to be like the boll weevil as it was pointed out. Of course, we have to make certain that we stay on top of it and stay focused.

I want to thank the gentleman who comes from an urban area that understands how important this is and spending time and focusing on it. So I want to let you know that from the full committee standpoint, we stand ready to support you in every way, but I'm happy to know that you're getting the message out, because it's important that we do so.

So again, thank you for taking time to be here even when the House is not in session, because you felt it was important to continue without cancellation and I want to salute you for that. Thank you and I yield back.

Mr. KUCINICH. Thank you very much for being here, Mr. Chairman. I want you to know that—well, it's true that I'm in a primarily urban area. There are a few small farms in the southern part of my district. But I became aware of this, in part, through meeting with farmers across the country during the time that I was campaigning nationally for the Democratic nomination. So I have had the chance to actually be on farms, talk to farmers about their concerns about the issues that are raised in this hearing today.

There are no additional opening statements, so our subcommittee is going to receive testimony from the witnesses before us today. I would like to start by introducing our panel. The Honorable Ann Wright, Deputy Under Secretary for marketing and regulatory programs at the U.S. Department of Agriculture. Previously, she served as senior policy advisor to Senate Majority Leader Harry Reid, on Agriculture Committee matters. Before joining the staff of Senator Reid, she was a lobbyist for Consumer's Union on energy and trade issues. Previously she worked with farmers and nonprofit organizations at the Sustainable Agriculture Coalition in Washington, DC, and served as a policy advisor on agriculture issues for Senator Paul Wellstone of Minnesota and Senator Paul Simon of Illinois.

Mr. Sid Abel, is the assistant deputy administrator for biotechnology regulatory service with the U.S. Department of Agriculture's Animal and Plant Health Inspection Service. In this role, he helps provide oversight of risk-based introductions of regulated genetically engineered biotechnology crops, as well as conducting

and providing oversight of broad environmental risk and impact assessments complaint with the National Environmental Policy Act.

Prior to this, he served as the associate director with the U.S. Environmental Protection Agency's Office of Pesticide Programs. He worked for the EPA in various capacities from 1989 to 2007. Mr. Abel will not deliver testimony, but will be available to answer subcommittee members' questions.

The Honorable James J. Jones is the principal deputy assistant administrator of the EPA's Office of Chemical Safety and Pollution Prevention. He is responsible for managing the day-to-day operations of the office, which implements the Nation's pesticide toxic chemical and pollution prevention laws. The Office has an annual budget of over $260 million, more than 1,200 employees. From 2003 to 2007 Mr. Jones served as a director of the office of pesticide programs. In this role he was responsible for the regulation of pesticides in the United States with a budget of approximately $150 million and 815 employees, making it the largest EPA headquarters program office. I want to thank each of the witnesses for appearing before the subcommittee.

It is the policy of our Committee on Oversight and Government Reform to swear in all witnesses before they testify. Now Mr. Able, even though you're not making an opening statement, I'm going to ask if you would agree to be sworn because your answers to your questions will put your testimony on the record. And I would ask that all the witnesses rise.

[Witnesses sworn.]

Mr. KUCINICH. Let the record reflect that each of the witnesses has answered in the affirmative.

I ask that each witness give an oral summary of his or her testimony to keep the summary under 5 minutes in duration. Your complete written statement is going to be included in the record. So what we want in 5 minutes is to try to get a sense of what you want to communicate to this committee. I would like to begin with Ann Wright, the first witness on the panel, please begin.

STATEMENTS OF ANN WRIGHT, DEPUTY UNDER SECRETARY, U.S. DEPARTMENT OF AGRICULTURE; SID ABEL, ASSISTANT DEPUTY ADMINISTRATOR, BIOTECHNOLOGY REGULATORY SERVICE, ANIMAL AND PLANT HEALTH INSPECTION SERVICE, U.S. DEPARTMENT OF AGRICULTURE; AND JIM JONES, DEPUTY ASSISTANT ADMINISTRATOR, OFFICE OF CHEMICAL SAFETY AND POLLUTION PREVENTION, U.S. ENVIRONMENTAL PROTECTION AGENCY

STATEMENT OF ANN WRIGHT

Ms. WRIGHT. Thank you, Mr. Chairman and Mr. Chairman. I appreciate the opportunity to be here today to discuss USDA's biotechnology regulatory programs and the issue of herbicide-resistant weeds. First, I would like to emphasize that at USDA, we support all forms of agriculture, including conventional, genetically engineered and organic crops to meet the Nation's and world's needs for security, energy production and the economic sustainability of farms. All three of those methods of production must be strong and viable. As the world population increases, the demand for food is

growing and the land available to farm is shrinking. We need innovative agriculture production systems to not only to maintain the competitiveness of the United States, but also to fulfill growing food needs. Biotechnology is just one tool to address those needs, but it's a critical one.

USDA's role in regulating the products of biotechnology is carried out in coordination with EPA and FDA. Through the Plant Protection Act, our animal, plant health inspection service regulates those products that may pose a plant pest risk, while EPA and FDA use their authorities to address the safety of our food supply and the safe use of pesticides.

USDA's biotechnology regulatory program, which has been in place since 1986, is rigorous and science based. Since the program began we have effectively overseen nearly 30,000 field trials at 86,000 locations and deregulated over 75 products. While our current biotechnology regulations have been effective in insuring the safe introduction of GE organisms, we are constantly learning from our experiences, reforming and refining our first rate program to protect American agriculture and the environment.

As part of those refinements, we are always looking at ways to improve our program. Chief among these is our effort to update our biotechnology regulations. USDA is examining the policy issue raised in over 66,000 comments that were submitted on our proposed regulations, with the goal of better positioning the agency to address new challenges while meeting current needs. Our biotechnology program has evolved as the number of environmental issues to be considered under NEPA has grown as well as in response to several NEPA-related lawsuits.

At the same time, it's important to remember that we have made thousands of regulatory decisions without legal challenge, and just as important, not one of our plant pest risk determinations have been overturned in court.

You also asked me to discuss how USDA approaches herbicide-resistant weeds in relation to GE crops. A key point is that while the consideration of the herbicide resistance in weeds under NEPA informs our decisionmaking, and we are fully committed to meeting our NEPA obligations, USDA's biotechnology regulatory decisions are ultimately based on plant pest risk, consistent with our authority under the Plant Protection Act.

It is also important to note that the development of herbicide resistance among weeds is natural and an evolutionary process. It is not exclusively associated with GE crops, and that GE crops provide many benefits, such as reduced pesticide use and decreased soil erosion thanks to no till farming. And we want to preserve those benefits.

We must also be cognizant that if we limit the use of herbicide tolerant crops, farmers will likely have to return to older, less environmentally friendly weed control methods.

Because herbicide resistance is an important issue for the agricultural community, USDA has multiple agencies engaged on the issue through research and education, as well as partnerships with outside groups and other Federal agencies. For instance, our National Institutes of Food and Agriculture's Competitive Grants Pro-

gram provided $4.6 million in 2009 research for the biology of weedy invasive species.

Further NIFA's extension outreach programs provide the connection between scientific research and its application on farms, the training sessions, field days and other outreach to growers.

USDA's Agricultural Research Service has nearly $4.4 million in herbicide resistant weed research in fiscal year 2010, which is part of $36 million it's dedicating to all weed science issues this year. And APHIS is partnered with the EPA and the Weed Science Society of America to better understand the extent of herbicide resistance in managed ecosystems as well as the methods being used to manage herbicide resistance in weeds.

We are fully committed to working with our partners to identify potential solutions and alternative techniques to address herbicide resistance. This will require a coordinated effort by everyone involved, the government, Congress, researchers, the agricultural community, technology and crop protection companies, and public interest groups. At USDA, we are looking at the broader context of herbicide resistance beyond just its relation to biotechnology. We look forward to working with our partners, including all in Congress. Together we are confident that we can find solutions that make sense.

Mr. Chairman, Mr. Chairman, thank you again for the opportunity to testify. I look forward to answering your questions.

[The prepared statement of Ms. Wright follows:]

Testimony of Ms. Ann Wright
Deputy Under Secretary for Marketing and Regulatory Programs
United States Department of Agriculture

Before the Subcommittee on Domestic Policy
of the
House Committee on Oversight and Government Reform

September 30, 2010

Thank you for the opportunity to be here today to discuss the U.S. Department of Agriculture's (USDA) biotechnology regulatory program, as well as the issue of herbicide resistant weeds. I am Ann Wright, Deputy Under Secretary of Marketing and Regulatory Programs. In this capacity, I oversee a broad array of issues within three USDA agencies, including the Animal and Plant Health Inspection Service (APHIS), which, among other things, regulates organisms derived through biotechnology. Additionally, several other USDA agencies are looking at herbicide resistant weed issues and I look forward to updating you on those efforts. Sidney Abel, Assistant Deputy Administrator of APHIS' Biotechnology Regulatory Services program, is joining me today.

First I would like to emphasize that at USDA, we support all forms of agriculture—conventional (including the use of genetically engineered (GE) products) and organic—to meet the nation's and the world's need for food security, energy production, and the economic sustainability of farms. As the world's population increases, the demand for food is growing and the land available to farm is shrinking. Innovation in agricultural production systems is vital to maintain the competitiveness of the U.S. agricultural sector and to help supply the world's food needs. This is why USDA is pursuing policies that promote the coexistence of conventional, organic, and GE crops. USDA believes that our future food security necessitates that all types of agriculture be able to coexist and thrive.

At the same time, it is critical that we ensure our regulatory oversight is consistent, effective, and science-based, that we are keeping pace with the latest scientific developments, and that we do so transparently. As you know, the Plant Protection Act authorizes USDA, through APHIS, to regulate the importation, interstate movement, and safe field testing of GE organisms that may pose a pest risk to plants. In regulating the products of biotechnology, APHIS works closely with the U.S. Food and Drug Administration and the U.S. Environmental Protection Agency (EPA). Together, we ensure that the development, testing, and use of the products of biotechnology occur in a manner that is safe for plant and animal health, human health, and the environment.

In March 2008, APHIS Administrator Cindy Smith updated this Subcommittee on a number of actions the Agency had taken to build a strong program for regulating the products of biotechnology. This included the development of more detailed environmental analyses, increased oversight of pharmaceutical and industrial crops, and the creation of a dedicated staff for compliance and enforcement. Today I would like to update you on more recent initiatives

that we are undertaking with our biotechnology regulatory program, as well as discuss activities we are undertaking to address herbicide resistant weeds.

USDA's Biotechnology Regulatory Program – A Constant Evolution

USDA's biotechnology regulatory program has been in place since 1986, and as I mentioned, we continue to evolve as the field of biotechnology grows and changes. Over time, we have developed a framework for regulating the products of biotechnology that is rigorous and science-based, and which serves as a model globally that encourages the safe and unimpeded trade in these products. Since the program began, APHIS has effectively overseen the safe adoption of products of biotechnology, with 26,000 field trials grown under our notification procedures and 3,000 field tests grown under the permitting process, encompassing field trials at 86,000 different locations. In addition, we have deregulated over 75 products in that time. While our current biotechnology regulations have been effective in ensuring the safe introduction of GE organisms, we're constantly learning from our experiences, reforming, and refining our first-rate program to protect American agriculture and the environment.

The broadest of these efforts is a comprehensive update to our current biotechnology regulations—to better position APHIS to address new challenges, as well as meet current needs in evaluating and addressing the plant pest or noxious weed risks associated with regulated GE organisms. We accepted public comments on the proposed regulatory changes for over 6 months and held 5 public meetings, resulting in over 66,000 public comments by the time the comment period closed last June. Many important policy issues were raised, and USDA's policymakers are currently examining those issues to determine how to proceed. Ultimately, we want to advance a rule that will continue to support innovation in biotechnology in a responsible way that provides farmers and consumers with safe and beneficial options.

In addition to our larger effort to improve our biotechnology regulations, we have made other changes to keep pace with innovation in this growing field. We have welcomed the critical looks taken by the Government Accountability Office and USDA's Inspector General, and have made improvements to our regulatory program consistent with their recommendations. We have addressed the majority of recommendations—many which were in line with ongoing Agency initiatives at the time—through efforts such as requiring additional information on field trials and enhancing tracking of inspections and field test reports.

Additionally, the 2008 Farm Bill included recommendations that APHIS had made and begun implementing in late 2007 to improve the management and oversight of regulated biotechnology products. A number of those recommendations are addressed in our proposed revisions to our biotechnology regulations. Others are ongoing, such as our partnership with the Association of Official Seed Certifying Agencies to examine isolation distances for field trials.

The Farm Bill also directed APHIS to take steps to ensure the quality and completeness of records and to develop standards for quality management and effective research. These and other issues are being addressed through our expanding Biotechnology Quality Management System (BQMS) Program—a voluntary compliance assistance program—to help biotechnology researchers and companies develop plans and manage their operations to comply with USDA's

biotechnology regulatory requirements. The program provides participating organizations with improved management capabilities for regulated activities, and requires internal as well as independent third-party audits to make sure that the quality management system is being followed at all levels of the organization. In 2009, five organizations representing large and small companies and university researchers participated in the BQMS pilot program and helped APHIS refine the program. We are now preparing to implement the refined BQMS program and are soliciting additional organizations to join. We are encouraging broad participation from large and small companies and academic research communities. We are also finalizing the BQMS audit standards and program requirements and have begun training our second cohort of participating organizations.

APHIS' biotechnology program has also evolved as more varied environmental issues have arisen that should be considered under the National Environmental Policy Act (NEPA), as well as in response to several NEPA-related lawsuits on APHIS regulatory decisions. However, it is important to point out that we've made thousands of regulatory decisions without legal challenge, and none of our plant pest determinations have been overturned in court. We have taken these decisions and built into our program process improvements to ensure that we fully document information pertaining to environmental issues so that we meet all environmental requirements.

We have also taken and continue to take other steps to improve the environmental review process within our biotechnology regulatory program. For example, Secretary Vilsack approved a reorganization of APHIS' biotechnology staff that includes the establishment of a new NEPA team that is devoted to preparing high-quality environmental documents to better inform our regulatory decisions.

As we move forward with making future reviews of the potential environmental issues associated with the regulatory requests before the Agency, APHIS will continue to use the best available scientific information, data, and expert advice to prepare the appropriate level of NEPA analysis. We consider each regulatory action on a case-by-case basis, in accordance with Council on Environmental Quality (CEQ) NEPA implementing regulations and the USDA and APHIS NEPA regulations and procedures. And we will continue to consult with EPA on our analyses related to requests to remove products from regulation, which currently include GE alfalfa and sugar beets. In these ongoing consultations, EPA provides valuable feedback to the Agency on its analysis and proposed alternatives. And we are receiving a positive response to our efforts—EPA, in a letter on our draft environmental impact statement (EIS) for alfalfa, indicated no objection to APHIS' determination to grant non-regulated status and rated the draft EIS as "Lack of Objections," which indicates EPA had no concerns regarding APHIS' determination.

Herbicide Resistance – Issues, Challenges, and USDA's Role

At USDA, we recognize that herbicide resistant weeds pose an important challenge. You've asked me to speak to the Subcommittee today about how USDA approaches this issue in relation to the regulation of GE crops. I'd like to lay out this relationship, and then discuss how we're looking at herbicide resistance more broadly within USDA.

First, the development of herbicide resistance among weeds is a natural and evolutionary process. Many weed species evolved resistance to a wide variety of herbicides long before the advent of GE crops, resulting from the common use of herbicides in agriculture for decades. This is not a new concern for agriculture and is not exclusively associated with GE crops. Any time an herbicide or any other weed control tactic is used continually—whether with GE or non-GE crops—it is going to put pressure on weeds to develop resistance. USDA understands that growers are being challenged by these issues, and that they're looking for guidance and assistance. And we want to help, which is why we have a number of initiatives underway that I'll mention shortly.

Second, we are committed to meeting our obligations under NEPA and are committed to performing the appropriate NEPA environmental reviews and seeking the views of the public on these issues. However, while the consideration of herbicide resistance in weeds under the NEPA process informs our decision making, USDA decisions on the regulation of GE crops are ultimately based on plant pest risk, consistent with our authority under the Plant Protection Act (PPA). Relatedly, I would like to clarify, in response to two questions the Subcommittee has asked me to discuss, that, because our regulatory decisions are ultimately based on plant pest risk under the PPA, 1) Herbicide resistance in weeds is not being addressed in APHIS' proposed revisions to its biotechnology regulations and, 2) APHIS has not considered alternatives to full deregulation of a GE product in order to address herbicide resistant weeds, because there must be a plant pest risk to deny a full deregulation, and herbicide resistance does not constitute a plant pest risk.

Third, as policy considerations are made, we must be cognizant not to lose the many benefits of GE crops, such as overall reduced pesticide use, increased use by farmers of less damaging pesticides, and decreased soil erosion due to increased use of no-till farming. According to the National Research Council's 2010 report, *The Impact of Genetically Engineered Crops on Farm Sustainability in the United* States:

> *For GE farmers, the general increase in yield, reduction in some input costs, improvement in pest control, increase in personal safety, and time management benefits have generally outweighed the additional costs of seed. The use of [herbicide resistant] crops...has generally improved weed control...improved farmers' incomes by saving time thus facilitating more off-farm work or providing more management time on the farm.*

Additionally, advances in biotechnology have provided farmers with safe, environmentally friendly tools for feeding our country and the world. If we limit the use of herbicide tolerant crops, farmers will likely have to return to older, often costly, and less environmentally-friendly weed control methods. At the same time, we are mindful of the economic impact on farmers caused by herbicide resistant weeds. This is why, as I'll discuss next, we are investing in research on solutions to this growing issue.

Multiple USDA agencies are engaged in addressing herbicide resistant weeds through research, education, and partnerships with other Departments and outside groups. USDA's National Institute of Food and Agriculture (NIFA) supports research, education, and extension programs

in the Land-Grant University System and other partner organizations. In 2009, NIFA relaunched its competitive grants program as the Agriculture and Food Research Initiative (AFRI), and offered $4.6 million in the Biology of Weedy Invasive Species in Agroecosystems program area. In 2010, NIFA restructured AFRI to be more responsive to important national issues. Of the five societal challenge areas scientists receiving grants will work under, weed science is included in both Climate Change and Global Food Security, and can also be addressed under the Sustainable Bioenergy Production focus area.

Providing the connection between the results of scientific studies and their actual application on farms is key to addressing herbicide resistance among crops derived through conventional methods and biotechnology. This is why NIFA supports Extension outreach programs to actively disseminate research findings to agricultural producers who could benefit from new knowledge about the management of herbicide resistance. For example, Extension weed scientists along with Extension integrated pest management and pesticide safety education specialists regularly discuss the issue of herbicide resistance management during training sessions and field day activities with growers. NIFA is also supporting the development of a web-based training system, called IPM^3, which offers training in a wide variety of topics related to integrated pest management (IPM). IPM^3 offers a weed module that includes herbicide resistance issues and management strategies. Anyone who completes this training will have a good understanding of weed biology and science-based management strategies that will reduce the potential for the development of herbicide resistance.

USDA's principal in-house research agency, the Agricultural Research Service (ARS) is funding nearly $4.4 million in herbicide resistant weed research in FY 2010, which is part of ARS' $36 million research effort this year on all weed science issues. I will briefly mention just two of the research projects underway. First, scientists at ARS' Crop Production Systems Research Unit in Stoneville, MS, are conducting studies on the development and management of herbicide-resistant weeds. The studies will examine the mode-of-action of herbicides and mechanisms of resistance, the reproduction and spread of weeds, and the development of integrated weed management techniques, in order to develop strategies for sustainable management of existing herbicide-resistant weed populations and to prevent future incursions. Second, scientists at the Natural Products Utilization Research Unit in University, MS, are conducting studies to discover natural product-based chemistries in order to provide new tools to control weeds resistant to current herbicides.

Additionally, APHIS has partnered with the Weed Science Society of America (WSSA) to identify methods being used to manage the spread and development of herbicide resistance in weeds, assess their effectiveness and degree of adoption, understand the reason for adoption or non-acceptance, and identify what can be done to increase the use of integrated resistance management programs. WSSA also recently completed a project for APHIS, in coordination with EPA, to understand the extent of herbicide resistance in managed ecosystems.

While these are just a few examples of USDA's efforts to address herbicide resistant weeds, we are committed to continuing to work with our partners to identify potential solutions and alternative techniques and technologies to address this important issue. This is going to require a coordinated effort by everyone involved—the government, researchers, the agricultural

community, technology and crop protection companies, and public interest groups, to name a few.

Moving Forward with Addressing Biotechnology in USDA

Biotechnology is a critical tool in addressing important global issues, including food security, biomass production, sustainability, and climate change. USDA continues to be committed to a strong, science-based regulatory system that ensures that the products of biotechnology are safe for agriculture and the environment, food, and feed. At the same time, we continue to see the direct results that the benefits that biotechnology can offer.

With that in mind, we are working to maintain rigorous polices and regulations that ensure product safety. We are also working to ensure that our policies and regulations keep pace with new technologies as they develop. And we want to develop and implement policies that promote the coexistence of genetically engineered, conventional, and organic crops, to help meet the agricultural challenges and consumer needs of the 21st century. Products produced through biotechnology will continue to be an important part of U.S. agriculture, and USDA has a complex and critical role in protecting consumers, the environment, and the farm economy while also contributing to global food needs.

Herbicide resistant weed development is not wholly a biotechnology issue, and we at USDA are looking at it in a much broader context to determine how everyone involved with this issue can evolve to address this challenge. Our agricultural producers are a resilient group, and we are confident that together, we can find sound solutions that make sense.

Thank you for the opportunity to testify today. I'd be happy to answer any questions.

Mr. KUCINICH. Thank you. Mr. Jones.

STATEMENT OF JIM JONES

Mr. JONES. Good afternoon, Chairman Kucinich, Chairman Towns. I am pleased to appear before you today to discuss the Environmental Protection Agency's regulation of transgenic B.t. crops, as well as EPA's involvement with the U.S. Department of Agriculture and their assessments of the environmental impact of herbicide-tolerant crops and herbicide-resistant weeds.

Under the coordinated framework for the regulation of biotechnology, EPA regulates products produced through biotechnology that are intended to have a pesticidal effect under its authorities under the Federal Insecticide, Fungicide and Rodenticide Act, and the Federal, Food, Drug and Cosmetic Act.

EPA first registered a transgenic B.t. crop in 1995. Over the past 15 years, B.t. crops have substantially reduced the need for growers to apply older, more risky conventional chemical pesticides to corn and cotton crops. Because sprayable B.t. formulations are naturally derived organic pesticides, they are very important to organic farmers. Given the importance of this technology to organic agricultural as well as the favorable environmental profile of B.t. as a pesticide, EPA has, from the very beginning of its regulation of transgenic B.t. crops, required registrants to market these products with specific mandatory insect-resistant management requirements.

EPA would consider the development of insect resistance to B.t. toxins to constitute and adverse effect on the environment. These IRM requirements have evolved as the science has evolved, and we have altered and tailored the IRM requirements to match the latest and most relevant scientific data and information.

The USDA regulates genetically engineered herbicide-tolerant crops, while EPA regulates the herbicides used on these crops. In order to coordinate our reviews in 2001, the agencies developed a Memorandum of Understanding that outlined the Agency's respective roles. In 2007, responding to increases in reported cases of resistance, EPA and USDA held discussions on the extent to which herbicide-resistant weeds were occurring in the herbicide-tolerant crops. As a result of these discussions, the EPA and USDA initiated a project with the Weed Science Society of America to develop a comprehensive manuscript to better understand the scope of herbicide resistance in genetically engineered, and non genetically engineered cropping systems. The report is due later this year.

As glyphosate-resistant weeds have become more widespread in herbicide-tolerant crops, technology providers and users have become more open to efforts to address herbicide-resistant weeds. The support for resistance management from technology providers and users has spurred the development of strategies to prevent or manage herbicide-resistant weeds in herbicide-tolerant crops.

EPA and USDA are working with researchers and professional societies to expand resistance management education and promote research aimed at increasing the understanding of the best practices and strategies for preventing and managing herbicide-tolerant weeds. EPA is also working with pesticide registrants encouraging them to include mechanism of action information on herbicide la-

bels. This information is critical to the implementation of resistance management plans, which typically involve rotation of two herbicides with different mechanism of action as a proven strategy for preventing or delaying development of resistance.

Recently, EPA and USDA have reinvigorated our efforts in this area to promote resistance management in herbicide-tolerant crops and preserve this valuable technology. We look forward to working with this committee, our fellow agencies, our stakeholders in the public, to ensure an environmentally and economically healthy country for all Americans. Thank you, and I'd be pleased to answer any questions.

[The prepared statement of Mr. Jones follows:]

TESTIMONY OF

JIM JONES
DEPUTY ASSISTANT ADMINISTRATOR FOR
CHEMICAL SAFETY AND POLLUTION PREVENTION
U.S. ENVIRONMENTAL PROTECTION AGENCY

BEFORE THE
DOMESTIC POLICY SUBCOMMITTEE
OVERSIGHT AND GOVERNMENT REFORM COMMITTEE
UNITED STATES HOUSE OF REPRESENTATIVES

September 30, 2010

Introduction

Good afternoon Chairman Kucinich, Ranking Member Jordan, and Members of the Committee. I am pleased to appear before you today to discuss the Environmental Protection Agency's (EPA) regulation of transgenic *Bacillus thuringiensis* (B.t.) crops. I welcome the opportunity to participate on this panel and explain the steps that EPA has taken to forestall the development of insect resistance to these important crops. Further, I look forward to discussing EPA's involvement with the U.S. Department of Agriculture in their assessments of the environmental impacts of herbicide tolerant crops and herbicide resistant weeds. EPA provided technical expertise to USDA to assist in the development of herbicide stewardship plans. More recently, as USDA has engaged in analysis of these crops under the National Environmental Policy Act (NEPA), EPA is expanding its support to USDA in its environmental analyses.

The Coordinated Framework and NEPA

EPA and USDA share responsibility, along with FDA, for regulating agricultural biotechnology. The Coordinated Framework for the Regulation of Biotechnology, released in 1986, describes each agency's role and sets forth a comprehensive scheme for federal regulation of biotechnology. The basic framework was that the products of biotechnology were to be regulated under existing statutory authorities and in a manner similar to products produced by means other than biotechnology. Thus, EPA regulates products produced through biotechnology that are intended to have a pesticidal effect under its authority under the Federal Insecticide, Fungicide, and Rodenticide Act (FIFRA) and the sections of the Federal Food, Drug, and Cosmetic Act (FFDCA) applicable to residues of pesticides in food and feed.

Under the Plant Protection Act, USDA's Animal and Plant Health Inspection Service (APHIS) regulates the introduction of organisms altered or produced through genetic engineering that are plant pests, may be plant pests, or may be related to plant pests. APHIS has procedures whereby a person may petition APHIS for a determination that an otherwise regulated article does not pose a plant risk and should not be regulated. USDA recently completed a NEPA analysis of glyphosate-tolerant alfalfa and EPA provided comments on the sections of that Environmental Impact Statement that discuss development of resistance. EPA is also providing support to USDA on an EIS for glyphosate-tolerant sugarbeet that is under development. EPA stands ready to provide whatever additional assistance may be needed in the future.

EPA's Regulation of B.t. Plant Incorporated Protectants

EPA first registered a transgenic B.t. crop product in 1995. Over the past fifteen years, B.t. crops have substantially reduced the need for growers to apply older, more risky conventional chemical pesticides to corn and cotton crops. As B.t. crops now comprise over 60% of planted corn acreage, and over 90% of planted cotton acreage, the decreasing usage of more risky pesticides has significantly reduced health risks to farm workers. Also as a condition of B.t. corn and cotton registrations, EPA required that registrants conduct field surveys to assess biodiversity in B.t. crop fields compared to non-B.t. crop fields.

Those data, along with independent assessments published in the scientific literature, have conclusively demonstrated that there is significantly greater insect biodiversity in B.t. crop fields compared to fields treated with conventional pesticides. Because sprayable B.t. formulations are naturally derived organic pesticides, they are very important to organic farmers and organic agricultural production in general. Given the importance of this technology to organic agriculture, EPA has, from the very beginning of its regulation of transgenic B.t. crops, addressed the potential issue of resistance by requiring that B.t. crop registrants market these products with specific mandatory insect resistance management (IRM) requirements. These requirements have evolved as the science has evolved, and we have altered and tailored the IRM requirements to match the latest and most relevant scientific data and information.

EPA's development of a regulatory scheme for plant incorporated protectants (PIPs) began in the 1980s. EPA held public meetings with the Agency's Biotechnology Safety Advisory Committee (BSAC), the FIFRA Scientific Advisory Panel (SAP), the Office of Pesticide Programs Pesticide Program Dialogue Committee (PPDC), and numerous public meetings and workshops with interested stakeholders. Through this long process of stakeholder consultation and external scientific peer review, EPA developed a rigorous and robust regulatory approach to PIPs that was based on the most up to date science. From the very beginning, it was clear that developing methodologies and approaches to forestall the development of insect resistance should be a major focus of the Agency in its regulation of B.t. crops. EPA has regularly met with the SAP on IRM issues, and, as the IRM requirements have evolved on the basis of new data and information, the SAP has provided key input into these regulatory developments.

To address the potential of insect resistance to B.t. proteins, EPA has imposed IRM requirements on registered B.t. PIPs. EPA would consider the development of insects resistant to B.t. toxins as a result of unmitigated exposure to PIPs to constitute an adverse effect on the environment. EPA's strategy to address insect resistance to B.t. is two fold: (1) mitigate any significant potential for pest resistance development in the field by instituting IRM plans; and (2) continually investigate and understand better the mechanisms behind pest resistance. Initially, IRM plans incorporating "refuges" (portions of the crop that did not produce and were not treated with B.t.) were determined on a case by case basis using data submitted with each application. As a consequence,

IRM requirements varied from product to product. In 2000, based upon input from the SAP, and working with the National Corn Growers Association and other groups, EPA imposed across the board IRM requirements of a 20 percent refuge for B.t. corn and a 5 percent refuge for B.t. cotton.

The baseline 20 percent refuge for corn and 5 percent refuge for cotton held for a number of years until more complex products were developed and supporting scientific data indicated that it was appropriate to alter these requirements. For B.t. cotton, registrants developed "pyramided" products that contained more than one B.t. protein efficacious against a specific pest ("stacked" products contain B.t. toxins efficacious against more than one pest). By targeting the pest with independently acting toxins, the likelihood of resistance developing to either toxin was substantially decreased, and it became possible for EPA to decrease the percentage of refuge crop required for a pyramided crop.

Also, registrants developed data demonstrating that in many cotton producing areas, non-cotton plants that are food sources for cotton pests often surround, or are close by cotton fields. In effect, in these areas, the cotton fields are surrounded by "natural" refuges.

These large alternative sources of habitat for cotton pests, combined with pyramided B.t. cotton products, precluded the need for growers to plant refuges for those products. Thus, for pyramided B.t cotton products planted from Maryland to Kansas,

there are no refuge requirements. Those same products planted outside of these areas maintain the requirement for planted refuges. Similarly for B.t. corn, new products are being developed that support refuge requirements different from the baseline 20 percent corn refuge. Registrants have developed pyramided corn products that require refuges of 5 percent or 10 percent non-B.t. corn seed. Also, registrants are developing products that incorporate refuge seed in the same seed bag as the B.t. corn seed, such that when planted, an in field refuge is automatically put in place. To date, there have been no confirmed instances of B.t. resistant pests appearing in the field in the Continental United States. We will maintain our diligent approach to forestalling potential resistance to B.t. crops.

In addition to requiring that registrants require purchasers of their products to plant crop refuges, EPA mandates that registrants monitor for resistant insects emerging during the growing season as an important early warning sign of resistance developing in the field and a check as to whether IRM strategies are working. Grower participation, e.g., reports of unexpected damage, is a critical component of such monitoring. Resistance monitoring is also important because it provides validation of biological parameters used in models. In 2000, the SAP concluded that resistance monitoring programs should be peer reviewed and used to assess the success of IRM plans. EPA's Office of Research and Development, National Risk Management Research Laboratory and Office of Pesticide Programs held a small expert group workshop in July, 2001, that provided guidance on insect resistance monitoring plan design and detection techniques for B.t. corn.

EPA and USDA Cooperation on Herbicide Resistance Concerns

USDA regulates genetically engineered herbicide-tolerant crops, while EPA regulates the herbicides used on these crops. Recognizing the need for EPA and USDA/APHIS to coordinate their reviews, the agencies developed a Memorandum of Understanding (MOU) in 2001 outlining a process for improved communication and information-sharing to facilitate better coordination of regulatory activities between the two agencies. Under the MOU, USDA was to request that each petition for "deregulated" status include a voluntary stewardship plan for the management of herbicide resistance, and then consult with EPA as to the viability of the stewardship plan during its environmental assessment.

To implement relevant portions of the MOU, USDA and EPA developed a draft document to assist applicants in the preparation of voluntary resistance management stewardship plans to be submitted with petitions for nonregulated status of herbicide-tolerant (HT) crops, and with applications to EPA to register herbicides intended to be used on HT crops. Initial efforts by EPA and USDA to implement the provisions of the MOU were met, however, with resistance from both users, pesticide registrants, and the technology providers. At that time, the development of resistance in weeds as a result of the use of HT crops was not widely documented in the scientific literature, nor was it viewed as a significant problem by these stakeholders, who considered the economic costs of developing and implementing a stewardship program unnecessary.

In 2007, responding to increases in reported cases of resistance, EPA and USDA held discussions on the extent to which herbicide resistant weeds were occurring in herbicide tolerant crops. As a result of these discussions, EPA and USDA initiated a project with the Weed Science Society of America (WSSA) to develop a comprehensive manuscript to better understand the scope of herbicide resistance in genetically engineered and nongenetically engineered cropping systems. This report is due later this year.

As glyphosate resistant weeds have become more widespread in HT crops, technology providers and users have become less resistant to efforts to address herbicide resistant weeds. The support for resistance management from technology providers and users has spurred the development of strategies to prevent or manage herbicide resistant weeds in HT crops. More recently, EPA has provided comments on the section of USDA's EIS that discuss the development of resistance as a result of the deregulation of glyphosate-tolerant alfalfa.

EPA and USDA are working with researchers and professional societies, including the Weed Science Society of America (WSSA), to expand resistance management education and promote research aimed at increasing understanding of the best practices and strategies for preventing and managing HT weeds in HT crops. EPA is also working with pesticide registrants, encouraging them to include mechanism of action information on herbicide labels. This information is critical to the implementation of resistance management plans, which typically involve rotation to herbicides with a

different mechanism of action as a proven strategy for preventing or delaying development of resistance.

There has been much attention given to the best way to delay or prevent the development of pesticide resistance to pests in general, beyond resistance in weeds in glyphosate-tolerant crops. Professional scientific societies, e.g., the Weed Science Society of America, the Entomological Society and the American Phytopathology Society, as well as Resistance Action Committees (composed of technical staff from pesticide producers) have been involved in identifying ways to accomplish this goal. EPA has been in discussion with each of these groups to obtain their input on how to incorporate guidance on resistance management on pesticide labels.

Additionally, EPA has been collaborating with its NAFTA partners (The Pest Management Regulatory Authority (PMRA) of Canada and Cicoplafest of Mexico) to develop harmonized approaches to resistance management language on pesticide labels EPA has and continues to encourage pesticide registrants to include mechanism of action information on pesticide labels to better inform growers and other pesticide users of one proven strategy for preventing or delaying development of resistance.

In summary, the early efforts by EPA and USDA to implement the resistance management provisions of the 2001 MOU were hindered by the lack of interest and support from the technology providers and user community. Recently, however, with the support of these sectors, EPA and USDA have reinvigorated their efforts in this area,

working collaboratively to promote resistance management in HT crops and preserve this valuable technology.

We look forward to continuing our work with this Committee, our fellow agencies, our stakeholders, and the public to ensure an environmentally and economically healthier country for all Americans.

Mr. KUCINICH. Thank you very much. I would like to begin the first round of questions with Ms. Wright. As you know, the USDA, since they began deregulating Roundup-Ready Corn, Soy And cotton, among other genetically engineered herbicide-resistant crops in the late 1990's, weed scientists estimate that there are up to 11 million acres of American farmland, and a dozen species of weeds that have evolved to be resistant to Roundup herbicide. The result for farmers has been greatly increased cost of weed management, and a probable loss of Roundup as an efficacious weed control chemical in large parts of the country. Is it the position of the USDA that it could not regulate genetically engineered herbicide-resistant crops in order to prevent this spread of herbicide-resistant weeds?

Ms. WRIGHT. Mr. Chairman, USDA recognizes the development of herbicide-resistant weeds across the board.

Mr. KUCINICH. What does that mean?

Ms. WRIGHT. It means that we recognize it as probably the No. 1 issue for farmers and ranchers whether they are raising crops using biotechnology, or organic, or conventional seed. I think we have a number of ways that we're looking at this through our active and dedicated research programs that are looking at critical national priorities like the sustainable production of bioenergy climate change, global food security. We continue to see this issue as critical to farmers bottom lines.

And right now, we have confidence in a science-based process that regulates in and around our plant protection authorities, our statutory commitments are to that act.

Mr. KUCINICH. Well, you know, that's very interesting, but the question that I asked is, is it your position that the USDA could not regulate genetically engineered herbicide-resistant crops in order to prevent the spread of herbicide-resistant weeds?

Ms. WRIGHT. That's correct. Our statutory authority allows us to make regulatory decisions based on plant pest risk.

Mr. KUCINICH. Tell me more about that.

Ms. WRIGHT. Well, what I can tell you is that the plant pest risk is determined by—well, I'm going to let——

Mr. KUCINICH. Let me go to Mr. Jones a minute. Mr. Jones, the EPA has taken a different position. EPA believed that it could regulate one genetically engineered plant variety in particular, those containing the B.t. or the Bacillus thuringiensis gene in order to prevent the development of pest resistance to B.t.; is that correct?

Mr. JONES. That's correct. We're operating under a different statute, in this case, FIFRA.

Mr. KUCINICH. Mr. Jones, I understand the EPA's been regulating B.t. crops to prevent pest resistance for about 15 years. Is there a problem with B.t. resistance in this country comparable to the problem of Roundup resistance in weeds?

Mr. JONES. There is not.

Mr. KUCINICH. Pardon?

Mr. JONES. No, there is not.

Mr. KUCINICH. Are there 11 million acres of B.t. resistant farmland right now?

Mr. JONES. We're not aware of resistance yet——

Mr. KUCINICH. How many acres of American farmland has been infested with B.t. resistant pests?

Mr. JONES. We're not aware of any. It doesn't mean there isn't some.

Mr. KUCINICH. Well, is B.t. still an efficacious pesticide in the United States?

Mr. JONES. It is.

Mr. KUCINICH. Does it concern EPA to learn that weed resistance to Roundup is now widely prevalent?

Mr. JONES. Yes.

Mr. KUCINICH. If so, why?

Mr. JONES. Glyphosate to Roundup is—has a very favorable, as you mentioned in your opening remarks, environmental profile. And so it's a compound that we think it's in the interests of the environment to have a long commercial life.

Mr. KUCINICH. So your saying that it's because the glyphosate is relatively benign?

Mr. JONES. It has a very favorable environmental profile.

Mr. KUCINICH. Ms. Wright, 11 million acres of infested farmland, $1 billion in added weed control costs to farmers. The loss of efficacy for a relatively benign pesticide in many places, these are some of the consequences of the USDA's position that it could not regulate Roundup Ready crops to prevent the evolution of resistant weeds.

Now, Ms. Wright, you say in your written testimony, "There must be a plant pest risk to deny a full deregulation. An herbicide resistance does not constitute a plant pest risk." Now I'm questioning your legal interpretation as to whether it's well-founded. Your position is that the sum total of the USDA's authority derives from section 411 of the Plant Protection Act which gives the Secretary authority to prevent the introduction of plant pests.

But that is not the sum total. The very next section of the act, section 412, covers your authority to prevent the spread of, "Noxious weeds." Section 412 "gives the Secretary authority to prohibit or restrict . . . the movement . . . of any plant . . . if the Secretary determines that the prohibition or restriction is necessary to prevent . . . the dissemination of a . . . noxious weed within the United States," from the statute. Now "noxious weeds" are defined by the statute at 7 U.S.C. section 7702 as, "Any plant or plant product that can directly or indirectly injure or cause damage to crops or . . . other interests of agriculture . . . or the environment."

Ms. Wright, a plain reading of section 412 gives the Secretary the broad authority to restrict the use of Roundup-resistant crops if sound science determines that those restrictions are necessary to prevent the spread of Roundup-resistant noxious weeds. How can you come to Congress and insist that effectively that section 412 doesn't even exist?

Ms. WRIGHT. Well, first let me say that this USDA is very committed to looking at all of our programs and policies, and ensuring that they are there for all forms of agriculture——

Mr. KUCINICH. I know you're not—this is your first time before a committee.

Ms. WRIGHT. It is.

Mr. KUCINICH. And I do appreciate your being here. I asked you a question, and I would like an answer. That was not responsive.

Ms. WRIGHT. We interpret our existing authorities as those focused on plant pest risk. Back in March 2009, we issued a set of updates to our rules and regulations that expanded our authorities into the Noxious Weed Act. We're now looking at 66,000 comments on those rule updates. This is a new administration, we will be taking a close look at the full range of comments that came in and be looking very carefully at where our authorities are.

Mr. KUCINICH. Are you familiar with section 412 of the act?

Ms. WRIGHT. No, sir.

Mr. KUCINICH. You're really not? Before the end of this hearing, I would like staff to have a copy made of section 412 of the act and provide it to the witness, because if the regulatory agency is not fully familiar with the extent of its authority, it may be one of the difficulties we're having here.

Ms. WRIGHT. I think the Agency is probably very familiar, but I personally am not, and I'm sorry.

Mr. KUCINICH. Well, I can understand that it is a new administration, and that you're new, and you do have a very good reputation where you come from. But I think it's important that you become familiarized with the act and with the sections that I articulate, particularly section 412, which actually does change the role of your agency and your office to effectively regulate herbicide-resistant weeds. If you—I'll take you at your word that you're not familiar with it.

But what I glean from that, since you are not familiar with it, you can't point to any provision of the Plant Protection Act that would deny the USDA the ability to use the authority of the section to prevent the spread of Roundup-resistant weeds.

I think it's clear from your testimony that the USDA's position is not too much a legal judgment as is a statement of policy. And that it's been the policy of the USDA not to use the authority that it does have under section 412, it's just very clear. I just want to make this statement to you as the chairman of this oversight subcommittee that a plain reading of section 412 makes it obvious that if the Agency wants to become involved in the enforcement of herbicide-resistant weeds, that it could do it, that you do have the statutory authority to do it, and that it's a policy question.

Now you may not be the person who makes the final call on that, but somebody all the way up to—the ladder at Agriculture is making that call, and this subcommittee's determined to see the statute enforced.

Now, Ms. Wright I know that the Department understands at this point, that the problem of superweeds is a crisis. What I don't understand, and what defies comprehension is this: That the Department does have the legal ability to help farmers deal with the crisis, and to prevent it from worsening, and that the USDA has not made a policy, a decision to use this authority or has made a policy decision not to use it. Do you have anything further that you can tell this subcommittee? You will read the statute?

Ms. WRIGHT. Thank you. Yes, I promise to fully read the statute and I would like to say—and thank you for the opportunity to address this problem and to address the entire issue of coexistence.

We're going to have to have a full slate of partners at the table looking at this, including Congress, as well as technical service providers, other Federal agencies, regulated entities and public interest groups. And together, I think, we will be able to solve this problem, including growers, it's not one that—as well as the markets, it's not one that exclusively rests on our shoulders.

Mr. KUCINICH. Ms. Wright, I want to draw attention to the Department's view that it currently has authority to regulate future planting of GE crops through administrative action. The Department outlined three such actions in a court filing from July of this year. I move to insert into the record the fourth declaration of the APHIS administrator Cindy Smith.

[The information referred to follows:]

UNITED STATES DISTRICT COURT
FOR THE NORTHERN DISTRICT OF CALIFORNIA
SAN FRANCISCO DIVISION

CENTER FOR FOOD SAFETY, *et al.*, Plaintiffs, vs. TOM VILSACK, *et al.*, Defendants, and MONSANTO COMPANY; SYNGENTA SEEDS, INC.; AMERICAN SUGARBEET GROWERS ASS'N, *et al*,: BETA SEED, INC.; and SESVANDERHAVE USA, INC., Defendant-Intervenors.	Case No.: 3:08-cv-00484-JSW

FOURTH DECLARATION OF CINDY SMITH

I, Cindy Smith, do hereby declare as follows:

1. I make the following statements based on my personal knowledge and experience as well as upon facts made known to me in my capacity as the Administrator of the Animal and Plant Health Inspection Service (APHIS), United States Department of Agriculture (USDA).

2. I previously provided declarations on February 12, May 7, and June 18, 2010.

3. I am providing this declaration to respond to the Court's June 24, 2010 Order requiring APHIS to address the Supreme Court's statement in Monsanto Co. v. Geertson Seed

Farms, __ U.S. __, 2010 WL 2471057, at *15 (2010), regarding the effect of an immediate vacatur of APHIS' determination of nonregulated status.

4. If the determination of nonregulated status on Roundup Ready sugar beets (RRSB) is vacated and the vacatur would go into effect immediately, RRSB would again be a regulated article under 7 C.F.R. Part 340 and the Plant Protection Act (PPA). As a regulated article, RRSB could neither be planted nor moved interstate without approval from APHIS. However, a new deregulation decision, whether in whole or in part, is not the only means for APHIS to approve future planting (release into the environment) and/or interstate movement of the regulated RRSB.

5. There are several administrative actions under the authority of the PPA and/or Part 340 that APHIS could take to allow the planting and/or interstate movement of regulated RRSB.

a. First, APHIS has the authority to allow the planting of RRSB as a regulated article under permit. Permitting is the regulatory scheme under Part 340. Permits are issued after appropriate NEPA analysis. The type of NEPA documentation needed will affect the timing of the issuance of the permit.

b. Second, APHIS may either revise the Part 340 regulations or issue a new rule, after notice and comment, in order to allow the APHIS Administrator to use her discretion to allow the planting of RRSB under a revised or new regulatory scheme pursuant to PPA statutory authority. (7 U.S.C. §§ 7711, 7712, 7714, and 7754). If APHIS revises Part 340 or issues a new rule to allow the Administrator the discretion to impose a different regulatory scheme than is currently employed under Part 340, such as the use of general permits, administrative orders or other PPA authority, APHIS would conduct the appropriate NEPA analysis prior to taking any regulatory action provided for by the rule change.

c. Third, the PPA provides APHIS with the authority to issue orders as the Secretary considers necessary to carry out the PPA. (7 U.S.C. § 7754). Prior to the issuance of such an order, APHIS would conduct the appropriate NEPA analysis and prepare the appropriate documentation, which will affect the timing of such an order.

6. The PPA prohibits the importation, entry, export, or movement (including release into the environment) of a plant pest unless the movement is authorized under a general or specific permit and is in accordance with such regulations as the Secretary may issue to prevent the introduction into or dissemination within the United States of a plant pest. 7 U.S.C. § 7711(a). APHIS currently allows the movement of genetically engineered regulated articles under a permitting scheme, using specific permits and notifications. Notification is a form of permit. APHIS reviewed its permitting process under Part 340 and in 1995 (60 Federal Register 6000) determined that permits and notifications complied with and satisfied the categorical exclusion requirements set forth in APHIS's NEPA implementing regulations. (7 C.F.R. §372.5(c)(3)(ii)). Prior to the deregulation of RRSB in 2005, RRSB was a regulated article which was allowed to be planted and grown under notification.

7. APHIS has overseen numerous field trials under Part 340. At least 142 of the authorizations since 2006 were for crops ranging from just over 1000 acres to 20,000 acres. The field trials were overseen by APHIS through inspections and/or third party inspections and auditing. APHIS ensures that every permit is inspected by APHIS staff or by a qualified independent third party inspector.

8. As I declared both in my second and third declarations, I respectfully proposed that the Court order a remand without vacatur until May 31, 2012, and impose the specific interim measures that I described in detail in paragraphs 44-45 of my second declaration pending

completion of the RRSB Environmental Impact Statement (EIS). (Second Smith Decl. at ¶¶ 44-45, Third Smith Decl. at ¶ 5). Such court-imposed measures would provide certainty for farmers of the RRSB seed and root crops that APHIS action, which is subject to challenge, cannot provide. In the alternative, if the Court is inclined to immediately vacate and remand APHIS's determination of non-regulated status of RRSB, I respectfully requested that the Court stay its vacatur of APHIS's Determination of Non-Regulated Status for RRSB until March 1, 2011, to allow APHIS adequate time to establish appropriate interim regulatory measures to deal with all regulated RRSB until completion of the RRSB EIS. (Third Smith Decl. at ¶ 6). If the Court is inclined to vacate APHIS's determination and remand but is not inclined to stay the vacatur until March 1, 2011, I respectfully requested that the Court, at the very least, stay the vacatur with respect to all RRSB in the United States currently planted as of the date of the Court's order. Such an order would prevent significant harm to the thousands of farmers that have currently planted RRSB in the United States and would prevent significant harm and disruption to sugar beet sugar supplies and prices. (Id. at ¶ 8).

9. If there is an immediate vacatur and remand, the following RRSB activities would either be taking place on the Court's August 13, 2010 hearing date or be imminent: (1) the harvest and interstate movement of the 2009-2010 seed crop from the fields to seed processing plants which is expected to occur between July and October 2010; (2) the interstate movement of the 2009-2010 seed crop harvested between July and October 2010, from processing plants along the sales chain (i.e. to distributors and individual growers), which is expected to take place from November 2010 to March 2011; (3) the planting of the 2010-2011 seed crop which is expected to take place as early as July 2010, and is likely to be completed by the end of September 2010; and

(4) the harvest and interstate movement of the 2010 root crop from field to sugar processing plants which is expected to take place from September 2010 to December 2010.

10. If the vacatur does not apply to any RRSB crop that has been planted as of the date of a vacatur, only new plantings after that date and other releases into the environment (e.g. flowering of the seed crop) would require the agency's approval. The planting of the 2010-2011 seed crop is the only activity that is imminent and would require immediate regulatory action by APHIS.

11. If permits for new plantings of the 2010-2011 RRSB seed crop were to be requested by Intervenors seed companies after vacatur, APHIS has the authority to issue permits solely for the planting of RRSB seed crop under a categorical exclusion as currently provided for under Part 340, provided that APHIS determines that none of the exceptions to the categorical exclusion applies. However, such permits for the planting of the RRSB seed crop would still take some time, possibly up to a month before they could be issued. The time needed to issue such permits could likely prevent certain seed growers from any further planting of the RRSB seed crop after vacatur, depending on factors such as the date by which they must complete their seed planting. It would be expected that any permits APHIS may issue in time for the planting of the 2010-2011 RRSB seed crop could allow planting but would not allow flowering, which would not be expected to occur until approximately May 2011. To address the flowering stage of the RRSB seed crop, APHIS may, after preparing an EA, issue a new permit or an amended permit under Part 340 or under other regulatory mechanisms (as described in paragraph 5 above). APHIS has considerable experience with the issuance of permits that do not allow flowering and with the issuance of permits that only allow flowering under strict conditions. An EA for new or

amended permits that would allow flowering of the RRSB seed crop would be expected to be completed by March 1, 2011.

APHIS could also use its authority under the PPA to issue a federal order to address imminent RRSB activity after the appropriate NEPA analysis and documentation is prepared. APHIS is currently considering how such authority to issue orders might be used.

12. In addition to the immediate activities related to regulating RRSB (both seed and root crops) in the United States as described above, the following are additional planting or interstate movement RRSB activities that would occur prior to the time when APHIS completes its RRSB EIS and that would require APHIS approval, if requests for such production actions were made: (1) the planting of the 2011 root crop which is expected to take place between April and July 2011 and the interstate movement of this 2011 harvested root crop, which is expected between September and December 2011; (2) the harvest and interstate movement of the 2010-2011 seed crop, planted after vacatur, from the fields to the processing plants, which is expected to occur between July and October 2011; (3) the interstate movement of 2010-2011 seed crop, planted after vacatur, from processing plants along the sales chain (i.e., to distributors and individual growers), which is expected to take place from November 2011 to March 2012; (4) the planting of the 2011-2012 seed crop which is expected to occur between July and September 2011; and (5) the planting of the 2012 root crop which is expected to occur between April and July 2012. With regard to these production activities, if requests for such production actions were made, APHIS could use any of the authorities as described in paragraph five above to allow the activities under PPA regulation with the appropriate NEPA analysis and documentation.

13. APHIS has the authority pursuant to 7 C.F.R. § 340.6 to approve a petition for determination of nonregulated status in whole or in part. If APHIS were to receive a new

petition or a supplement or amendment to a previous petition for a determination of nonregulated status of RRSB, APHIS could consider granting that petition in whole or in part. Depending upon the specific petition and its complexity, if APHIS were to approve such a petition, APHIS anticipates that it could take at least until March 1, 2011, to complete the appropriate NEPA analysis and documentation and the appropriate plant pest risk assessment.

I declare under penalty of perjury that the foregoing is true and correct.

Executed this 15th day of July, 2010, in Washington, D.C

Cindy J. Smith, APHIS Administrator

Mr. KUCINICH. My question, Ms. Wright, is this: Is it also the Department's view that it could, by means of any of those administrative actions, place requirements on a permitted planning of GE herbicide-tolerant crops to prevent the proliferation of herbicide-resistant weeds.

Ms. WRIGHT. In both the case of GE alfalfa as well as GE sugar beets there are currently formal petitions before the agency for us to look at ways to partially deregulate these.

Mr. KUCINICH. So that's a yes?

Ms. WRIGHT. We're in the process of looking at that.

Mr. KUCINICH. So that's a yes?

Ms. WRIGHT. So the industry has come to us and asked us to look at that options.

Mr. KUCINICH. So is this consistent with the testimony that has been given in court?

Ms. WRIGHT. Yes.

Mr. KUCINICH. You found expansive authority to devise three administrative actions allowing to you approve large scale planting under a permit system. What is the basis? Do you have——

Ms. WRIGHT. No, sir. The industry came to us and asked us to look at partial deregulation as one way to allow the planting of a GE crop.

Mr. KUCINICH. Are you talking about the cases that were struck down by Federal district courts?

Ms. WRIGHT. Yes, sir.

Mr. KUCINICH. That was at the request of the industry, right?

Ms. WRIGHT. Yes.

Mr. KUCINICH. OK. What's the—I'm still trying to figure out the basis for your view here today that a permit system which the GE crop would remain a regulated article and nevertheless not permit to you to place requirement on planting and preventing the spread of Roundup resistance in weeds.

Ms. WRIGHT. Unless we determined there a plant pest risk, we do not have it that expansive authority.

Mr. KUCINICH. So you're still stuck on one section of the act and haven't read the other.

Ms. Wright, isn't it true that the Department has had under development, a new biotechnology rule and that the rule was also under development during the previous administration?

Ms. WRIGHT. Yes.

Mr. KUCINICH. OK. And with the change in administration, can this Congress expect to see any differences in the Department's approach to herbicide-resistant weeds and the rule you're now working on.

Ms. WRIGHT. I can tell you that we're having internal discussions about our policies, and around coexistence, and that we just honestly cannot afford to look at options and alternatives that are not supportive of various cropping systems, including biotechnology, organic and conventional. They all play a very critical role in the health of our rural economy and in our agricultural economy.

Mr. KUCINICH. I know that was in your opening statement. I heard that. But it's not responsive to the question I asked.

Ms. WRIGHT. Can you ask your question again? Will you please restate your question?

Mr. KUCINICH. There has been a change in administrations, can we expect to see any difference in the Department's approach to herbicide-resistant weeds in the rule that you're now working on?

Ms. WRIGHT. I think we're looking at all—a lot of options, and we're going back and looking, considering the comments that were submitted. We're internally having discussions across the Department. We have a Secretary and an administration that's very committed to the idea of addressing the issues of coexistence, and that's as much as I can say today.

Mr. KUCINICH. See the thing that I'm concerned about—and I am really trying to give you the benefit of the doubt on what you're saying, the thing that I'm concerned about, is that when you go back to your talking points, you actually inadvertently shut the door on consideration of the science and experience that's been brought forward through the EPA's enforcement through the practical experience of farmers, through the NRC report. And so I'm trying to—because it's important that we understand—you've made it clear that the policy, you know, what the policy is, you haven't extended that to a legal interpretation, but if you're just saying well, you know, we have different ways of supporting agriculture, we're going to try to support them all.

But if you rest on that and don't go deeply into expressing to this subcommittee a concern that the extent to which herbicide-resistant weeds may represent an attack on the rights of farmers, the economic rights of farmers, the environment, if you don't articulate that, it causes me to pause.

Ms. WRIGHT. Well—out of all due respect, I would say that it's not that we don't recognize this as a bottom line issue for farmers and ranchers——

Mr. KUCINICH. It's what?

Ms. WRIGHT. It's not that we don't recognize this as a critical issue for farmers and ranchers, but I think this administration and USDA see biotechnology as being a very important tool for farmers to use in addressing some very critical issues, globally and here domestically. And all of the options that we look at have to be supportive of that, they have to encourage and support innovation in a smart way.

Mr. KUCINICH. Do they look the other way if there is a problem?

Ms. WRIGHT. No, I don't think so. We take our NEPA process and documents very seriously. In fact, the Secretary just approved a reorganization of our BRS services, we have a whole team, a new team, a whole program dedicated to NEPA now. We have a budget increase request before Congress for 2011, fiscal year 2011 of $5.8 million to hire new scientists. We take these issues very seriously. And as we learn more about the environmental impacts of this technology, we try to adjust and we try to make our rules and regulations.

Mr. KUCINICH. Just out of curiosity, you think—genetic—you just talked about the importance of biotechnology, is it your view, personally, that genetically engineered crops are the functional equivalent of conventional crops?

Ms. WRIGHT. Well, I'm not prepared to reflect on that.

Mr. KUCINICH. OK, that's fine. For the last couple of decades, the EPA and the USDA had pledged in various Memoranda of Under-

standing to promote integrated pest management. One of the key objectives of integrated pest management is preserving the efficacy of relatively benign pesticides and preventing herbicide resistance in weeds. Now I move to insert into the record one such Memorandum of Understanding from 2001.

Now, to the EPA, I want to address this question, does it concern the EPA from the perspective of integrated pest management that more and more acres of farmland are showing signs of infestation by Roundup-resistant weeds?

Mr. JONES. Yes, it does.

Mr. KUCINICH. Now, in general, isn't proliferation of Roundup-resistant weeds across millions of acres of farmland a setback for integrated pest management?

Mr. JONES. Sure.

Mr. KUCINICH. And to the USDA, does the USDA agree with the EPA that from the perspective of integrated pest management to widespread infestation of Roundup-resistant weeds constitutes a setback?

Ms. WRIGHT. I'm sorry, can you please repeat that?

Mr. KUCINICH. Does the USDA agree with the EPA, which just responded yes, that the proliferation of Roundup-resistant weeds across millions of acres of farmland is a setback for integrated pest management. I asked you, do you agree with the EPA from the perspective of integrated pest management, the widespread infestation of Roundup resistance weeds constitutes a setback?

Ms. WRIGHT. Possibly, yes.

Mr. KUCINICH. Mr. Jones, in communication with the majority staff, the EPA has stated that the USDA did solicit EPA's input in its Environmental Impact Statement for Roundup Ready Alfalfa, but as we've already seen, the Environmental Impact Statement will not consider any measures for preventing the spread of Roundup-resistant weeds.

USDA testified that EPA raised no objection to their draft environmental impact strategy on alfalfa, which USDA characterizes as meaning, "The EPA had no concerns."

Is that a complete representation of EPA's comments to USDA on the Roundup-Ready Alfalfa Environmental Impact Statement?

Mr. JONES. Chairman, to be fair to my colleagues at USDA——

Mr. KUCINICH. I'm asking you to answer the question, not to be fair, but to answer the question.

Mr. JONES. The answer to the question is that an Agency's formal response that went through our office of Federal activities, we did not raise the issue of insects—I'm sorry, herbicide resistance. In informal conversations, when we've had a number of them, and they continue to this day.

Mr. KUCINICH. So you did raise a concern about weed resistance management; is that right?

Mr. JONES. That's correct.

Mr. KUCINICH. Now Ms. Wright, this is somewhat at a variance with your written testimony. And contrary to that, does the USDA now acknowledge that the EPA did, in fact, express concern about the weed resistance management issue in the alfalfa Environmental Impact Statement?

Ms. WRIGHT. Yes, we did.

Mr. KUCINICH. Mr. Jones, did USDA ever ask EPA to offer its expertise in preventing pest resistance in the context of the USDA's preparation of an environmental impact statement for deregulating GE alfalfa?

Mr. JONES. Once we raise the concerns that we have identified through informal mechanisms that led to an ongoing dialog between USDA and EPA to address those, and so——

Mr. KUCINICH. Did they ask you to offer your expertise?

Mr. JONES. That is correct.

Mr. KUCINICH. What did they ask you to do?

Mr. JONES. When we raised our—we raised some issues associated with resistance management, and as it was characterized in EIS. And the Department said to us, you've raised some very good points, let's talk about that, we want to understand this better. And those conversations continue, as I said, to this day, and I believe will continue until we feel like we're on the same page on that issue.

Mr. KUCINICH. Well, given the scientific verification of the rapid spread of Roundup-resistant weeds, do you think it might be justifiable for the EPA and the USDA to revisit the question in preparation for the final environmental impact statement for Roundup Ready Alfalfa, Mr. Jones?

Mr. JONES. I believe that's what we're doing right now.

Mr. KUCINICH. And to Ms. Wright, given the EPA's successful effort thus far in preventing the Bacillus thuringiensis resistance in pests, wouldn't it make sense for the USDA to want to utilize the EPA's expertise to help regulatory means to prevent and mitigate Roundup resistance in weeds?

Ms. WRIGHT. Yes. And if it's OK with you, I'd like to ask Sid Abel to address more of the specifics around how we are working with EPA.

Mr. KUCINICH. He's sworn, he can do that.

Mr. ABEL. We are—right now we're working very directly at the staff level with our partners at the EPA to address specifically the issue of glyphosate tolerance among weeds. We agree, both with EPA and with other parts of our Federal partners, that this is a serious issue for farmers. It's also a serious issue for the technology. We see that this is a very favorable compound to be used in controlling weeds, and to preserve that technology is very important to us. So we've entered into these discussions with EPA at the staff level with the Weed Science Society of America, and with others, universities and extension agents to get a better handle on the extent to which glyphosate tolerance is occurring out there, not just in GE crops, but also in conventional crops. We believe that by going through this process, we'll be able to put forward some strategies for managing these crops in a way to preserve these technologies into the future.

Mr. KUCINICH. Have you read section 412 of the act?

Mr. ABEL. It has been a while, but yes, sir, I have.

Mr. KUCINICH. Would you read it again?

Mr. ABEL. Yes, I would.

Mr. KUCINICH. I want to thank the members of this panel for participating in this important discussion. And this committee will

continue to retain jurisdiction over this matter, which means that there will be more hearings.

We are very interested in the policies of the USDA as it affects the environment, farmers. And I'm grateful for your presence here today and for the EPA's continuing work in this area as well.

The first panel is dismissed and I'm going to call the second panel to come forward, and we will begin the second panel in a couple of minutes as soon as you're all in place.

I am going to read the introductions at this moment while staff is getting set up. I want to welcome to this subcommittee Congresswoman Diane Watson, Ambassador Watson from California, for gracing this hearing.

We have here today Mr. Steve Smith. Mr. Smith, welcome. Mr. Smith is director of agriculture at Red Gold, Inc., the largest privately-held canned tomato processor in the country. In his position he works closely with their growers in Indiana, Ohio and Michigan. He is co-chair for Red Gold's new sustainability initiative and serves on the Sysco Corp.'s national sustainability advisory board. Mr. Smith has served on the Purdue University dean of agriculture advisory board, the board of directors of the Mid-America Agriculture and Horticultural Services, as director of the American Fruit and Vegetables Processor and Grower's Coalition, and as an inaugural member of the Indiana Department of Agriculture advisory board. Thank you for being here.

Dr. Phil Miller currently serves as a vice president in the Monsanto Co. He leads the regulatory group which is responsible for the development of health and safety research on new agricultural and biotech products, global regulatory approvals, product safety defense, and management of numerous key scientific and regulatory issues. Dr. Miller joined Monsanto in 1994 and has held numerous roles in chemical discovery in biotechnology research and development. Some key roles include director of biotechnology, crop enhancement and crop genomics research, and Monsanto's Sirius Research Collaboration League.

Thank you for being here, sir.

Next is Mr. Bill Freese who is science policy analyst with the Center for Food Safety, a D.C.-based nonprofit group. Mr. Freese has written and lectured extensively on the science regulation and societal implications of agricultural biotechnology for over a decade. In 2004 he coauthored a peer-reviewed scientific paper on common myths about U.S. regulation of genetically engineered crops. Mr. Freese is a frequently quoted expert on agriculture biotechnology in the mainstream media as well as the scientific press. He has reviewed and critiqued numerous petitions for deregulation of herbicide-resistant crops, the subject of today's hearing.

Finally, Mr. Jay Vroom, who is president and chief executive officer of CropLife America, the largest national trade organization representing developers, manufacturers, formulators, and distributors of agricultural pesticides across the United States. Mr. Vroom has held his position since 1989. Previously Mr. Vroom served as executive vice president and chief executive officer of National Fertilizers Solutions Association in St. Louis, Missouri. He began his professional career on the staff of the Fertilizer Institute.

As with the previous panel, I want to make you aware that it is the policy of the Committee on Oversight and Government Reform to swear in all witnesses before they testify. I ask that you gentlemen rise and raise your right hands.

[Witnesses sworn.]

Mr. KUCINICH. Let the record reflect that each of the witnesses has answered in the affirmative.

I would now ask that each witness give an oral summary of your testimony. I would ask that you keep the summary under 5 minutes. And I remind you that your entire written statement will be included in the record of the hearing and will be distributed to the members of this committee as well as to the media. We are going to begin with Mr. Smith. You are the first witness. I would ask you to proceed.

STATEMENTS OF STEVE SMITH, DIRECTOR OF AGRICULTURE, RED GOLD TOMATO; PHIL MILLER, VICE PRESIDENT, GLOBAL REGULATORY, MONSANTO CO.; BILL FREESE, SCIENCE ADVISOR, CENTER FOR FOOD SAFETY; AND JAY VROOM, CEO, CROPLIFE AMERICA

STATEMENT OF STEVE SMITH

Mr. SMITH. Thank you, Chairman Kucinich, and members of the Domestic Policy Subcommittee. I thank you for the opportunity to present to you some important concerns about the pending release of dicamba-resistant soybeans.

My name is Steve Smith, director of agriculture for Red Gold, the largest privately-held canned tomato processor in the United States. Red Gold is based in Indiana and has three processing facilities. Our tomatoes are grown by 54 family farming operations in Indiana, Ohio, and Michigan.

Our concerns about the upcoming increased use of dicamba are not just about tomatoes but all fruit and vegetable crops and rural homeowners living near local farms. The use of dicamba is not new. It is effective, it is a great weed killer, and it is economical to apply. So many may be wondering why a product that is effective, proven, and economical is not the No. 1 herbicide in use today. The answer is simple: dicamba has also proven itself to move off target and injure adjoining crops, so it is not currently widely used.

New technology is good and needs to be pursued, but must be examined for unintended consequences. At one time the conventional wisdom thought it was a good idea to use lead in paint. The theory of dicamba-tolerant soybeans might appear sound on the surface—the ability to kill weeds is proven—but the potential damage to other sectors of agriculture and rural homeowners demands that we take a closer look at this particular advance.

When put in the spotlight, the answer will become abundantly clear: The widespread use of dicamba is incompatible with Midwestern agriculture. dicamba is highly vulnerable to offsite movement in three forms: direct drift, volatilization, and spray-tank contamination.

You would think that the risk of direct drift could be completely controlled by good management practices such as spraying in little or no wind or when the wind was blowing away from sensitive

crops such as tomatoes. But unfortunately, that is not always the case. Red Gold has suffered over $1 million in drift claims over the last 4 years. A reduced application window has forced otherwise good farmers to spray on windy days when they know they shouldn't.

But I want to focus on volatilization because it is the real issue that makes dicamba a danger to Midwestern agriculture. Volatilization occurs when the active ingredient evaporates and then can be moved with the surrounding air mass for up to 4 days after application; and its killing capabilities can spread up to 2 miles or more in certain geographic areas such as in a valley.

Even the best farmer, the most conscientious farmers can't control or predict what will happen for up to 4 days after application. Ironically, the very conditions that minimize direct drift actually maximize volatilization: little or no wind, high temperatures, and high humidity—normal conditions for when this product is applied in June and July.

A good neighbor that awakens early in the morning to spray before the winds pick up would be at the highest risk of causing volatilization injury.

In other testimony offered, we learn that new formulations of dicamba will reduce the risk of volatilization. We believe those claims to be overly optimistic as even the newest formulations are still proven to move off target. It simply is impossible to control or predict its movement. The science is clear and settled in regard to dicamba's susceptibility to off-target movement due to volatilility.

If, as you might hear from others, the risks of off-target movement of dicamba due to volatilization are low and can be controlled through improved product stewardship and formulations, it only makes sense that those who will profit from the sale of this seed technology and the makers of dicamba should willingly step up to the plate and establish an indemnity fund to cover crop losses and homeowners' claims for damages.

If they are unwilling to cover potential losses, is this an admission that the safety of this technology is not as safe as we have been led to believe? The Midwest is the home to a unique system of family farms that are known as the bread basket of the world. The introduction of dicamba-tolerant soybeans is a classic case of shortsighted enthusiasm over a new technology, putting this region at unneeded risk, and blinding us to the reality of damage that is sure to come.

Even the best, the most conscientious farmers cannot control where this weed killer will end up. Increased dicamba usage made possible through the introduction of dicamba-tolerant soybeans is poor public policy and should not be allowed.

Thank you for the opportunity to present my concerns to you today. I will be happy to answer any questions you might have concerning this topic.

Mr. KUCINICH. Thank you, Mr. Smith.

[The prepared statement of Mr. Smith follows:]

1

Testimony before Congress

Steve Smith

September 30, 2010

Domestic Policy Subcommittee

of

Committee on Oversight and Government Reform

Dennis J. Kucinich, Chairman

Deployment of Dicamba-resistant soybeans and what it will mean to canned and frozen food processors and specialty crop growers in the Midwest

Thank you Mr. Chairman and members of the Domestic Policy Subcommittee, for the opportunity to present to you some important concerns about the pending release of Dicamba-resistant soybeans. My name is Steve Smith, Director of Agriculture for Red Gold, the largest privately held canned tomato processor in the United States, based in Indiana with three processing facilities located there. We purchase tomatoes from 54 family farming operations in Indiana, Ohio and Michigan.

In my capacity at Red Gold, I am privileged to interact with a wide segment of the specialty crop industry in the Midwest, home to a diverse array of canned and frozen fruit and vegetable production, as well as local fresh market and organic production marketed directly to local consumers. A growing wine grape industry has also begun to flourish in Indiana, adding to our diverse production base. These specialty crop industries are worth 254 million dollars to the State of Indiana, providing thousands of jobs throughout our state. These groups, and nearly every food crop represented on the grocers shelves and produce stands, all have an intense interest about the effects of the widespread use of dicamba and the devastation it will cause to the sensitive crops grown in our region.

My life experiences include growing up in central Indiana on a traditional family farming operation, graduating with distinction from Purdue University in Agriculture and being named a Distinguished Alumni in 2009, serving as a Regional Sales Manager for a seed corn and soybean

company, holding a Certified Crop Advisor certificate and having 22 years of experience in the specialty crop industry with Red Gold. **I am convinced that in all of my years serving the agricultural industry, the widespread use of dicamba herbicide possesses the single most serious threat to the future of the specialty crop industry in the Midwest.**

The use of dicamba is not new. It has been a labeled product for use on corn for decades. It has been proven effective for many uses and is not particularly vulnerable to developing resistant strains of weeds. It is economical to apply.

So many may be wondering why a product that is effective, proven, and economical is not the number one herbicide in use today. The answer is simple. Dicamba has proven itself to move off-target and cause injury and yield reductions to soybeans and so in a large sense, it is rarely used. Farmers respect their neighbors and know they are at risk of causing injury if they use dicamba, so it is not widely and routinely used in corn production. However, when soybeans become tolerant to dicamba, it is very likely that the amount of dicamba used in corn production will skyrocket when the fear of soybean injury is eliminated. As an example, when glyphosate soybeans were first introduced, there was significant injury due to drift on corn the first few years. It didn't take long for applicators and farmers to gain a higher degree of respect for the injury that could occur. But once the widespread use of glyphosate resistant corn became common, that level of caution began to erode because it didn't really matter if you drifted onto your neighbor, because their crop was also glyphosate resistant. I also predict a similar fate for dicamba use once soybeans are made tolerant. With no fear of soybean injury, the use of dicamba on corn acreage will dramatically increase, raising the overall exposure of sensitive crops to injury. Because dicamba is deadly to weeds and cheap to use, it is a sure prediction that dicamba use will increase dramatically, followed by escalating crop losses.

In other testimony offered, you may hear that new formulations of dicamba will reduce the risk of volatization. Volatization is the process where the active ingredient literally evaporates into the air and can relocate as the air moves. We believe those claims to be overly optimistic as the characteristics of this molecule have been well documented for about 50 years, and even the newest formulations are still proven to move off-target.

Some might interpret this testimony to imply that I am opposed to advances in technology, and that progress is not a thing to be pursued. Nothing could be further from the truth. The technological progress made in the last twenty years is responsible for us having the world's safest,

most nutritious and affordable food supply. Many might suggest that technology has taken us the wrong direction and is harming our environment and the sustainable nature of agriculture. I would suggest just the opposite to be true when good stewardship practices are implemented and followed. Productivity is a good thing. It lifts our standard of living. If Red Gold can produce a nutritious product for our consumers at a cost they can afford, everyone wins.

However, technological advances need to be critiqued and examined for their overall contributions and unintended consequences. Just because we can do something doesn't mean that we should. At one time, the conventional wisdom thought it was a good idea to use lead in paint. The theory of dicamba tolerant technology might appear sound on the surface. The ability to kill weeds is proven. But the potential damage to other sectors of agriculture and rural homeowners demands that we look further at this particular advance. There may even be geographic areas of the country where this technology would cause only minimal harm and adequate protective measures might even be put into place to protect the public's interest, but definitely not in the Midwest. If dicamba tolerant soybeans are released onto the market place in the Midwest, they will be used and cause harm to our traditional cropping system. Anything that has the potential to cause that type of widespread crop damage should have intense discussion and oversight. When that occurs, the answer will become abundantly clear. **The widespread use of dicamba is incompatible with Midwestern agriculture.**

Since the introduction of glyphosate resistant crops, the pattern of weed control in the Midwest has changed from predominantly pre-plant applications of herbicides, to almost entirely a post-plant, in-season application practice. The effects of this paradigm shift in herbicide applications has affected our company and family growers in a very negative way, due to the potential for direct drifting of spray material onto our tomato fields from applications during windy conditions. The majority of herbicide applications were historically made prior to the planting of most specialty crops, so the drifting of products caused little or no harm. However, the transformation to herbicide applications during the growing season in June and July has put drift prevention at the forefront of concerns to sensitive crop producers of all kinds. Over the last four seasons, our company and growers have been involved with cropping losses exceeding a million dollars due to glyphosate drift.

In addition to the financial loss to our growers, Red Gold is placed in considerable risk of supply disruption due to the drifting of post-applied herbicides. Unlike commercial grain

production, if our tomatoes are damaged, processing tomatoes are not available to be purchased on the open market to make up the losses. We suffer from the risk of having inadequate product for our customers, which could result in the permanent loss of business due to lack of supply. We willingly have chosen to deal with all the traditional production risks and plan our business to minimize those risks, but we are helpless to anticipate the cropping losses that occur due to the misapplication and drift of glyphosate onto our tomatoes. Good stewardship by neighbors and applicators has been fairly successful in preventing direct drift. Unfortunately, with dicamba tolerance being added to soybeans, a whole new challenge far more dangerous and unpredictable than direct drift is knocking on our door.

With glyphosate, crop injuries are the result only from direct drift. Glyphosate is not a volatile compound that will pick up and move in the days or hours following application. Dicamba on the other hand, is highly vulnerable to off-site movement in three forms:

1. **Direct drift.** Dicamba is readily moved by the wind during application. Direct drift is in theory, always preventable, by either applying within label restrictions of wind or by applying when the wind direction would not result in a threat to a sensitive crop.
2. **Volatization**. Dicamba is proven to volatize, or more simply, for the active ingredient to evaporate into the air where it is easily moved off-target as the air mass moves. It can move up to two miles in distance, or even more in certain regions such as down a valley. As opposed to direct drift, the environmental conditions that effectively minimize drift, ironically, **maximizes** the potential for volatilization. Those conditions are high temperatures and high humidity, conditions that are common during a Midwestern summer when a post-applied application of dicamba would be most likely. A producer trying to be a good neighbor, who awakens early so he can spray next to our tomato field before any wind picks up, actually would be applying the material in the most vulnerable fashion for volatilization to occur. Because this can occur for up to four days following the initial application, an applicator cannot adequately take measures to prevent both drift and volatilization. He is in a no-win situation, as is every sensitive crop within a two or more mile radius where dicamba would be applied. **The science is clear and settled in regard to dicamba's susceptibility to off-target movement due to volatility.**
3. **Spray tank contamination.** Dicamba has characteristics that make it extremely hard to get completely cleaned out of spray tanks following use. Some commercial applicators have

told me that they refuse to spray dicamba because they risk damaging the crops of their customers. Even small quantities left in a spray tank will injure crops.

Crop losses caused by direct drift are a violation of label restrictions; however, crop losses caused by volatization are not a violation of the pesticide label. The weather conditions during the application are the deciding factors of misapplication, not what happens at a later time. There will be no recourse for growers or processors for crop losses resulting from volatilization. It is likely that the source of losses might never even be completely pinpointed because under widespread use, the problem could have come from a multitude of sources. Our very livelihoods, and those of our growers, are under severe risk if the widespread use of dicamba is permitted.

The risk of off-target movement is not limited to only tomatoes and other fresh market produce. Growers of non-dicamba tolerant soybeans will be at risk. Organic producers not only risk the loss of produce for sale, but also risk their organic certification for three years if off-target movement of dicamba would occur. Grape and vineyard production is extremely vulnerable and production could be lost for multiple seasons if a serious off-target movement occurred. This would be devastating for many of the most vulnerable small farm producers. These are the farms that produce the fruits and vegetables that become our main weapon in our fight to reduce our national obesity epidemic.

The nature of the common layouts of Midwestern farms, places all of these sensitive crops in close proximity to soybean production where dicamba would be used in a widespread manner. But in addition to the cropping risks posed by the widespread use of dicamba, the desire for country living environments has driven the trend for home construction out into the countryside. Home gardens and landscaping would be extremely vulnerable to off-target movements because of their proximity to the farming areas of the Midwest. In an atmosphere of consumers worried about where their food comes from and worries of residues from all crop protectants in the food supply, damage caused by the off-target movement of dicamba would give all of agriculture a black-eye if home gardens or landscaping were damaged.

If the risks of off-target movement of dicamba due to volatization are low and can be effectively controlled through product stewardship and formulations, it only makes sense that those who will profit from the sale of this seed technology and the makers of dicamba should willingly step up to the plate and establish an indemnity fund to cover crop losses and homeowner's claims

for damages. If they are unwilling to cover potential losses, is this an admission that the safety of this technology is not as safe as we would be led to believe?

Agriculture needs to be building up the confidence of producers and consumers instead of giving them cause for alarm. The Midwest is the home to a unique system of family farms that have been the breadbasket of world agricultural production. The introduction of dicamba tolerant soybeans is a classic case of short-sighted enthusiasm over a new technology blinding us to the reality that is sure to come. **Increased dicamba usage, made possible through the introduction of dicamba tolerant soybeans, is poor public policy and should not be allowed.**

Thank you for the opportunity to present my concerns to you today. I will be happy to answer any questions you might have concerning this topic.

Mr. KUCINICH. Mr. Miller, please proceed.

STATEMENT OF PHIL MILLER

Mr. MILLER. Chairman Kucinich and members of the subcommittee, thank you for inviting me to testify on matters relating to modern agricultural technology.

I work at Monsanto whose only focus is agriculture. I spent much of my youth in a small agricultural community in Lawrence County, Illinois, where I had the privilege of helping my grandfather on his farm. I also have a farm in Nebraska. Through my experiences, I have a great appreciation for what the American farmer has and can achieve with the right tools and a willingness to adopt new technologies and practices.

I currently serve as vice president of regulatory, with more than 500 scientists in my organization, and it is responsible for the global product approval and stewardship.

The topic of today's hearing is an important one. The world population is growing. In the next 40 years or so, there will be 9 billion people on our planet. That is 3 billion more people that will show up to the dinner table, and many will want to use the foods we have grown up with. To put it in context, that is the equivalent of three more Chinas. The challenge is: How do we do it using fewer resources?

Farmers are increasingly being asked to produce more with less, and helping to do this is what Monsanto is all about. Our company has a commitment to sustainable agriculture. We will do our part to help farmers double yield in the core crops of corn, cotton, and soybeans between 2000 and 2030, while producing each bushel or bale with one-third fewer resources.

Just as important, in doing so we will help farmers earn more, and improve the lives of their families and rural communities globally. Agricultural innovation has provided farmers with improved agronomic practices, advances in breeding, and novel traits through modern biotechnology, which increases yield and profits.

In 1996, the Roundup Ready system was first introduced into soybeans. The Roundup Ready system was attractive to farmers because it offered superior crop safety and the use of a familiar and proven herbicide that controls more than 300 weeds. In Roundup Ready Soybeans, glyphosate sprayed after the crop's weeds emerge provide a level of weed control and ease of use that surpasses other options.

Importantly, in addition to the benefits provided in weed control, the Roundup Ready system has made the adoption of conservation tillage practices feasible. Conservation tillage contributes to the long-term sustainability of farming practices.

Before the Roundup Ready system was introduced, the environmental benefits of conservation tillage were documented, but adoption by growers had been limited. The broad enrollment in conservation tillage due to the Roundup Ready system has led to the reduction and extensive plowing and tillage which has significantly reduced the loss of topsoil due to erosion, improved soil structure, reduced runoff of sediment and fertilizer, reduced on-farm fuel use, reduced CO_{50} emissions, and increased carbon sequestration in the soil.

Controlling weeds is paramount in maintaining and improving crop productivity. Unlike insects and diseases which occur in some years and not others, weeds occur in crops every year. Experts recommend using multiple herbicides to provide more than one mechanism of action. Applying multiple mechanisms of action reduces the likelihood of a resistant weed population developing because there is a low probability that a particular weed within a population would have resistance to both mechanisms of action.

In addition, farmers may choose to use mechanical or cultural techniques in addition to or in place of herbicides. The specific program employed would depend on the farmer's choice and the best management practices on his or her farm.

Monsanto has shared interest with farmers in effective weed management. The proactive adoption of best management practices based on the principle of diversity in weed management will improve weed control, help ensure that conservation tillage systems are sustainable, and that the yield, economic, and environmental benefits are fully realized.

As I stated at the beginning of my remarks, Monsanto's only focus is agriculture. If farmers don't succeed, Monsanto doesn't succeed. That is why as we bring new technology to the market, we value growers' input, such as Mr. Smith who is here today, who we have invited and has become a member of our dicamba advisory council. We are committed to invest and develop seed and trait systems to provide farmers with effective, affordable, convenient and sustainable agricultural solutions, including weed control.

Thank you, Mr. Chairman, for your time and attention today. I look forward to answering your questions.

Mr. KUCINICH. Thank you for your testimony.

[The prepared statement of Mr. Miller follows:]

**Written Statement of Philip W. Miller on behalf of Monsanto Company
for the September 30, 2010 hearing of the Domestic Policy Subcommittee
of the US House of Representatives Oversight & Government Reform Committee**

Chairman Kucinich, Ranking Member Jordan and Members of Subcommittee, thank you for inviting me to testify on matters relating to modern agricultural technologies.

I work at Monsanto, a company 100 percent focused on agriculture. We develop improved seed through advanced breeding as well as biotechnology. We work with others to build cropping systems that help farmers produce more bountiful harvests on each acre, with plants that can protect themselves from many pests. We enable weed control within conservation tillage systems that reduce soil erosion, water loss and carbon emissions.

Using these tools, American farmers reach unparalleled levels of productivity to feed and clothe more people with every acre. They are driving the U.S. economy, while helping to meet the demand for food, fuel and fiber that is increasing with global population and income levels.

Our company has a three-pronged commitment to improve sustainable agriculture: We will do our part to help farmers double yields in our core crops of corn, cotton and soybeans between 2000 and 2030, while producing each bushel or bale with one-third fewer resources (such as land, water and energy) in aggregate. And, just as importantly, in so doing we will help farmers to earn more and improve the lives of their families and rural communities.

We made this commitment in recognition that we are privileged to work in an amazing industry – agriculture – that is at the heart of some of our planet's biggest challenges, ranging from hunger, malnutrition and rural poverty to land degradation, water scarcity and climate change.

By the end of this day, the world will have 210,000 more people than the day before who are in need of food, fiber and fuel from agriculture. Experts have suggested that the requirements of food production over the next 50 years will exceed the production we have achieved in the past 10,000 years, cumulatively. Irrigated crop production accounts for 40 percent of the world's food supply; however, with global water use growing at twice the population rate, farmers are becoming more challenged to secure enough water for their crops. In the face of these challenges, the agricultural sector needs to focus on farm management practices and technologies that can improve productivity while conserving natural resources and minimizing the global footprint of agriculture. Monsanto is committed to helping farmers become more productive and sustainable each year.

Agricultural innovation has provided farmers with improved agronomic practices, advances in crop breeding, and novel traits through modern biotechnology to increase yields and profits.

Farmers utilize a wide range of technologies on the farm to maximize yields while minimizing the risk of crop failure.

Controlling weeds is paramount in maintaining and improving crop productivity. Unlike insects and diseases, which occur in some years and not others, weeds are ubiquitous. They return every year from millions of seeds, tubers or rhizomes, deposited in the soil annually from weeds that survive in the field, fence rows, and irrigation ditches, and spread from field to field on planting, crop treatment and harvesting machinery.

In the 1930's, farmers relied on deep plowing and tillage for weed control but excessive tillage caused devastating soil losses due to wind erosion and run-off. The invention and commercialization of synthetic chemical herbicides over the past 60 years has offered growers new tools for controlling weeds.

The herbicide glyphosate, introduced in the early 1970's, expanded the weed management options available to farmers. Glyphosate controlled a broad spectrum of weeds more effectively than combinations of herbicides used previously, resulting in improved weed control for farmers and improved farm management and profits. However, because glyphosate killed nearly all leafy green plants, it had to be used in ways so that it did not come into contact with crops. Glyphosate controls more than 300 annual and perennial grass and broadleaf species, providing the widest spectrum of control compared to any other herbicide. Farmers quickly recognized the benefits of glyphosate herbicides.

In 2000, Monsanto's US patent on glyphosate expired. Today, farmers in the United States have several choices of generic glyphosate herbicide products. Monsanto continues to sell Roundup® brand glyphosate herbicide products.

In 1996, the Roundup Ready® system (seeds modified to be tolerant to glyphosate and which allowed the use of glyphosate for weed control in the crop) was first introduced in soybeans. The Roundup Ready system was attractive to farmers because it offered superior crop safety, and the use of a familiar and proven herbicide that was active on a broad spectrum of annual and perennial weeds (grasses and broadleaves). In Roundup Ready soybeans, glyphosate sprayed once or twice in a season after the crops and weeds emerged provided a level of weed control and ease of use that surpassed other options.

The same was true for glyphosate tolerant corn, cotton, and canola that were commercialized in the late 1990's. Importantly, in addition to the benefits provided in weed control, the Roundup Ready system has made the adoption of conservation tillage practices feasible on many more farms. Conservation tillage contributes to the long-term sustainability of farming practices. Before the Roundup Ready system was introduced, the environmental benefits of conservation

tillage, including low-till and no-till practices, were documented but adoption by growers had been limited, in part, because they could not get acceptable weed control without tillage in many instances. The use of herbicides and in particular glyphosate for weed control instead of extensive plowing and tillage has significantly reduced the loss of topsoil due to soil erosion, improved soil structure with higher organic matter, reduced runoff of sediment and fertilizer, reduced on-farm fuel use, reduced CO_2 emissions, and increased carbon sequestration in soil.

Over the past 20 years, the number of corn, soybean and cotton acres in conservation tillage has nearly doubled to a total of 82 million acres in 2008. Farmers have consistently indicated that Roundup Ready technology has been a critical innovation allowing them to shift to conservation tillage. In 2001, a survey by the American Soybean Association (ASA) of its members revealed that the adoption of Roundup Ready technology was the primary reason farmers reduced tillage in soybean production.

The topic of herbicide resistance in weeds is of interest to the Subcommittee. A herbicide resistant weed will survive an application of a herbicide that will normally kill the weed. Within a weed population, individual plants with resistance to a particular herbicide and/or herbicide class can occur naturally. Such biological variability is not caused by use of the herbicide. Subsequent use of the herbicide merely selects for those plants that already have the resistance.

Weed resistance to herbicides is not new. Guided by continuing research, new strategies to manage herbicide resistance have been developed and continue to evolve. Monsanto, other companies, universities, government agencies, and crop commodity groups are working to provide farmers with the most up-to-date recommendations and to educate them on the importance of adopting practices to manage herbicide resistance.

There are inherent differences among the herbicide classes. Some herbicide classes are more prone to resistance than others. The first instance in the United States of a weed being determined to have resistance to a herbicide occurred in 1957 when spreading dayflower in Hawaii was found to be resistant to the herbicide 2,4-D. Although resistant weed populations have been known for over 50 years, 2,4-D is still widely used around the world and is an ingredient in products familiar to consumers such as Weed B Gone. The first weed displaying resistance to glyphosate was annual ryegrass discovered in Australia in 1996. In 1998, ryegrass resistant to glyphosate was observed in California where glyphosate was being used for weed control in orchards.

Today there are 19 weed species worldwide with confirmed resistance to glyphosate, 10 of which are present in the U.S. This compares to 107, 68, and 37 species with confirmed resistance to the three other major classes of herbicides (ALS inhibitors, PSII (triazines) and ACCase inhibitors, respectively) used by many farmers growing soybean, cotton and corn in the U.S. As with glyphosate, farmers continue to use these products because they provide significant value in

their weed management programs. As weed resistance occurs, farmers adjust their weed management practices. The best way to manage weed resistance on a particular farm depends on the particular circumstances on that farm.

Weed resistance is an herbicide issue, not a biotech crop issue, and is dependent on how herbicides are used. Under the Federal Insecticide, Fungicide and Rodenticide Act (FIFRA) and the Federal Government's Coordinated Framework for regulating biotechnology-derived products, EPA is the agency charged with analyzing the potential environmental impacts from the use of a pesticide. Specifically, EPA must evaluate whether the use of a pesticide in accordance with instructions on its label will result in "unreasonable adverse effects [to humans or] the environment." EPA balances the risks and benefits of pesticide products when applying this standard to determine whether to register a particular pesticide for a specific use.

Before an herbicide is authorized for a particular use, including over the top of a herbicide-tolerant crop, EPA must register that use in accordance with FIFRA. Since its introduction in the 1970's, EPA has regulated the use of glyphosate and for over fifteen years, EPA has registered glyphosate for use over the top of Roundup Ready crops.

EPA recognizes and has addressed weed resistance as an issue requiring attention. The Agency has issued guidance to pesticide registrants concerning weed resistance management information on pesticide labels. This guidance instructs registrants on information to provide to farmers regarding the mechanism of action of the herbicide and recommendations on practices to implement for delaying herbicide resistance. Monsanto follows EPA's guidance on its glyphosate labels and goes beyond EPA's specific guidance in providing recommendations to farmers.

Monsanto is actively evaluating and reevaluating herbicide resistance in order to refine further the best proactive management practices. Over the last 5 years Monsanto has invested more than $30 million dollars in collaboration with academics in the U.S. alone to study developments in resistance to glyphosate and improve management practices. EPA, USDA-ARS, and others in industry are also devoting resources to actively address herbicide resistance.

Today there is broad agreement among public and private sector scientists on practices that can minimize the potential for additional weeds developing resistance to herbicides. These practices were highlighted in a National Research Council Report issued in April. A summary of these best management practices is published on the Herbicide Resistance Action Committee (HRAC) website (www.hracglobal.com) and the Weed Science Society of America (WSSA) website. Experts recommend using multiple herbicides to provide more than one mechanism of action. Using multiple mechanisms of action reduces the likelihood of a resistant weed population developing because there is a low probability that a particular weed within a population would

have resistance to both mechanisms of action. In addition, farmers may choose to use mechanical and/or cultural techniques in addition to, or in place of, herbicides. In many cases a proactive weed management program, in fields where no resistant weeds are present, will be identical to the weed control practices that a farmer would employ to control resistant weeds. The specific program employed will depend on the particular circumstances on that farm.

Even in locations where there are glyphosate resistant weeds, glyphosate continues to provide significant benefits to farmers and continues to be recommended by academics and extension agents as a key component in weed management systems. Glyphosate provides a foundation for economical and effective weed control in a diversified weed management program.

The need for proactive management of weed resistance continues to be addressed in many diverse venues. Weed scientists have learned from over 30 years of research that there is more than one way to manage herbicide resistance. University and industry experts believe that the best way to influence grower behavior is through intensive training and education programs. Monsanto, university/cooperative extension services, and other companies have devoted significant time and resources to grower/retailer education and training programs. Other organizations are also involved. For example the National Association of Conservation Districts and USDA's National Resources Conservation Service (NRCS) have brought together weed scientists and soil conservation officials from the south, southeast and mid-west to explore opportunities to further expand outreach to farmers on the need to implement best management practices for weed resistance. As growers are educated, more and more of them are adopting diverse weed control practices.

The Weed Science Society of America, in particular, has been active in coordinating activities of the scientific community regarding farmer education programs. Farm publications have also focused on the issue, raising awareness and serving as a means for public and private sector scientists to promote best management practices. These efforts are also leading more farmers to adopt diversified weed management programs on their crop acres.

In addition to farmer education and training about on-farm weed control practices, many companies are investing in the development of new weed control tools for farmers. At Monsanto, some specific technologies under development include new formulations of existing herbicide products and the development of new herbicide tolerant traits for soybeans and cotton plants that will provide additional options for weed control practices.

For example, Monsanto has been in the process of developing crops tolerant to dicamba because the ability to use dicamba in the Roundup Ready system would give growers more weed control options and flexibility. With dicamba tolerant soybean, for instance, the grower has the option to use dicamba as an effective weed control treatment prior to planting and can then plant soybeans without further delay. Furthermore, the ability to use glyphosate and dicamba together

throughout the growing season enables growers to manage resistant weeds and improve control of tough broadleaf weeds.

After more than 40 years of use there are four plant species with populations that are resistant to dicamba in the U.S. and Canada, and 5 worldwide. Dicamba is a member of the auxin family of herbicides.

Proper stewardship of dicamba in dicamba tolerant crops is imperative, and includes attention to guarding against the development of weeds resistant to dicamba and minimizing off-site movement of dicamba. To address weed resistance, we will continue training growers on the importance of a diverse weed management program and will only recommend the use of dicamba in combination with other herbicides. It is well known by scientists and farmers that off-site movement of pesticides occurs. Monsanto is aware of the concerns regarding the off-site movement of dicamba and is working with multiple stakeholders to address this issue. We are also working with other companies to develop improved dicamba formulations that reduce the potential for off-site movement.

Monsanto has a shared interest with farmers in effective weed management and in conservation tillage systems that are sustainable. The proactive adoption of best management practices based on the principle of diversity in weed management will improve weed control, help ensure that conservation tillage systems are sustainable, and that the economic and environmental benefits are fully realized. As we educate farmers, more and more are adopting diverse practices.

As I stated at the beginning of these remarks, Monsanto is 100% focused on agriculture. If the farmer doesn't succeed, Monsanto doesn't succeed. We are committed to developing seed and trait systems that provide farmers with effective, affordable, convenient, and sustainable agricultural solutions, including weed control. We recognize that proactive and diverse weed management practices are needed to preserve the benefits of the Roundup Ready system. To support best practices for sustainable weed management, Monsanto is broadly engaged in education and outreach efforts. We're also involved in public and private sector initiatives committed to sustaining the farmer and environmental benefits of herbicide tolerant crops and conservation tillage systems. And, Monsanto will continue to invest in research to provide our customers with products and recommendations that make them successful and promote sustainable agriculture.

Mr. KUCINICH. Mr. Freese.

STATEMENT OF BILL FREESE

Mr. FREESE. Yes. Chairman Kucinich and members of the subcommittee, thank you for inviting me here today to testify. I would just like to preference my remarks quickly to respond to something Ms. Wright and Mr. Miller just said about world hunger and productivity.

Actually, the subject here, Roundup Ready crops, do not have higher yields. That is a myth. It is basically designed to save time and save labor and help farmers get bigger. Also, there is an increase in pesticide use with these crops, actually quite substantial, not a decrease. And the conservation tillage benefits that Mr. Miller mentioned, conservation tillage was mostly adopted before the introduction of these Roundup Ready crops.

Just as Roundup Ready crops were being introduced in 1997, Monsanto scientists published a paper in which they presented all of the reasons weeds were not likely to evolve resistance to glyphosate. It is not the first time they have been wrong, and they turned out to be disastrously wrong. As discussed in part 1 of this hearing in July, unregulated use of these crop systems has triggered an epidemic of glyphosate-resistant weeds, and it fostered sharp increases in herbicide use, greater use of soil-eroding tillage operations, and is substantially raising weed control costs for evermore growers.

Now Monsanto and other pesticide firms assure us that multiple herbicide-resistant weeds are the solution to glyphosate-resistant weeds.

Dupont, for instance, even envisions a single crop resistant to seven or more different classes of herbicides. There are hundreds of millions of dollars being invested in resistance genes to just about every herbicide imaginable, including paraquat, for instance, and about half of the GE crops pending deregulation at USDA right now are herbicide-resistant.

We shouldn't let ourselves be misled again. These new herbicide-resistant crops are the wrong response to glyphosate-resistant weeds. Just very briefly, and I can go into detail in questions if you would like, but one reason is that they simply won't work. At best we will get a short-term reprieve until nature cleverly evolves resistance to the new and multiple herbicides deployed against them.

Second, farmers will pay in multiple ways through increasingly expensive biotech seeds and the multiple herbicide cocktails that come with them, and through crop damage, as Steve mentioned, or through purchasing the HR seed in order to defend oneself against drift.

Third, both public health and the environment will suffer from a substantially increased use of toxic herbicides such as 2,4-D and dicamba.

Finally, this new wave of crops diverts attention from truly sustainable weed control practices, which I would like to get to in a moment.

I think it is very clear that the glyphosate-resistant weed epidemic is a symptom of regulatory breakdown. We have USDA which regulates an herbicide-resistant crop, and the EPA the herbi-

cide; but no one regulates the combination, the herbicide-resistant crop, the herbicide system. And it is the system, the continual use of a herbicide, glyphosate on Roundup Ready crops, that is responsible for the growing epidemic of resistant weeds. This system has been presented to farmers as self-contained, two component, seed and Roundup, and that is the way it has been used. I am tired of people blaming farmers for this.

When a Federal district court judge reversed APHIS's deregulation of Roundup Ready alfalfa, he underscored APHIS's failure to examine glyphosate use. APHIS now gives purely pro forma attention to herbicide use in their regulatory reviews, and even this minimal treatment is grossly inadequate.

APHIS, for instance, dismissed analysis of herbicide use of Roundup Ready crops in the Roundup Ready draft and Environmental Impact Statement that relied on gold-standard data from its sister agency, the National Agricultural Statistic Service, and in its place it used bogus data from simulations conducted by pesticide industry-funded groups, like the National Center for Food and Agriculture Policy and PG Economics.

In other cases, USDA cited completely irrelevant data that was 10 years old or more, no relevance. APHIS also ignored research by scientists from USDA's Agricultural Research Service and others that point to potentially increased disease susceptibility in Roundup-treated, Roundup Ready crops. And, unfortunately, USDA does not require testing of Roundup Ready crops to which Roundup has been applied, which is the invariable practice of farmers. In view of the growing evidence of disease, possible disease susceptibility issues, that is inexcusable.

I would just like to say USDA should definitely follow the lead of the EPA. The successful insect resistant management program could be followed by USDA. And I don't buy Ms. Wright's protestations that USDA doesn't have authority. The noxious weed provisions of the Plant Protection Action clearly gives them authority to regulate practices that foster noxious weeds, and that is exactly what these Roundup Ready systems are.

Mr. KUCINICH. I thank the gentleman for his testimony. As I said, your entire testimony will be included in the record of this hearing. I am sure that we will get back to you with some questions. Thank you very much.

[The prepared statement of Mr. Freese follows:]

Testimony Before the Domestic Policy Subcommittee of the House Oversight and Government Reform Committee

by William Freese
Science Policy Analyst
Center for Food Safety

September 30, 2010

In 1997, just as Roundup Ready crops were being introduced, Monsanto scientists published a paper in which they presented all the many reasons weeds were NOT likely to evolve resistance to glyphosate, the active ingredient in Roundup [1]. Well, this prediction turned out to be wrong, disastrously wrong for a growing number of farmers. As discussed at Part 1 of this hearing in July, unregulated use of glyphosate-resistant crop systems has triggered an epidemic of glyphosate-resistant weeds infesting 10 million acres or more. It has also fostered sharp increases in herbicide use and greater use of soil eroding tillage operations, and is substantially raising weed control costs for ever more growers. Syngenta's Chuck Foresman projects a 40% annual increase in area with glyphosate-resistant weeds, which would infest 38 million acres, or one of every four row crop acres, just 3 years from now in 2013 [2].

Now Monsanto and other pesticide firms assure us that the solution to glyphosate-resistant weeds lies in a dizzying array of new crops resistant to older, more toxic herbicides like 2,4-D [3] and dicamba [4], and to multiple herbicides. DuPont envisions a single crop resistant to seven or more different classes of herbicides [5]. This is the major R&D focus of the industry, with hundreds of millions of dollars being invested [6], and resistance genes available for practically every major class of herbicide, including the notorious neurotoxin paraquat [7]. Nearly half of the genetically engineered (GE) crops pending deregulation at USDA are herbicide-resistant [8], and most will be offered in multiple herbicide-resistant (HR) cultivars.

We should not let ourselves be misled once again. These new HR crops are the wrong response to resistant weeds, for several reasons. First, they will substantially increase use of the associated herbicides, increasing our exposure to them in water and food. And as recently highlighted by the President's Cancer Panel, many pesticides are known or suspected

carcinogens that we should be reducing, not increasing, or exposure to [9]. Some pesticides, like 2,4-D, can also mimic human hormones, disrupting the body's intricate signaling system that plays such a crucial role in development, metabolism and reproduction. For instance, male pesticide applicators exposed to 2,4-D had lower sperm counts and more spermatic abnormalities than men not exposed to it. 2,4-D has also been shown to significantly depress levels of thyroid hormone, essential for normal development of the brain, in ewes treated with the chemical [10]. 2,4-D-resistant soybeans and corn break down 2,4-D into a still more toxic compound known as dichlorophenol, presenting food safety risks [11].

Second, HR crops facilitate ***mid-season*** use of herbicides that drift and volatilize to damage neighbors' crops. In some cases, farmers will purchase expensive HR seeds not because they want them, but to ***defend against*** drift from or misapplication by neighbors. Of course, even this is only possible if an appropriate HR cultivar of the pertinent crop is available. In either case, whether through crop damage or "defensive" purchase of expensive HR seed, the non-adopting farmer is incurring costs he should not have to bear.

Third, HR crops will accelerate the evolution of weeds resistant to HR crop-associated herbicides. Already, common waterhemp resistant to three and four classes of herbicides are rampant in Missouri and Illinois. Weeds can acquire resistance to herbicides one at a time, or to several at once via a mechanism known as metabolic degradation. The evolution of weed resistance to several herbicides simultaneously will be fostered by increased use of herbicide mixtures with multiple HR crops, a very troubling development. I would be happy to explain further why faith in multiple herbicide resistance as a "solution" to HR weeds is misplaced, and in fact will likely accelerate the evolution of weeds resistant to multiple herbicides.

The glyphosate-resistant weed epidemic is a symptom of regulatory breakdown, a devastating example of how thoroughly discoordinated the Coordinated Framework for Regulation of Biotechnology actually is. USDA's Animal and Plant Health Inspection Service (APHIS) regulates the HR crop, EPA regulates the associated herbicide(s). But NO ONE regulates the combination, the HR crop-herbicide system. And it is ***the system*** – the invariable use of glyphosate made possible and fostered by glyphosate-resistant seeds, for instance – that is

responsible for the growing epidemic of glyphosate-resistant (GR) weeds. This is clearly demonstrated by the near complete absence of GR weeds for the first 20+ years of glyphosate's use, and the explosion of weed resistance in the decade since the widespread adoption of Roundup Ready crop systems. We can anticipate similar issues with future HR crop systems unless serious regulatory action is taken.

When a federal district court judge reversed APHIS's deregulation of Roundup Ready (RR) alfalfa due to inadequate environmental assessment, he underscored APHIS's failure to examine glyphosate use linked to the RR crop, and the interrelated issue of resistant weeds, as a major failing [12]. Since that time, APHIS has given purely pro forma attention to herbicide use in association with glyphosate-resistant and other HR crops. And even this minimal treatment is grossly inadequate. In APHIS's draft environmental impact statement (EIS) on Roundup Ready alfalfa, for instance, it dismissed analysis of herbicide use with RR crops by an independent scientist that relied on gold-standard data from its sister agency, USDA's National Agricultural Statistics Service (NASS) [13], and mistakenly criticized these data as lacking in ways they aren't. Instead, APHIS relied on misinformation from bogus "simulation studies" conducted by pesticide-industry funded groups or contractors, such as the National Center for Food and Agriculture Policy (NCFAP) and PG Economics. In other cases, USDA cited pesticide usage data that were 10 or more years old, largely before Roundup Ready (RR) crops and the resistant weeds fostered by these crop systems drove substantial increases in herbicide use. I would be happy to provide more detail on these matters.

In still other cases, APHIS has ignored or dismissed research by scientists from another USDA sister agency, the Agricultural Research Service (ARS), that points to mineral deficiencies and increased disease susceptibility in Roundup-treated Roundup Ready crops [14], and in non-RR crops planted in the same field in subsequent seasons [15]. Interestingly, APHIS allows companies (e.g. Monsanto) submitting petitions for deregulation of glyphosate-resistant crops to submit the results of agronomic observation trials (to assess seedling vigor, growth habit, crop susceptibility to disease and insects, and similar features) that do NOT involve application of Roundup/glyphosate to the glyphosate-resistant crop. In view of the considerable and growing body of research by USDA ARS and other independent scientists alluded to above, this is

inexcusable. When a new GR crop is deregulated, the applicant has thus provided essentially no information on whether it is more prone to mineral deficiencies or fungal diseases than a conventional variety – despite peer-reviewed literature on similar GR crop systems suggesting that it very well may. A crop system that increases the disease susceptibility of a crop presents a potential plant pest risk that may require regulation under the Plant Protection Act.

In the programmatic EIS APHIS conducted for its GMO rules revision process that was completed in 2007, herbicide-resistant crops and weeds were almost completely ignored. Incredibly, the brief discussion of GR weeds referred to reports in Australia in the 1990s, and completely neglected to discuss the resistant weed epidemic triggered by RR crop systems in the U.S., much less any regulatory options for managing it.

USDA should follow the lead of the EPA, which has largely forestalled evolution of insect resistance to the insecticidal toxins in Bt crops through mandatory insect resistance management (IRM) plans. These plans have helped greatly to prevent the emergence of Bt toxin-resistant insect pests, despite serious compliance problems. Compliance deficits probably relate to the fact that IRM plans, though mandatory, are largely administered by the biotech-seed companies themselves. One example is Monsanto's illegal distribution of Bt cotton seeds in Texas over the five years from 2002 to 2007 without informing farmers of IRM planting restrictions in grower guides, for which EPA levied a $2.5 million fine on the company [16]. Thus, more direct involvement and oversight by EPA would be desirable.

EPA determined that because the insecticidal protein was incorporated in and inseparable from the Bt plant's tissues, its regulatory jurisdiction extended to the Bt plant. Based on its assessment that Bt insecticidal toxins are less toxic than conventional chemical insecticides, and that selection pressure for evolution of Bt toxin-resistant insects would be enormous, and thus rapidly degrade the efficacy of these compounds through resistance, EPA determined that mandatory resistance management was called for – to preserve the efficacy of these compounds as a public good.

Very similar considerations apply to glyphosate and glyphosate-resistant crops. The mere fact

that the GR plant and glyphosate are not physically joined as Bt toxins are in Bt crop tissues matters little in practical terms if indeed the two are invariably used together, as they are, by design. And since glyphosate is generally regarded as less toxic than most herbicides, it would be beneficial to preserve its efficacy. We should note, though, that many scientists have found that certain supposedly "inert" ingredients added to Roundup formulations to increase the efficacy of glyphosate are more toxic than glyphosate itself. One such "inert" ingredient in particular, polyethoxylated tallowamine (POEA), has long been implicated in causing high mortality to populations of frogs exposed to Roundup formulations containing it at field-relevant concentrations [17]. (To its credit, Lisa Jackson's EPA is taking initial steps towards improved regulation of these often toxic "inert" ingredients.)

However the science eventually plays out on the toxicity/safety of glyphosate and its various formulations, it would be beneficial to preserve its efficacy, and that means checking the GR weed epidemic. Roundup Ready crop systems have proven to be wonderfully adapted to breed rapid evolution of GR weeds. Such weeds, once emerged, can spread to infest the fields of other growers, including those who do not use glyphosate-resistant crops at all. (The windborne seed of horseweed can travel for miles on the wind [18], and it is perhaps not a coincidence that GR horseweed is the most prevalent of GR weeds, infesting at last count up to 6.3 million acres in the U.S. [19]). Such a grower (say of wheat) may well use glyphosate as a burndown herbicide. Single season burndown use of glyphosate is much less likely to foster evolution of GR weeds than the two and three in-crop applications that are becoming ever more common for Roundup Ready growers. A wheat grower whose fields are infested with GR weeds in this manner, through no fault of his own, would have to apply more toxic herbicides like 2,4-D instead of (or in addition to) glyphosate, incurring both added cost and potential harm to health.

USDA has the authority to regulate HR crops for their clear propensity to foster rapid evolution of HR weeds under the noxious weed provisions of the Plant Protection Act, as well as the general provisions charging APHIS with protection of the "interests of agriculture." When one considers the huge costs imposed on cotton growers by glyphosate-resistant Palmer amaranth and horseweed, regulation becomes not just possible, but an urgent necessity. According to University of Georgia's Brad Haire, speaking of glyphosate-resistant Palmer amaranth: "We're

talking survival, at least economically speaking, in some areas, because some growers aren't going to survive this" [20]. Eminent weed scientist Alan York has a similar take, once comparing glyphosate-resistant Palmer amaranth to the boll weevil in terms of the threat it poses to the U.S. cotton industry [21]. The boll weevil devastated cotton growers throughout the South, making it impossible to grow for many years in some areas, and necessitated massive campaigns for its eradication. By one account, the boll weevil cost the cotton industy $46 billion dollars over the past century [22]. In the face of costs and risks from GR weeds that are even a fraction of this magnitude, continued inaction by USDA is irresponsible.

CFS has the following recommendations.

1) USDA should refrain from deregulation of any new HR crop, particularly Roundup Ready alfalfa and Roundup Ready sugar beets, unless or until:
   a. Weed resistance management plans, and
   b. Protection plans for those farmers who choose not to adopt the HR crop;
   are made mandatory conditions for commercial planting. Good resistance management plans will take study and work, and input from growers as well as extension agents, independent scientists and the EPA.

2) Such management plans would best incorporate some prohibition on continual, year-in, year-out planting of an HR crop in order to lessen selection pressure for evolution of resistant weeds from continual use of the associated herbicides(s). Such management plans should be developed for existing GR crops as well. This would be the temporal equivalent to the spatial refugia required (or once required) by EPA for IRM. USDA should consult with EPA in formulating such plans.

3) USDA should promote integrated weed management practices ***that prioritize non-chemical modes of weed control, such as cover crops,*** and do this at every level: research, stronger IWM curricula at land grants, demonstration plots, training of extension agents and farmers, etc. Winter cover crops such as cereal rye, hairy vetch and red clover are planted in the fall after the main crop's harvest, grow in the fall and

next spring, and when killed prior to spring planting provide physical suppression of weeds in the following main crop. Cover crops provide multiple additional benefits as well, including uptake of excess nitrogen and phosphorus from fertilizer application (reducing adverse nutrient loading of water bodies from runoff) and inhibition of soil erosion during snow thaw in the spring. Weed scientists have specifically recommended increased use of cover crops to suppress glyphosate-resistant weeds. Such promotion of IWM practices could be funded by USDA's National Institute of Food and Agriculture, and perhaps also by an HR seed fee that is collected from each pesticide-biotech firm for each acre of HR seed or HR trait acre that is sold. USDA should also fund active and comprehensive monitoring of herbicide-resistant weeds led by independent land grant scientists, as recently recommended by the Government Accountability Office, given the inadequacies of the current system, funded largely by the pesticide industry.

Mr. KUCINICH. Mr. Vroom.

STATEMENT OF JAY VROOM

Mr. VROOM. Thank you, Chairman Kucinich and Congresswoman Watson, for allowing me to come and provide testimony today on behalf of the crop protection industry and CropLife America. Thank you for introducing me earlier.

In addition to my role as CEO of our trade association, I also have an Illinois farm background and happen to still own the family farm that I was reared on.

I happen to have been in Illinois twice in the last 6 weeks. Six weeks ago I stopped to take a look at one of the fields that is now being operated by my cousin. It was planted this year in Roundup Ready Soybeans. It was planted as a no-till crop, and Mr. Chairman, I would love to share this photograph. There are three of them here. I am most proud of this particular view, because it shows this field in the direction in which a terrace that my father installed as a charter member of our Bureau County, IL, soil and water conservation district, one of the first terraces installed in the country, to provide then the cutting-edge technology for soil conservation at that time.

I remember as a youth hand-weeding and hand-cultivating with mechanical means fields of soybeans and other crops on this very field, and we were not able to control the soil erosion as we can today with the Roundup Ready technology. If I can pass this up and maybe ask your staff to share that with you.

Mr. KUCINICH. We will include it in the record. Without objection, so ordered.

[The information referred to follows:]

Mr. VROOM. Thank you.

So conservation tillage is an important component of the introduction of biotechnology.

I also have a report by our Crop Protection Research Institute that illustrates on page 2 a graph of introduction of modern biotechnology and then the takeoff of the adoption of conservation tillage in this country. It has made a meaningful difference, and I believe there are clear USDA statistics to that effect.

Mr. KUCINICH. Without objection, that will be included in the record of the hearing.

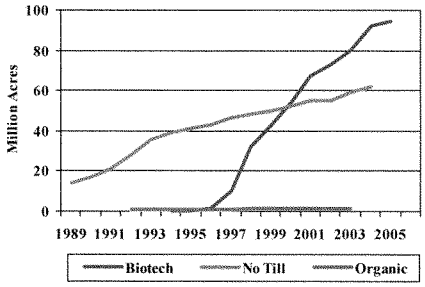
The Value of Herbicides in U.S. Crop Production: 2005 Update

Executive Summary

Herbicides are chemical pesticides that kill weeds. U.S. farmers have sprayed herbicides on nearly 90% of the nation's cropland acreage for the past 30 years.

The value of the use of herbicides in 2005 is estimated to have been $16 billion in increased crop yields and $10 billion in reduced weed control costs.

The use of herbicides greatly reduces the need for fuel and laborers on U.S. farms. If farmers did not use herbicides, the alternatives for weed control would be increased mechanical cultivation and increased hand labor to pull weeds. The need for fuel would be 337 million gallons higher, since twice as many cultivation trips would be needed to replace herbicide spray trips and cultivators use four times more fuel per trip than herbicide sprayers. A minimum of 1.1 billion hours of hand labor would be required at peak season for hand weeding, necessitating the employment of 7 million more agricultural workers. Even with the increased cultivation and hand weeding, crop yields would be 20% lower. Approximately 70 million workers would be needed to prevent any yield loss without herbicides.



The largest production loss would be in corn, with a reduction of 2.7 billion bushels. Corn is the main feedstock for U.S. ethanol production, a major alternative being developed to reduce dependence on oil. The corn production loss due to the non-use of herbicides is equivalent to 7.3 billion gallons of ethanol, which is equal to the entire projected capacity of U.S. ethanol production by 2010.

Without herbicides, U.S. growers would have to abandon no-till production practices, which are effective and popular techniques for reducing soil erosion. Without tillage, growers kill weeds with herbicides. If U.S. growers stopped using herbicides and resumed tillage on the 62 million acres that were not tilled in 2005, soil erosion would be 356 billion pounds higher than it is today. Soil erosion deposits sediments in streams and rivers resulting in downstream damages. The damage resulting from increased soil erosion due to farming without herbicides is estimated at $1.4 billion.

Value of Herbicides in U.S. Crop Production: 2005	
Total Acres Treated with Herbicides	215 million
Current Herbicide Cost to Growers	$7.1 billion
Herbicide Non-Use Cost Increase	$9.7 billion
Herbicide Non-Use Yield Loss (*Volume*)	295.7 billion pounds
Herbicide Non-Use Yield Loss (*Value*)	$16.3 billion
Herbicide Non-Use Labor	+1.1 billion hours
Herbicide Non-Use Erosion	+356 billion pounds
Herbicide Non-Use Fuel Consumption	+337 million gallons
Herbicide Non-Use Net Income Impact	-$26.0 billion

Phone 202-296-1585 www.croplifefoundation.org Fax 202-463-0474

This report for 2005 is an update of a previously issued report for 2001. The same methodology was used in both reports, which makes it possible to report on fluctuations in the herbicide market and changes in the benefits of herbicides. Due to significant price decreases, U.S. farm expenditures for herbicides declined by $300 million between 2001 and 2005. The price decline for herbicides was outweighed by increases in the costs of applying herbicides due to higher labor and fuel costs (+$500 million) and increases in the premium prices paid for biotech herbicide-tolerant seed (+$312 million). Thus, the total cost of herbicides and their application increased by $512 million between 2001 and 2005.

Increased fuel and labor costs, however, also made the costs of alternatives to herbicides higher. The aggregate cost of cultivation and hand weeding as replacements for herbicides increased from $14.3 billion in 2001 to $16.8 billion in 2005, resulting in a net increase in weed control costs without herbicides from $7.7 billion in 2001 to $10 billion in 2005. The value of the crops also increased significantly between 2001 and 2005, which means the 20% loss in production without herbicides is worth more in 2005 ($16 billion) than in 2001 ($13 billion). Overall, the value of herbicides increased from $21 billion in 2001 to $26 billion in 2005.

Three trends that occurred in crop production and weed control between 2001 and 2005 are noteworthy, especially those relating to no-till, biotech, and organic crop production. Two of these practices are dependent on herbicides and one is not. The number of no-till acres on which herbicides substitute for tillage increased from 52 million acres to 62 million acres. The number of biotech herbicide tolerant acres where herbicides are used with crops that have been genetically-engineered for tolerance increased from 66 million acres to 94 million acres. Meanwhile, the number of cropland acres grown according to organic standards where herbicides are not used increased by 100,000 acres to 1.4 million. Organic farmers substitute labor and tillage for herbicides, which is very costly. The problem of controlling weeds without herbicides has been cited numerous times as the single largest obstacle that organic growers encounter. The following quotation from Earthbound Farms (the largest organic producer in North America) underscores the expense of doing without herbicides:

> *Controlling weeds without herbicides takes a lot of time and is very costly for us. We do all our weeding by tractor or by hand, which is very labor intensive. Conventional farmers spend only about $50 an acre on herbicides that knock out every weed in sight. Organic farmers may have to spend up to $1,000 an acre to keep weeds under control.*

There is not likely to be a vast expansion in domestic organic acreage due to the high cost of labor in the U.S. in comparison to many developing countries.

The full report, *The Value of Herbicides in U.S. Crop Production: 2005 Update*, including state and crop specific data, is available on the Crop Protection Research Institute's web site at: http://www.croplifefoundation.org/cpri_benefits_herbicides.htm. For more information, please contact the authors: Leonard Gianessi at 202-872-3865 or lgianessi@croplifefoundation.org or Nathan Reigner at 202-872-3866 or nreigner@croplifefoundation.org.

Mr. VROOM. Thank you.

My experience, and I just talked to my cousin who was combining soybeans this morning, he assured me that he was aware of weed resistance and he has taken steps to manage it on this particular field, and we know that we don't have the most severe weed-resistance problems with regard to glyphosate situations, as are apparent in some of those 11 million acres that you refer to.

Our industry, along with USDA—and unfortunately Ms. Wright probably didn't have adequate time or background to explain to you the full resources the USDA brings to bear with regard to helping farmers manage weed resistance in both biotechnology crops and elsewhere. Extension, our industry scientists, crop consultants that are private individuals, crop input retailers, all have a stake in all of this and we have a marvelous system to help farmers manage these issues. But we do appreciate the fact that you have an interest in examining the regulatory authority of the agencies that are charged with overseeing these technologies, and we look forward to working with you as you give consideration to ways to have oversight and consideration of these matters.

Last, I would just tell you that our industry has formed a herbicide resistance action committee. It is a global entity that CropLife and our partner associations around the world are involved with, and it provides a mechanism for the common research that herbicide companies engage in with regard to helping to stay ahead of the curve and ensure that we can manage herbicide resistance in both biotechnology-enhanced crops and conventional crops as well.

So we believe that we do have a system in place that allows us to continue to manage these issues. We understand the particular media attention that has been given to herbicide resistance in biotechnology crops, but we believe that we have an adequate system, and we appreciate the attention that you will continue to provide to this issue.

Mr. KUCINICH. Thank you very much, Mr. Vroom.

[The prepared statement of Mr. Vroom follows:]

Testimony of Jay Vroom
President and CEO
CropLife America

Before the Domestic Policy Subcommittee,
House Oversight and Government Reform Committee

"Are Superweeds and Outgrowth of USDA Biotech Policy"

September 30, 2010

Thank you, Chairman Kucinich and Ranking Member Jordan, for the opportunity to address the Subcommittee on behalf of CropLife America and its members, as well as their customers the American farmers. CropLife America is the leading trade association representing the U.S. crop protection industry and our members supply virtually all of the crop protection products used by American farmers. CropLife America's member companies, and members of our counterpart association at RISE[1], proudly discover, manufacture, register and distribute crop protection products for American agriculture, and specialty use products outside of agriculture, such as those used for public health protection and commercial pest management inside of homes and commercial buildings.

CropLife America members work with farmers, ranchers and growers everyday to ensure that crop protection tools are registered properly and used correctly. As a matter of fact, America's abundant, affordable food supply depends on the availability of safe, effective crop protection products. Careful use of crop protection products contributes substantially to production of U.S. farm exports valued at some $100 billion per year. CropLife America members support modern agriculture by looking forward: each year the agrochemical industry spends hundreds of millions of dollars on research and development, with much of that investment going into producing data that meet or exceed the Environmental Protection Agency's (EPA) information requirements and requests for pesticides.

---

[1] Responsible Industry for a Sound Environment (RISE) – www.pestfacts.org

Three major points are essential to understanding weed resistance to herbicides and the need for best management practices to minimize the potential for resistance development:

- First, herbicide resistance occurs naturally, and best management practices need to be applied in ensuring that resistance development is avoided or delayed.
- Secondly, the market can and will facilitate the development of solutions to combat the issue of weed resistance in crop production to ensure production of safe, affordable, and plentiful food.
- Third, the current regulatory framework for herbicides is robust.

Weeds, insects and fungi readily adapt genetically to their environments. Pesticides and other pest control technologies, used over widespread areas, will control many target pests, but some pests may have a genetic advantage and survive. The survivors, if not removed from fields physically or with an alternative chemical control option, will grow and become more prominent in the local environment. Weed adaptation has been happening as long as man has tried to grow crops and is not unique to the use of chemical control or adoption of biotech crops. Under a regimen of physical control, weeds might become physically harder to distinguish or more difficult to remove. While 'superweeds' might be a catchy moniker, there is nothing particularly super about the weeds that have developed resistance to any particular herbicide. Resistance of a particular weed species to a particular herbicide has arisen multiple times over the past several decades. The problems have been overcome through adjustments to the use of the specific herbicides, and through availability and use of additional herbicides and weed control strategies, all acting by different mechanisms, so that no one weed species or variety can escape all of the control approaches.

To avoid the onset of resistance growers need to be aware of and adopt best management practices (BMPs). Information regarding BMPs and integrated weed management is available from multiple reliable sources. Growers who ignore that information do so at their peril, with potentially serious economic consequences. Adoption of biotechnology hasn't caused the rapid onset of resistance in weed species; appropriate use of all technologies will reduce its impact.

The market can and will facilitate the development of solutions to the issue of weed resistance in crop production to ensure production of safe, affordable and plentiful food. Farming is a long-term investment, and growers will adapt their operations to succeed. They need the flexibility to manage their farm operations for the current season and for the future. That flexibility requires access to the tools that enable them to take care of their business interests and sufficient latitude in terms of how and when they are used. Growers are in the best position to know their fields, the weeds growing in them, and how to best manage their farm inputs. Such knowledge will enable them to make the best decisions on what tools to use, including crop protection products and biotech crop seed, considering the economics and their future management plans.

Weed control options will continue to be developed. Crop protection is a competitive business. If a weakness in a particular weed control option emerges, there will be other new or existing technologies that will seek to fill that void. The market favors maximization of the tools currently available. The development of new herbicides is an involved and expensive process. To make that investment worthwhile requires that the useful life of a product will be extended as long as possible with available means. Some recent marketing programs have included manufacturer rebates for use of competitive products in combination with a company's product, in order to stem the onset of resistance. This is one example of how the market addresses the issue.

Regulation of pesticides, including herbicides, is science-based, stringent, thorough and robust. The approval process and use of pesticides are overseen by the Environmental Protection Agency (EPA) through implementation of the Federal Insecticide, Fungicide, and Rodenticide Act (FIFRA). Development and registration of a new pesticide active ingredient takes 8 to 10 years, costs over 200 million dollars, and requires at least 120 scientific studies, conducted at the manufacturer's expense and thoroughly reviewed by EPA. EPA must approve the product label before it grants a "registration" for sale and use of the product. The label contains the necessary instructions and precautions to use the product safely and effectively. When used according to the label, registered pesticides will not harm humans, animals or the environment. EPA continues to monitor use of the pesticide in the marketplace. If problems in product efficacy are discovered by EPA or the registrant or users, adjustments are made as necessary to the label

instructions to make sure the product can continue to be used safely and effectively. The changes may be initiated either by EPA or the manufacturer, but must be approved by EPA.

I appreciate the opportunity to appear before the Subcommittee today to discuss the important issue of resistance management on behalf of the chemical crop protection industry. We remain committed to continuing to work with the Congress, our regulator and our end-users who use our technology to produce our nation's safe, affordable and abundant food supply. I look forward to answering any questions you may have regarding my testimony.

Mr. KUCINICH. I just want to assure you that we provided Ms. Wright with as much time as she needs to be able to answer this committee's questions, and we will continue to do that.

Let's go to questions of this second panel.

Mr. Miller, with Monsanto's 100 percent focus, as you have said, on agriculture, I am wondering who is responsible for the proliferation of weeds and weed species that have become Roundup-resistant since the introduction of Roundup Ready crop systems?

Mr. MILLER. Thank you, Mr. Chairman. As I mentioned earlier, if our farmers are not successful, we are not successful, and we take this matter very seriously.

I would say herbicide-tolerant weeds is not a new thing. It is something we have had to manage in the industry as well as with university weed scientists and farmers in how they run their operations on their farm. So we invest a lot in the science of weed resistance and understanding that and providing technical solutions to growers along with others. That is really our focus.

Mr. KUCINICH. I don't know if you have testified before a congressional committee, and all committees are different.

Mr. MILLER. No, sir.

Mr. KUCINICH. I am the kind of chairman that when I ask a question, I would like to get a direct answer.

Would you tell me who is responsible for the proliferation of weeds and weed species that have become Roundup-resistant since the introduction of Roundup Ready crop systems?

Mr. MILLER. I think weeds that are resistant to glyphosate are the responsibility of industry, government, weed sciences, as well as farmers, to properly steward the product.

Mr. KUCINICH. So industry—you are part of the industry with Monsanto. The USDA is part of that system. There is a responsibility there. There is a whole feedback loop here, you are saying; right?

Mr. MILLER. I think there is a feedback loop, but this is a herbicide issue, and I believe herbicides are regulated under the Environmental Protection Agency.

Mr. KUCINICH. It is encouraging that you have stated that industry has a responsibility here. But you also stated that government has a responsibility as a regulatory authority, did you not?

Mr. MILLER. Mr. Chairman, I believe that our regulatory agencies have clear responsibilities to demonstrate and prove the safety in use of these products.

Mr. KUCINICH. Thank you. Let me direct your attention to this ad circulated before 2005. This is Monsanto, Mr. Miller, in this ad, telling farmers to use more and more Roundup and to use it exclusively to control weeds. That was just 5 years ago. And it was also 5 years after Roundup-resistant horseweed was discovered in Roundup Ready crop yields in Delaware.

Mr. Miller, help us out here. Isn't it true if farmers followed Monsanto's advice conveyed in this ad, that they would have Roundup-resistant weeds in their fields today?

Mr. MILLER. Mr. Chairman, weed resistance is caused by many factors. Prior to 2005, and many systems that we developed and co-developed with the university weed science academics and the Weed Science Society of America—and, by the way, I believe one

of those academics was actually referenced in that ad just reflecting on a picture I saw—the recommendation was that glyphosate had a low probability of developing resistance, and our recommendation was to utilize that in the system.

But in cases where we have begun to discover there are resistant weeds, we have done a lot of training, education with growers, retailers, and other in the industry to recommend multiple modes of actions into our cropping systems.

Mr. KUCINICH. I am going to ask staff to copy this and give you a copy. Have you read this? Just look at it. I'm not trying to trap you here, because I believe in having a conversation. It says no benefit in rotating glyphosate. No benefit.

Can you explain that to me in light of what you said a moment ago? Take your time. When you are ready to answer, go ahead. If you want to rephrase anything for the record, you can do that, too.

Mr. MILLER. Actually, I would like to read the recommendation as stated by Monsanto in this particular article.

In many Midwest cropping systems, agronomic conditions and cultural practice are conducive to preemergent application, an herbicide that is not glyphosate, so one mode of action, followed by Roundup agriculture herbicides, or a tank mix of residual, two different modes of action, agricultural herbicide before weeds exceed 4 inches.

So this particular ad does actually steward two growers, and I am responding to the title, "No Benefit from Rotating Glyphosate," was the fact that you use multiple modes of action in your system, and if you use a Roundup Ready crop in the same field the next year, and you steward it properly by using multiple modes of action, there is no need to change your overall cropping system.

Mr. KUCINICH. This is your ad. It says, no benefit in rotating glyphosate, as you just read.

Now, I showed the same ad and asked the same question to a prominent weed scientist who testified at our previous hearing. I am sure that somebody in your organization read that testimony. He was the author of the weed chapter of the National Research Council's report published in April.

Do you want to guess what his response was to the question of whether farmers would have Roundup-resistant weeds in their fields today if they followed the advice that was conveyed in Monsanto's ads? What do you think his answer was?

Mr. MILLER. Chairman Kucinich, I wouldn't want to speculate on that.

Mr. KUCINICH. OK. That is fine. It is recommended reading for you. His answer was "yes."

Mr. Miller, why was the discovery of Roundup-resistant horseweed as early as the year 2000 not sufficient evidence of Roundup resistance in weeds to move Monsanto to change its advice to farmers?

Mr. MILLER. Congressman, first of all, I will go back to if our growers are not successful, we are not successful. So as we actually had the evidence of the first resistant weeds, we actually enabled university research, our own research, to understand the mechanism of that resistance.

The second thing that we did was enlisted those regional university extension agents to help us develop what the recommendation for the grower was in order to keep their farming operations successful. Once we had that identified, we actually went out and did significant training with producers, often recommending our competitor's product as part of the solution to ensure that the farmer has a weed-free field.

Mr. KUCINICH. Let me just share something with you. About 5 hours ago, I was in a full committee hearing with Johnson & Johnson looking at how they let two different products enter the market, one of which had potential serious health consequences for consumers. And one of these drugs, they sent in phantom purchasers to get the drug back. There was active concealment going on.

The thing that strikes me that you said about if your customers are not successful, you are not successful. You said that earlier in your testimony. I actually wrote it down here. If farmers don't succeed, Monsanto does not succeed. It is eerily similar almost to the words except changing "Johnson & Johnson" to "Monsanto" to the testimony of the CEO of Johnson & Johnson. That is the reason I am calling it to your attention. I don't question your background. You have a tremendous background and you are certainly qualified to testify before this subcommittee. There is no question about that. You represent Monsanto well.

The question I have is the aspirational expressions that you make on behalf of Monsanto do not square with the experiential elements of the use of this crop. That is kind of where we are going with this. I am not condemning you; I just want to say that there is some difficulty in squaring this.

Now, Mr. Freese, is it true that Roundup-resistant weeds was a development that took everyone, including Monsanto, by surprise? Or was it a foreseen danger?

Mr. FREESE. I think it was mixed. I know there were some weed scientists who thought there wouldn't be resistance evolving, but others predicted it.

Mr. KUCINICH. Some were surprised?

Mr. FREESE. Yes.

Mr. KUCINICH. What about you?

Mr. FREESE. I wasn't following the issue at the time.

Mr. KUCINICH. But you have a 1980 report; isn't that right?

Mr. FREESE. A 1990 report, yes, by some colleagues in the public interest community called "Biotechnologies: Bitter Harvest." It is a very searching and comprehensive report on what at that time was still an experimental technology. 1990, this was 6 years before the introduction of the first Roundup Ready crop—in this report the scientists clearly see huge potential for development of herbicide-resistant weeds, and particularly with this technology.

There was a 1996 report by Consumers Union, another consumer group.

Mr. KUCINICH. So you are saying that scientists did see the potential for herbicide-resistant weeds. Which scientists are you talking about?

Mr. FREESE. This report was written by Dr. Rebecca Goldberg with Environmental Defense Fund; and Jane Rissler, who is now

with Union of Concerned Scientists; and Hope Shand and Chuck Hassebrook.

Mr. KUCINICH. What year was that?

Mr. FREESE. 1990.

Mr. KUCINICH. Mr. Miller, you have been with Monsanto since 1994, right?

Mr. MILLER. That is correct.

Mr. KUCINICH. I actually took notes during your testimony, and you said in your testimony that Monsanto has 500 scientists who work for the company. Did you say that?

Mr. MILLER. Actually, sir, my statement was that in my regulatory group there are 500 scientists. There are over a couple of thousand scientists in our company.

Mr. KUCINICH. That is even more impressive. A couple thousand scientists. Do you have any knowledge within the sphere of your activities in the regulatory group of any reports that were brought to you expressing concerns about herbicide-resistant crops?

Mr. MILLER. I was not in that responsibility at that time. But I can say——

Mr. KUCINICH. When did you come into that responsibility?

Mr. MILLER. Just in the last 6 months, sir. But I have been in the company 16 years as a researcher. I can share with you that I think it is even documented in literature that with the Roundup or glyphosate tolerance, we stated there was a possibility. We said it was a low probability.

And I would say anytime we develop any of our products, as I mentioned earlier, including with Mr. Smith here, before we develop them, we actually create forums to understand the data that is out there and the concerns that exist, and take that into consideration as we develop our safe products.

Mr. KUCINICH. What I would like to do, and I want to direct the subcommittee staff here to work with Mr. Miller in gaining access to the studies that were done by the scientists at Monsanto with respect to herbicide-resistant weeds, because what we can do here is to be able to identify the progress that has been made through this scientific research with the 500 scientists who are working for you and perhaps thousands of scientists who are working with Monsanto.

So we will produce from this hearing a followup request for documents so that we can enable a better understanding of Monsanto's awareness of this. I would appreciate your cooperation.

Mr. MILLER. Mr. Chairman, I will be happy to work with you on that request.

Ms. WATSON. Mr. Chairman, can you yield just 2 minutes to me? I have another subcommittee hearing.

Mr. KUCINICH. I am pleased to yield to the gentlelady at this moment. I was going to yield 10 minutes to you. If you need 10 minutes, you can have it now.

Ms. WATSON. Thank you. I won't use all of that time. I am very interested in this subject matter, because just recently they announced that there is a new salmon that is going to be on the market that has been, shall I say, biologically bred to grow larger, and you might recall some of the advertisements in the last few days.

We are questioning whether that will have an impact on humans once they consume that salmon. And so I was listening very closely to see if Monsanto or other companies like you test the environmental impact of these new—what you are working with is an herbicide—but do you test first to see what the impact will be on the environment. Or does it grow?

The chair is asking for you to kind of document what was done prior to putting it on the market, and I am wondering how far do you go putting these products out there before you test their effect on the environment?

Mr. MILLER. Would you like me to answer that?

Ms. WATSON. Yes.

Mr. MILLER. OK. You know, I am very proud of the process that we use both to validate the value that we bring to growers, as well as the safety of our products. As you know, the products that we have put out on the market , if it is a chemistry, it is EPA. Biotech, it could be EPA, USDA, FDA. All of those go through thorough health and safety assessments both internally in our organization as well as with those agencies.

Often we have other third parties that look into that, because at the end of the day, we want to ensure the health and safety, and we believe that system has worked extremely well.

Ms. WATSON. What do you feel you have to do now in light of this, the findings that this superweed is so strong that it doesn't react to whatever you have out there to try to kill it? It is going to have an impact, and it is going to have a financial impact certainly on the farmers and all.

And so what do you see that needs to be done? We are the subcommittee of oversight. What is it that we can do within this process to guarantee that people won't be harmed, crops won't be harmed? What needs to be done? What are we missing?

Mr. MILLER. Chairman Watson, I am not sure I can address the question of what we are missing, but I can address what we are doing. I think this is being taken very seriously by Monsanto, as well as other technology providers in the industry. I think it is being taken extremely seriously by weed scientists. And as was mentioned by Jay earlier, our growers take this very seriously, even before they have weed-resistance issues. What we are doing about it, we have invested well over $30 million in just the last 5 years.

Mr. KUCINICH. If the gentleman would suspend. Ms. Wright, I just want to put it on the record that Ms. Wright did stay for most of the testimony because that doesn't always happen, and I want to thank you for your presence here and for listening to the witnesses' testimony and questions. Thank you very much. I just wanted to put that on the record.

If you are ready to continue, you may. Thank you.

Mr. MILLER. Yes. So we are putting significant research, as well as working with those local academics to help come up with best recommendation for farmers.

Two things that I want to bring out. There are glyphosate-resistant weeds, but there are still greater than 290 weeds that do not have resistance, so this is still a hugely available tool to growers, and they acknowledge that every time I go out and visit with them.

I am not going to diminish the fact that if one of the weeds is resistant to glyphosate, that there needs to be a control option provided for that grower, and we actually have spent a lot of time, even with the ad that was shown earlier, working on that particular species of weed. There are control options available on the market, and we are helping growers be trained on how to use that in their agricultural systems.

Ms. WATSON. I am really concerned about the consumer side of all of these new products that are out there, and so we are going back and the chair is asking that we have some documentation so that we can guarantee that we who have the oversight have done all we can to ensure that these products will not have a negative effect on whatever it is, and on consumers. So we are just probing right now to see what our responsibilities are.

And if you are looking at evaluating the environmental impacts of your product, I want to say thank you so much. That is what I would like to know. And I am sure that the chair has also asked for that information.

With that, I will wait to see it. As we probe in this area, Mr. Chairman, I want to be a partner with you.

I am really concerned about that new—does anybody remember seeing the information on television? If so, put your hand up. I want to know about this salmon that is going to be three or four times the size of any normally grown salmon. If we are to consume it, what is the impact going to be on our digestive systems with this larger salmon?

So in all good faith, we are just asking you to let us know what we need to look at so we can protect the consumers.

Thank you very much.

Mr. KUCINICH. I thank the gentlewoman for her questions. The subcommittee is also looking at the issues with respect to genetically engineered salmon.

I want to say, when the gentlelady asked the question, What are we missing, she was actually inviting Mr. Miller to help us in our probe here. But I would say this; that we look forward to cooperating with you, that cooperation through information that brings us to a level of comfort that the public interest is being protected. And in pursuit of the public interest, we try not to miss too much.

Mr. Miller, you have heard testimony today about concerns that your dicamba/Roundup-tolerant soybean will cause collateral injury to fruit and vegetable farmers, and I would add, even backyard gardeners. That is essentially what Mr. Smith was testifying to. Your testimony, in fact, acknowledges concerns.

Now, in the event that an injury should materialize, apropos of a question Mr. Smith raised, who would be liable for the economic costs to the affected farmers? Would it be Monsanto or another party?

Mr. MILLER. Mr. Chairman, you know, I am not an attorney.

Mr. KUCINICH. I am not either. I just play one on TV.

Mr. MILLER. I don't believe I can answer that. We would be happy to followup with you later at the appropriate time when we have that information.

Mr. KUCINICH. I will accept you are not an attorney and you don't want to answer a question that gets you, excuse the expres-

sion, into the weeds about the legal implications of this policy. But I would say that we would seek to entertain that discussion with Monsanto attorneys, because this is one of the questions that is being raised here. You have a product, if it has some adverse effect on certain people, there are some questions of liability.

I am not asking you to accept liability here. I know what your limitations are as a witness at this moment. You made that clear.

But let me ask you this: Do you think it is correct to classify the injury fruit and vegetable farmers fear from the use of the dicamba soybean system as an indirect cost of the development of Roundup resistance in weeds?

Mr. MILLER. Mr. Chairman, I am not sure that I follow your question. I would appreciate if you could restate it.

Mr. KUCINICH. Well, you have Roundup resistance in weeds that is showing up. Farmers are concerned, and some farmers have expressed that there has been an injury to their fruits and vegetables. You have sold this dicamba soybean system. If the farmers are experiencing this loss, isn't that loss essentially an off-loading of expense, an indirect cost of the development of Roundup resistance in weeds?

Mr. MILLER. You know, we are 5 years away from introducing dicamba/Roundup Ready soybeans into the market. So as we bring these forward—and it takes us well over a decade from the time we begin to develop these products until we launch it—5 years before the launch, we actually set up a dicamba grower or dicamba advisory council, including many of the producers in the fruit, vineyard, and tomato industry.

And by the way, as Monsanto, we are one of the largest vegetable seed producers in the world. Tomato customers in that business are some of our biggest customers. And as I mentioned earlier, we care about our customers' success.

Our focus is to continue to bring weed-free cropping systems to our producers in corn, soybean, and cotton, as well as serve the interest of those fruit and vegetable producers. We have a significant amount of research going on, with their input, to ensure when that product comes on the market it is successfully implemented.

Mr. KUCINICH. Do you have legal counsel here with you?

Mr. MILLER. Yes, I do.

Mr. KUCINICH. Would counsel identify himself, please?

Mr. SOPKO. John Sopko of Akin Gump.

Mr. KUCINICH. OK. Actually, I know you gave an answer. You didn't answer the question; but if I pressed you to answer the question, I know counsel would advise you not to, so I will move on.

Mr. Freese, can you answer the question I asked about do you think it is correct to classify the injury fruit and vegetable farmers fear from the use of the dicamba soybean system as an indirect cost of the development of Roundup resistance in weeds?

Mr. FREESE. I think that is very good way to describe it. The way that the Roundup Ready crop system is used and is meant to be used, I would say it has led to some pretty massive weed resistance. Unfortunately, the way we approach weeds in this country is so completely focused, so completely focused on using pesticides, that a new herbicide-resistant crop, resistance to different herbicides, seems to be the only thing that a lot of our companies and

even the USDA takes seriously. In fact, there are many very viable, nonchemical ways to control weeds.

Mr. KUCINICH. I am going to go back to Mr. Smith here, because you are in touch with a base of people about these products. You have testified, and I am quoting from your testimony, "The widespread use of dicamba is incompatible with Midwestern agriculture."

Mr. SMITH. Yes, sir.

Mr. KUCINICH. I am from Ohio. I hear that. How significant is the risk of injury to fruit and vegetable farmers and processors from planting the dicamba soybean in Indiana farm fields, and do you have any estimate of potential cost?

Mr. SMITH. We are working on providing an estimate of that through a study with Purdue University at this time.

Mr. KUCINICH. Would you produce that to the subcommittee when that is done?

Mr. SMITH. Yes.

Mr. KUCINICH. You testified, "Increased dicamba usage, made possible through the introduction of dicamba-tolerant soybeans, is poor public policy and shouldn't be allowed."

Is there is a technological fix to the collateral harm you foresee occurring, such as having Monsanto develop dicamba-resistant fruit trees, melons, peas and tomatoes; is that the path we should take?

Mr. SMITH. From a consumer standpoint, that is a path we cannot take.

Mr. KUCINICH. Why?

Mr. SMITH. There is consumer resistance to the consumption of genetically modified crops.

Mr. KUCINICH. Why?

Mr. SMITH. I am not an expert to answer that.

Mr. KUCINICH. You don't have to answer.

Mr. Miller, your testimony explains that the dicamba/Roundup soybean is designed to "give growers more weed control options." It sounds somewhat artful. It sounds like an artful way of saying that farmers can't rely on Roundup to control weeds anymore, so they now need to use another pesticide.

Is it your belief, Mr. Miller, that the best solution to Roundup resistance in weeds is a farmer using another pesticide?

Mr. MILLER. I would say my belief, a broad array of university scientists, other industry scientists, the Weed Science Society of America, believes that adding multiple modes of action into an agricultural production system is good agricultural practice, Mr. Chairman.

Mr. KUCINICH. Thank you.

Mr. Freese, is the only or best way to control weeds after Roundup resistance has set in more and more chemicals and new chemical-tolerant crops?

Mr. FREESE. I think that is actually a very dangerous path to take.

Mr. KUCINICH. Why?

Mr. FREESE. We are learning lots of new things about weed resistance, and new mechanisms are being discovered all of the time.

Mr. KUCINICH. Why is it dangerous? You used the word "dangerous." What do you mean?

Mr. FREESE. I think it is dangerous because it is going to lead to greater resistance down the line.

Mr. KUCINICH. How do you know that?

Mr. FREESE. Because what we have seen is an increase in multiple herbicide-resistant weeds already.

Mr. KUCINICH. So you use more chemicals. And we had testimony earlier from Ann Wright about the evolution of crops that contain herbicide resistance generally, right?

Mr. FREESE. Yes. So, for instance, in the eighties and nineties, a popular class of herbicides was called the ALS inhibitor.

Mr. KUCINICH. And ALS stands for?

Mr. FREESE. Acetolactate synthase. And they generated a huge expanse of herbicide-resistant weeds, and those resistant weeds were one reason farmers adopted Roundup Ready crops. Now we are getting weed populations that are resistant to both herbicides.

In Missouri and Illinois, we have weed populations resistant to three and four different herbicides.

Mr. KUCINICH. For those who are not initiated, what are the implications of that? Draw out for us the practical implications that this scenario that you envision happening as a result of your scientific background—tell us where we are going.

Mr. FREESE. Well, we are headed toward more pesticide use, for one thing. That is pretty clear. At the last superweed hearing, one of the weed scientists spoke on the order of a 70 percent increase in 2,4-D and dicamba use soon after the introduction of the 2,4-D and dicamba-resistant soybeans.

Mr. KUCINICH. What happens then?

Mr. FREESE. One thing is you have greater levels of these residues of these herbicides on the crop. A little-known fact about herbicide-resistant crops is the companies seek increases in what are called tolerances, the maximum allowable residue of the pesticide on the crop. We have seen that repeatedly with Roundup Ready, greatly increased glyphosate tolerances each time a new Roundup Ready crop is approved.

Now, it is very troublesome when we think about that with more toxic herbicides like 2,4-D and dicamba, both of which have been linked to cancer in pesticide applicators and farmers. 2,4-D is a likely endocrine disrupter; that is, a disrupter of our hormone systems which are so important in controlling our development, our reproductive system, and our metabolism.

EPA was supposed to start looking at endocrine effects on all of our pesticides in 1998, but hasn't been funded to do that, and so it is only just now getting started.

Mr. KUCINICH. Are there any weed scientists to recommend an approach other than Monsanto's preference for dealing with weed resistance to their product Roundup.

Mr. FREESE. Can you restate that?

Mr. KUCINICH. Is there another approach that weed scientists would recommend in dealing with this problem of resistance?

Mr. FREESE. Yeah, and as a matter of fact, it's quite interesting because there is a technique that's long been used by organic growers, but also conventional growers. It involves planting winter cover crops. And basically it just—it means after harvest of the main crop, you can plant a cereal like rye, or a legume like hairy

vetch or clover. And this cover crop grows in the fall, and then more in the spring, and it holds the soil, and it also absorbs excess nitrogen and phosphorous fertilizer. And then in the spring, it's killed off and forms a thick mat into which you can plant your main crop, that mat suppresses weeds physically. Sometimes the cover crop also releases chemicals that inhibit the growth of weeds. It's a very, very beneficial practice, because again, it's effective—it effectively suppresses weeds and provides multiple other benefits as well.

Mr. KUCINICH. All right. I want to thank you for answering that. Did you want to add something, Mr. Vroom?

Mr. VROOM. Yes, Mr. Chairman. So we've delved into a lot of detail, but one important broad category of differentiation among weed control with regard to crop protection products is whether the chemistry is used after the weeds emerge, are sprayed on to the weeds, or it's applied to the soil as a pre-emergent control product.

The ALS herbicide Mr. Freese is talking about are pre-emergent products, they are applied to the soil before the crop is planted. And so the—while the registrants for those chemicals that are pre-emergent products oftentimes do have protective tolerance levels, should some tiny amount be left in the soil and then get into the crop plant, there's virtually no evidence of residual in the actual crop from those kinds of products that are applied by the farmers.

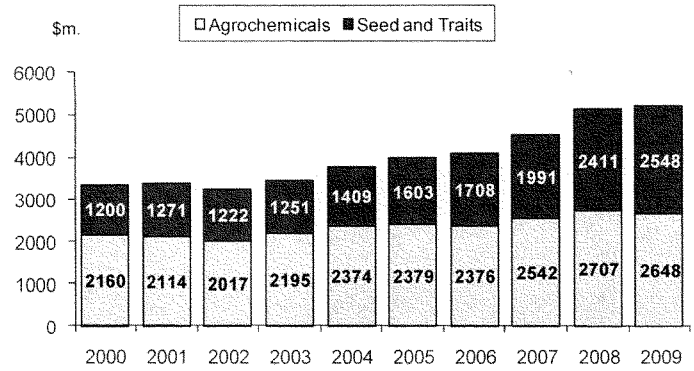
So big difference there between the technologies that all herbicides aren't applied the same way. And again, I think we come back to the industry, farmers, the USDA and the extension are all looking at redeploying a lot of old technologies—I'm certain that Monsanto and others have already reinvented some of the formulation technologies so that it can be better managed than it was when that particular product was more prominently used.

And so it's all part of the solution, and I think what you're drawing out here is that we all have to work together, reinvent old products, because we also have evidence, and I've got a study here that I would also like to ask you to consider submitting into the record by——

Mr. KUCINICH. You can submit it.

[The information referred to follows:]

AgriFAX Futura
McDougall AgriService



June 2010 **No. 128**

Agrochemical Industry R&D

In 2009, the level of research and development expenditure for the fifteen leading companies within the agrochemical industry is estimated to have increased by almost 1.5% in nominal US dollar value to reach a total of $5196 m. Because of the relative change in the value of the US dollar versus the Euro during the year, in Euro terms the increase is closer to 7.0%.

Since 2000, the overall level of R&D expenditure incurred by the 15 leading companies in the agrochemical sector has grown at a compound annual growth rate (CAGR) of 5.0%, raising the level of R&D expenditure from $3360 million to a total of $5196 million in 2009.

Total R&D Expenditure by the Leading Agrochemical Companies

Although the overall level of R&D expenditure by these 15 leading companies increased in 2009, the value of expenditure devoted to conventional agrochemical R&D actually fell back by 2.2% in nominal terms in 2009 to reach $2648m. In contrast to this the level of R&D expenditure devoted by these fifteen leading companies in the seed and trait sector, in the same time period, increased by 5.7% in 2009 over 2008 to reach $2548 m.

As outlined above, one of the key factors driving industry R&D expenditure has been the increasing focus by several of the leading companies on the seed and trait sector. As a result of the higher rate of growth, the overall proportion of the R&D budget of the fifteen leading companies devoted to the seed and trait sector has increased from 35.7% in 2000 to reach 49.0% last year. This result reflect a compound growth rate (CAGR) of 8.7% per annum in seed and trait R&D since 2000, compared to the equivalent value of 2.3% per annum for conventional agrochemical R&D expenditure.

It is evident that the environment for chemical crop protection R&D is becoming exceedingly more competitive, the cost of developing a new active ingredient is increasing (see AgriFutura 125, March 2010), whilst the regulatory environment is also becoming stricter, particularly in the EU with the updating of the requirements for re-registration. This coupled with the shift in R&D focus by the major companies to seeds and traits and the consolidation of the industry has not only reduced the number of companies involved in basic agrochemical R&D, but also resulted in these companies becoming more selective regarding which product candidates are selected to advance from research into development. These combined factors have resulted in fewer new active ingredients being introduced.

It is also evident that the growth in the uptake of GM crops has resulted in a reduction of R&D activity in sectors affected by GM technology, notably soybean herbicides and cotton insecticides. Whilst a number of new insecticides for Lepidoptera control have been introduced recently, it is notable that the key crop focus for these products is fruit & vegetables, rather than the traditional market for Lepidoptera control products, cotton, a sector which is now dominated by B.t. technology.

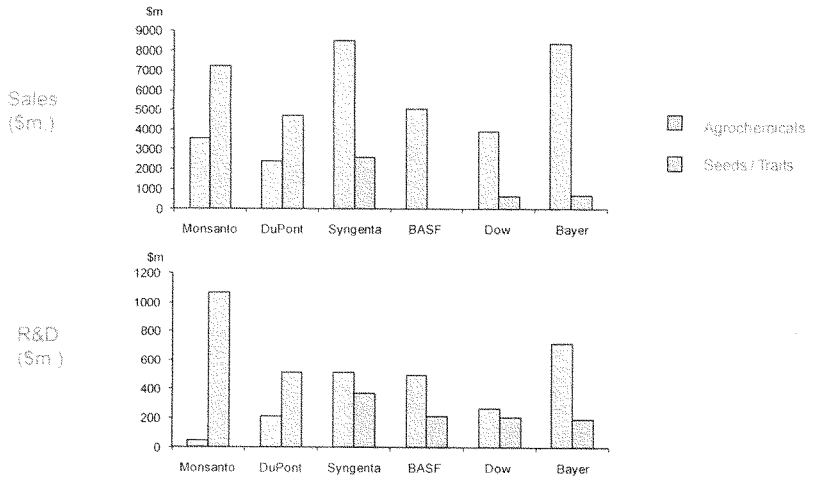
Product Introductions and R&D by Crop

Number of new Active Ingredients		Time period			
		1980/1989	1990/1999	2000/2009	In R&D
Herbicides	Cereals	15	12	12	3
	Soybean	11	10	1	0
	Maize	2	10	9	1
	Rice	11	19	14	4
	F&V	2	1	0	1
	Other	10	5	2	1
	Total	51	57	38	10
Insecticides	F&V	11	16	15	6
	Rice	5	2	3	3
	Cotton	9	12	3	1
	Others	4	7	5	3
	Total	29	37	26	13
Fungicides	F&V	13	9	17	6
	Cereals	14	16	8	8
	Rice	9	5	7	5
	Others	0	0	0	1
	Total	36	30	32	20
Others		7	3	5	1
Total		123	127	101	44
Average annual rate of introduction		12.3	12.7	10.1	8.8

The final line of the table shows the average rate of new active ingredient introduction by decade, and indicates a slowdown in the rate of new products coming to the market. At present there are 44 product candidates in the development stage, which are anticipated will enter the market within the next five years. If this is realized then the average rate of new introduction will fall to 8.8 products per annum, in comparison with 10 per annum in the 2000s and 12.7 per annum in the 1990s.

Despite the attractions of the seed sector, significant opportunities in the agrochemical market are still evident, notably as a result of re-registration issues in the EU and especially following the adoption of revised regulations at the end of 2009. As endocrine disruption is becoming an issue, the registrational position of a number of products has been brought in to question, some of which hold important positions in resistance avoidance strategies. Removal of these products from the market would clearly create an opportunity for new active ingredients.

The table below compares R&D expenditure with market performance since 2000.



R&D Expenditure Compared to Market Performance

Market $m	2000	2008	2009	2009/08 %	2009/00% p.a.
GM Seed	2194	9150	10570	15.5	19.1
Conventional Seed	14269	16870	16160	-4.2	1.4
Total Seed	**16463**	**26020**	**26730**	**2.7**	**5.5**
Agrochemical	31977	46130	43720	-5.2	3.5
Overall Total	**48440**	**72150**	**70450**	**-2.4**	**4.2**

R&D $m	2000	2008	2009	2009/08 %	2009/00% p.a.
Seed and Traits	1200	2411	2548	5.7	8.7
Agrochemicals	2160	2707	2648	-2.2	2.3
Overall Total	**3360**	**5118**	**5196**	**1.5**	**5.0**

Since 2000, the total seed market (GM and Conventional) has grown at an average annualised rate of 5.5% p.a., whilst Seed and Trait R&D expenditure for the leading 15 agrochemical companies has increased on average by 8.7% p.a. Over the same period the agrochemical market (crop protection and non-crop) has grown by 3.5% p.a., whilst R&D expenditure of the top 15 companies has grown by only 2.3% p.a. indicating the continuing shift in R&D expenditure towards the seeds and traits area.

Company Sales and R&D Expenditure 2009

In 2009, Monsanto was the leading company in terms of R&D expenditure on agrochemicals and seeds & traits. It is clear that almost all R&D expenditure by Monsanto is devoted to the seeds and traits area, with a modest level of agrochemical R&D limited to product defense, formulation development and seed treatments; the company is no longer involved in the research of new chemical active ingredients. The second leading company, again both in terms of sales and R&D expenditure, is Bayer. Over the last few years, Bayer has been increasing the proportion of its R&D budget to seeds and traits however currently the majority of the R&D budget is targeted at conventional agrochemical R&D.

Analysis of the active ingredients that have left the EU market due to either not being supported through re-registration, or not achieving acceptance, indicates that the market sector most affected has been fruit & vegetables. An increasing focus of R&D on fruit & vegetable insecticides and fungicides is now evident, not only with chemical crop protection products, but also with biologicals.

In addition to the R&D products listed in the table above, there are also believed to be around 50 active ingredients in development in China, the majority are understood to be analogues of chemistry already introduced outside China. These products are not included in this analysis as the majority do not have GLP registration packages; hence the potential for their introduction in markets outside China is limited.

If the rate of active ingredient introduction of the major companies also involved in R&D in the seed sector is compared with time, then a slowdown in new product introduction can be seen. Over the same time period the rate of introduction from companies not involved in seed R&D has increased.

Rates of New Active Ingredient Introduction

	A.I. introductions since 1980	Rate p.a.	A.I. introductions since 1994	Rate p.a.
Companies with Seed R&D	213	7.1	99	6.6
Others	138	4.6	79	5.3
Total	**351**	**11.7**	**178**	**11.9**

It can be seen that the rate of new active ingredient introduction by the companies involved in seed R&D has declined from 7.1 products per annum on average over the last thirty years to 6.6 p.a. over the last fifteen years. Conversely, the rate of introduction from other companies has increased from 4.6 p.a. to 5.3 p.a. over the same periods.

Active Ingredient Introduction and in R&D by Company

	Introduced 1994-2009	Currently in R&D
Bayer	35	6
Syngenta	17	5*
BASF	19	5*
Dow	19	2
Sumitomo	15	2*
DuPont	7	3*
Monsanto	1	0
Other Japanese	44	18
Rest	21	5
Total	178	46**

* Some in co-development with other companies
** some licensed products counted twice

For the future it seems likely that investment in seed and trait R&D will continue to outpace that of agrochemicals. In 2009 the overall spend on R&D for agrochemicals, by the leading fifteen companies was $2648 m., down 2.2%, whilst expenditure by these companies on seed and trait R&D increased by 5.7% to $2548 m. With the crop protection market forecast to grow at 1.8% p.a. through to 2014 in 2009 dollar terms, and the GM sector anticipated to expand by 4.0% p.a. over the same period, it is likely that this shift in R&D emphasis is likely to continue.

Phillips McDougall do not accept any liability for any loss, damage or any other accident arising from the use of the information in this report.

Mr. VROOM. McDougal organization that shows that in the decade of the 1980's and 1990's, our crop protection companies were able to discover and bring to market more than 50 new herbicide products. In the decade of the 2000's, that number has dropped to 38. And so it's just a reminder that while our research goes on, we found the ease to discover and most broad spectrum efficacious herbicides, and now we're needing—now we're looking for things that are much more targeted and the need to reinvent the older products that are proven safe that can be reformulated and applied by farmers in different ways. Thank you.

Mr. KUCINICH. Thank you very much. I would just like to say in response to the point that you raise something that's obvious, that we're really probing here into cause and effect. Some causal chains begin in nature. With biotechnology and genetic engineering, some causal chains begin in the laboratory. So we just are trying to find out which way things are going here, and doing the best we can.

Mr. VROOM. Thank you.

Mr. KUCINICH. Thank you for being here. I want to thank each of the witnesses. You've given this subcommittee additional information; we'll continue to seek more. We're going to do it in a dispassionate way. Just try to gather information so that we can recommend policies that would be in the best interest of all parties concerned.

I do take note of Mr. Miller's testimony that government does have a role to play, it's not only the industry that's the question here, and I appreciate that you raise that.

So without any further testimony, this is the Domestic Policy Subcommittee of Oversight and Government Reform. The subject of today's hearing "Are 'Superweeds' an Outgrowth of USDA Biotech Policy?" This is the second part of this hearing.

The subcommittee will continue to retain jurisdiction over this matter. I want to thank the staff for its presence here today and its participation in helping to structure this hearing. There being no—and thank the witnesses certainly. There being no further businesses before this subcommittee, this subcommittee stands adjourned. Thank you.

[Whereupon, at 4:08 p.m., the subcommittee was adjourned.]

[Additional information submitted for the hearing record follows:]

Response to Questions From the Domestic Policy Subcommittee of the House Oversight and Government Reform Committee

With Regard to Herbicide-Resistant Weeds Following Testimony Delivered Before the Subcommittee on September 30, 2010

by William Freese
Science Policy Analyst
Center for Food Safety

What does your research reveal about when Monsanto should have known and reacted to development of Roundup-resistant weeds?

Prior to the confirmation of the first glyphosate-resistant weed population in 1996, weed scientists had collected abundant evidence showing that resistant weeds were likely to evolve with frequent use of glyphosate. For instance, Duncan & Weller (1987) conducted experiments on five biotypes of field bindweed that had been shown by DeGennaro & Duncan (1984) to have substantial variability in their tolerance to glyphosate. They concluded from their experiments that: "These results further suggest that glyphosate tolerance in a field bindweed population could be enhanced by selection pressure in the form of ***repeated glyphosate applications***."[1] Boerboom et al (1990) similarly found a three-fold range of glyphosate tolerance in specimens of the weed birdsfoot trefoil.[2] As with field bindweed, repeated glyphosate applications would kill off the more susceptible types, leaving the more tolerant to propagate, potentially leading to a resistant population quite rapidly.[3]

In 1996, the eminent weed scientist Dr. Jonathan Gressel reviewed some of the evidence pointing to the likelihood that glyphosate-resistant weeds would emerge, and rebuked Monsanto scientists for giving the false impression that glyphosate was "invincible" to

---

"Heritability of glyphosate susceptibility among biotypes of field bindweed," The Journal of Heredity 78: 257-60.

[2] Boerboom, C.M. et al (1990). "Mechanism of glyphosate tolerance in birdsfoot trefoil," Weed Science 38: 463-467.

[3] Although "tolerance" and "resistance" to herbicides are formally distinct, in practice the terms are often used interchangeably by weed scientists. In common usage, tolerance denotes a weed that withstands lower doses of an herbicide, while resistant weeds survive higher doses.

resistance.[4] Dr. Gressel first presented the following excerpt of a paper written by Monsanto scientists Steven Padgette and colleagues for a symposium in Spain.[5]

> "Evolution 'of weed resistance to glyphosate appears to be an unlikely event, based on the ***lack of weeds or crops that are inherently tolerant to glyphosate*** and the long history of extensive use of the herbicide resulting in no resistant weeds. ***Unique properties*** of glyphosate such as its mode of action, chemical structure, limited metabolism in plants, and lack of residual activity in soil indicates that ***the herbicide exerts low selection pressure*** on weed populations' (Padgette et al 1995)." (emphasis added)

As noted above, at least two weeds had been shown in peer-reviewed studies in the 1980s and 1990 to have precisely the "inherent tolerance to glyphosate" of which Monsanto's Padgette and colleagues profess ignorance in 1995. Many other weeds, such as morninglories, yellow nutsedge, field horsetail, prairie cupgrass, wild buckwheat, and dayflower species have long been recognized as glyphosate-tolerant.[6] The statement that glyphosate "exerts low selection pressure on weed populations" is grossly misleading, in that it considers only certain chemical properties of glyphosate, and ignores the much more important factor of how glyphosate is used. The frequency, intensity and timing of glyphosate use with Roundup Ready crops generate tremendous selection pressure for evolution of resistant weeds, whatever "unique properties" the glyphosate molecule may or may not possess.

Dr. Gressel's commentary on the quote presented above makes it clear that Monsanto scientists were not innocently wrong, but rather guilty of intentional misrepresentation. Speaking directly to Padgette and colleagues' 1995 paper that contains the statement quoted above, Gressel said:

> "The impression of invincibility from resistance was enhanced by ***not citing*** the growing literature on the known inter-, and especially intra-specific, genetic variability in quantitative levels of glyphosate resistance. ***This literature was known to the various authors,*** yet must have been considered irrelevant. ***In turn, this led to dismissing the need to set resistance management strategies in motion, and the ensuing appearance of a glyphosate-resistant population*** in the management system and the weed where it was most likely to occur." (emphasis added).

Dr. Gressel goes on to discuss the ample evidence for likely resistance that Monsanto scientists had conveniently ignored. For instance, he cites and discusses eight published scientific articles that present ***eight different mechanisms*** by which weeds might evolve resistance to glyphosate. The lead author of one of these papers was Monsanto scientist Stephen Padgette. We discuss Dr. Gressel's reference to a glyphosate-resistant weed population below.

Why would Monsanto scientists misrepresent this important issue of glyphosate's potential to foster glyphosate-resistant weeds? (And they did this not only in Padgette et al (1995), but in a flurry of papers presenting essentially the same distorted view, for instance: Bradshaw et al (1995), Padgette et al (1996) and Bradshaw et al (1997)[7]). The answer is clear. In the mid 1990s when these papers appeared, Monsanto was in the midst of launching the company's first Roundup Ready (RR) crop, RR soybeans, which were first planted commercially in 1996. While Monsanto's microscopic focus on the supposedly "unique properties" of the glyphosate molecule had some success in quelling resistance concerns (e.g. see Jasienuik 1996),[8] most weed scientists were not fooled. Dr. Gressel and many others were convinced that Roundup Ready crop systems would likely do what two decades of glyphosate use had thus largely far failed to do: foster rapid evolution of GR weeds.

As early as 1990, public interest scientists published a strong critique of the herbicide-resistant (HR) crop paradigm entitled *Biotechnology's Bitter Harvest*, which highlighted the high potential for HR weed evolution presented by HR crop systems, among other risks, such as increased use of toxic herbicides.[9] In 1992, Dr. Rebecca Goldburg (co-author of *Biotechnology's Bitter Harvest*) published a peer-reviewed paper in the journal *Weed Technology*, which made similar points. Interestingly, Dr. Goldburg conceded that HR crops resistant to newer and safer herbicides (e.g. glyphosate vs. older, more toxic herbicides like 2,4-D) might offer some short-term benefits in terms of displacing more toxic herbicides, but cautioned that: "resistant weeds already limit use of some of the newer chemicals, and the availability of crops that tolerate the newer herbicides could further encourage the evolution of resistant weeds..."[10]

Weed scientist Dr. Brian Sindel (1996) made the same point in an article discussing the first glyphosate-resistant weed population (discussed further below), quoting his colleague Dr. Roger Cousens of Latrobe University to the effect that herbicide-resistant crops that rely entirely on herbicides for weed control are "in danger of crashing down around our

ears" due to weeds developing resistance to herbicides.[11] Dr. Sindel also explained why glyphosate had thus far fostered so little weed resistance. Used as a "pre-sowing, knockdown herbicide" (Australian terminology for pre-emergence burndown use) with conventional crops, any resistant weeds would likely be killed off by tillage or subsequent use of other herbicides. Such would not be the case with Roundup Ready crops, where glyphosate would likely be the only weed control tool applied. Dr. Sindel concluded by stating that "glyphosate must be retained as an effective herbicide. Integrated weed management, a combination of weed control techniques, is promoted to avoid the further emergence of herbicide resistance."[12]

In 1997, Dr. Ian Heap, who has long managed an online database that registers the occurrence of herbicide-resistant weed populations worldwide, also warned of the need for resistance management with Roundup Ready crops:

> "The recently developed glyphosate-resistant crops ***will need to be used in rotation with conventional cultivars, and in conjunction with non-chemical weed control*** and other herbicides if the selection of glyphosate-resistant weeds is to be avoided." (emphasis added).[13]

Finally, we cite a prescient 1992 article by EPA scientist Dr. Diana Horne in the journal *Weed Technology* entitled "EPA's response to resistance management and herbicide-tolerant crop issues."[14] In 1992, U.S. regulation of genetically engineered (GE) crops was still in the planning stages, and EPA's role had not yet been fixed. While it was clear that EPA would regulate insecticide-producing insect-resistant GE crops by virtue of its traditional role as pesticide regulator, "EPA's role in the regulation of herbicide-tolerant (HTC) varieties is more oblique. EPA has no direct authority over the plant, as herbicide tolerance does not include production of pesticidal compounds. But, EPA will regulate new herbicide uses."

Dr. Horne went on to discuss the widespread occurrence of weeds resistant to other herbicides, and EPA's "strong interest in promoting the development and broader use of integrated pest management (IPM) technologies" to forestall evolution of resistant insects and weeds and reduce use of herbicides overall and their adverse environmental impacts. In a passage that could not have escaped Monsanto, she posed the following question:

> "Would it be appropriate, for example, for the Agency to require that transgenic plants (both of the pesticidal, as well as the herbicide-tolerant varieties), be used ***only within the context of a resistance management program***?" (emphasis added)

---

[11] Sindel, B. (1996). "Glyphosate resistance discovered in annual ryegrass," Resistant Pest Management Newsletter, Vol. 8, No. 2 (Winter 1996), pp. 23-24.
[12] Ibid.
[13] Heap, I. (1997). "Occurrence of herbicide-resistant weeds worldwide," Pesticide Science 51: 235-243.
[14] Horne, D. (1992). "EPA's response to resistance management and herbicide-tolerant crop issues," Weed Technology 6: 657-661.

Unfortunately, Dr. Horne's paper was prescient only in its discernment of the weed resistance threat posed by HR crop systems. While EPA went on to institute mandatory resistance management for insect-resistant GE crops, its halting efforts to establish even weak voluntary weed resistance management plans for glyphosate-resistant and other HR crops foundered on opposition from HR crop developers and growers.[15]

Why were Monsanto scientists virtually alone in denying the threat of glyphosate-resistant weeds? The answer seems clear. Any resistance management plan with a chance to be effective would have to limit selection pressure by imposing restrictions on the use of glyphosate and/or Roundup Ready crops. This is consistent with Dr. Heap's statement above that RR crops would need to be rotated to conventional cultivars to avert further weed resistance. We note that EPA's successful insect resistance management (IRM) plans for insect-resistant crops involves the requirement that growers plant substantial refugia of non-Bt corn and cotton alongside their Bt crop plantings.[16] In short, resistance management would have meant a perhaps substantial crimp in Monsanto's profits via reduced sales of glyphosate and RR crop seed. Another important factor is that farmers often respond to lower-level glyphosate-resistance in weeds by "increasing the magnitude and frequency of glyphosate applications"[17] – a counterproductive, but for Monsanto profitable, response. This helps explain why Monsanto has always recommended using the "full rate" of glyphosate as its keystone "weed resistance prevention" strategy, despite rebukes from weed scientists that use of alternatives to glyphosate is the proper response.[18]

Still, didn't Monsanto understand that it had a longer-term financial interest in preventing the evolution of glyphosate-resistant weeds so as to prolong the useful life of its Roundup Ready technology? Dr. Gressel in fact appeals to Monsanto with this "enlightened self-interest" argument in the conclusion of his piece, cited above. CFS believes that such appeals are based on a misunderstanding of the market forces guiding biotechnology-pesticide firms such as Monsanto.

First, consider that pesticide industry has long familiarity with weed resistance, which has been evolving since the 1970s. Second, that the pesticide treadmill phenomenon whereby a frequently used herbicide fosters resistance, leading to supplementation or replacement with a new "mode of action" (different type of herbicide), has been a major driver in the pesticide industry's development and sale of new herbicides. Finally, consider that the

most profitable period for sale of patented HR seeds and their associated herbicides is limited to the 20-year terms of the associated patents.

Glyphosate went "off-patent" in the year 2000. Despite competition from cheaper generic versions of glyphosate, Monsanto continued to sell large quantities of its Roundup formulations of glyphosate after the year 2000 by tying the use of Roundup to its patented Roundup Ready seeds.[19] The major patent on Roundup Ready soybeans (the largest acreage RR crop) expires in 2014.[20] For a variety of reasons, Monsanto has been relatively unsuccessful in selling farmers on its second generation RR2 soybeans: some object to their high price; others that they do not provide the promised yield boost; and still others find the value of the technology eroded by glyphosate-resistant weeds, which require use of expensive, supplemental herbicides anyway.[21] For many, it is a combination of these factors – more expensive seed plus the expense of additional herbicides to combat GR weeds. When Roundup Ready 1 soybeans go off-patent in 2014, cheap generic versions will presumably become available; and farmers will likely have the legal right to save and replant them, offering further potential savings. Finally, other firms are poised to introduce their own glyphosate-resistant crops, posing a competitive challenge to the company.[22] In short, Monsanto could be facing the imminent loss of its lucrative Roundup Ready soybean franchise, followed by loss of market share in Roundup Ready corn and cotton when their associated patents expire.

What would persuade farmers to continue buying Monsanto soybeans, corn and cotton? One strong enticement would be the ability to control glyphosate-resistant weeds. Indeed, Monsanto has developed and is awaiting USDA approval of soybean varieties resistant to the broad-spectrum herbicide dicamba, which will be "stacked" with resistance to glyphosate as well.[23] These dual HR soybeans are being offered as a tool to help manage glyphosate-resistant weeds. Triple-stack versions of corn and cotton – which combine resistance to dicamba, glyphosate and a third herbicide, glufosinate – are not far behind.[24]

Finally, consider the market potential for these dual and triple-stack HR crops, which will certainly be more expensive than their Roundup Ready-only predecessors. Clearly, those farmers with GR and other HR weed-infested fields would be the most likely market, since

those without resistant weeds would have little incentive to purchase pricier multiple HR crops if cheaper Roundup Ready-only varieties do the job. Glyphosate-resistant weeds are currently estimated to infest 6% of the 173 million acres planted to soybeans, corn and cotton in the U.S., or 10.4 million acres.[25] This represents roughly four-fold greater acreage than in late 2007, when CFS collated figures from the same definitive data source on resistant weeds and found the GR weed-infested acreage totalled just 2.4 million acres. Though no one can say with certainty how rapidly GR weeds will emerge in the future, Syngenta's weed resistance manager, Chuck Foresman, estimates that 38 million acres – or one of every four row crop acres – will be infested with GR weeds in the U.S. by the year 2013.[26] This 38 million acres of GR weed-infested fields would represent a substantially greater market opportunity for the sale of Monsanto's dual and triple-resistant HR crops than the current 10 million acres. Clearly, glyphosate-weed evolution opens up substantial new marketing opportunities for Monsanto. In contrast, serious stewardship measures to slow or stop GR weed evolution works against the company's financial interest.

It will perhaps be objected that this is a cynical interpretation of Monsanto's motives. Not at all. CFS is intimately familiar with Monsanto's long-standing voluntary stewardship efforts with Roundup Ready crops, whose ostensible purpose is indeed to slow the emergence of GR weeds. While it is beyond the scope of these comments to elaborate, we have done so elsewhere, demonstrating that some of Monsanto's supposed resistance management recommendations are not only ineffectual, but exacerbate the problem by supporting continual planting of Roundup Ready crops every year.[27] However, the bottom line of rapidly expanding GR weed populations speaks more than any analysis to the inefficacy of Monsanto's recommendations. Of course, having such programs in place is good public relations. And it must be said that biotech-friendly USDA regularly touts such voluntary, Monsanto-sponsored measures as an excuse not to take regulatory action, ignoring their failure.[28] Recall, however, that the EPA's Jim Jones has testified that biotech companies successfully foiled weak attempts by EPA and USDA to introduce voluntary weed resistance management programs under their auspices in 2001. As virtually the sole provider of genetically engineered HR crops at that time, the objectors must have included Monsanto.

Yet in fairness, it should be stated that Monsanto is not alone in anticipating considerable profits from the GR weed epidemic. As recently reported in the Wall Street Journal, pesticide-biotechnology companies are investing hundreds of millions of dollars in new HR crops as a temporary hi-tech "fix" to glyphosate-resistant weeds. Dow Agrosciences scientist Jim Jachetta stated that these new HR crops represent "a very significant

opportunity" and "a new era" for chemical companies.[29] Mr. Jachetta was probably thinking in particular of Dow's new corn and soybeans varieties that resist high doses of 2,4-D, a close chemical cousin of dicamba that formed part of the Vietnam War defoliant Agent Orange. Dow took the opportunity of press attention to the GR weed epidemic to issue a press release touting its 2,4-D tolerant crops as a fix to GR weeds.[30]

When should Monsanto have known and reacted to the development of Roundup-resistant weeds? The short answer is, no later than the introduction of the first Roundup Ready crop in 1996. As documented above, there was widespread concern in the weed science community that Roundup Ready systems would foster GR weeds, and Monsanto scientists not only ignored the evidence, but in several publications intentionally gave the false impression that resistant weeds would not emerge, so as to avoid resistance management regulations that the EPA was seriously considering, and that would have limited the company's profits.

However, there is also solid evidence that Monsanto scientists denied the existence of the first confirmed GR weed population, rigid ryegrass in Australia, in a peer-reviewed scientific publication. This is the GR weed population referred to by Dr. Gressel (in the above-cited article), who stated that Australian researchers had confirmed to him its existence in discussions at a weed science conference in June of 1996. The Australian press had reported the resistant ryegrass even before that. In another paper (also cited above) appearing in the same issue of the same journal as Dr. Gressel's, Dr. Brian Sindel stated that: "Researchers at the Centre for Conservation Farming at Charles Stuart University at Wagga Wagga ***confirmed*** that the ryegrass was resistant to glyphosate," and that Monsanto Australia's Bill Blowes was working with the University to determine the cause of the resistance. Nevertheless, Monsanto scientists said not a word about this GR weed in a 1997 paper that appeared in the journal *Weed Technology*,[31] and in fact repeatedly denied the existence of any "verified" GR weed population in world, despite the confirmation cited above.[32] Though the editors received the original paper in April of 1995, they note that a revised version was received on July 17, 1996 – at least weeks and probably months after University researchers had confirmed the resistance.

This historical footnote, however revealing it may be as to Monsanto's (lack of) corporate character, is of minor importance now. Much more significant is the company's ***continuing*** obfuscation of the glyphosate-resistant weed issue, even today, as it strives to introduce new Roundup Ready crops (such as alfalfa and sugar beets) free from the regulation that is urgently

---

[31] Bradshaw, L. et al (1997). "Perspectives on glyphosate resistance," Weed Technology 11: 189-198.

[32] In one passage that reveals they know of the resistant population, Bradshaw and colleagues tellingly state that "evidence of weeds evolving resistance to this herbicide [glyphosate] under field situations has not been verified," citing two papers from 1993 and 1994. Elsewhere in the paper, they state: "no verified reports of a glyphosate-resistant plants have arisen following an extensive history of broad-scale glyphosate applications in the field." Yet as noted by Dr. Gressel, the population had been confirmed as resistant by no later than June of 1996.

needed to prevent further epidemic spread of weed resistance. Monsanto's position today is that planting a GR crop every year in the same field is consistent with forestalling GR weed evolution, provided only that it is not the same GR crop every year. This position – uncritically adopted by USDA[33] – stands in direct contradiction to the concensus view of every legitimate member of the weed science community, as expressed in a recent National Research Council report, which stated explicitly that the value of crop rotation to forestall glyphosate-resistant weeds is undermined when the crops in the rotation are glyphosate-resistant.[34]

Thus, the question of when should Monsanto have known and reacted to the development of Roundup-resistant weeds is perhaps wrongly put, as it implies that the company has in fact reacted in an effective manner to glyphosate-resistant weeds. The truth, however, is that Monsanto continues to employ its considerable expertise not to forestall GR weeds, but rather to obfuscate the issue. This in turn serves to the interests of avoiding any serious resistance management, selling as many Roundup Ready seeds and as much Roundup as possible, and generating (via GR weeds) market demand for its successor herbicide-resistant crops.

Can you elaborate on why multiple-resistant crops are not, as some claim, a solution to the resistant weed epidemic?

Agrichemical-biotechnology companies have invested hundreds of millions of dollars in the development of crops resistant to high rates of older, more toxic herbicides as the supposed "solution" to glyphosate-resistant weeds.[35] In most cases, such crops are resistant to multiple herbicides, often including glyphosate.

Prominent examples include corn, soybeans and cotton resistant to 2,4-D, developed by Dow Agrosciences; and soybeans, corn and cotton resistant to dicamba, developed by Monsanto. Dow's 2,4-D resistant corn also resists the "fop" class of ACCase inhibiting herbicides,[36] and will be offered with resistance to glyphosate and/or glufosinate as well for triple or "quad-stack" resistance to three or four major classes of herbicide. Dow's soybeans will be resistant to glufosinate and glyphosate as well as 2,4-D, for "triple-stack" resistance to three herbicide families.[37] Monsanto's dicamba-resistant soybeans will also be resistant to glyphosate, while the company has triple-stack versions of corn and cotton in the works that resist dicamba, glufosinate and glyphosate.[38] There are many other

examples from other companies. In fact, fully eleven HR crops are awaiting deregulation (approval for commercial cultivation) by USDA. These include 2,4-D resistant corn and soybeans and dicamba-resistant soybeans.[39]

The agrichemical-biotechnology industry intends for these crops to be sprayed with either premixed herbicide cocktails containing some or all the herbicides to which the crop is resistant, or with one or more of them sequentially, on an as-needed basis.[40]

The rationale behind these multiple HR crop systems is simple. Weeds resistant to one herbicide mode of action will be killed by the other(s). Unfortunately, such a simple-minded approach to weed control will offer at best short-term relief to growers, and even then only at the cost of sharply increased use of more toxic herbicides, with associated adverse impacts on the environment and public health. In the medium to longer-term, Nature will evolve clever responses to the chemical onslaught accompanying multiple-HR crop systems in the form of multiple herbicide-resistant weeds. Real solutions to resistant weeds, as opposed to temporary fixes, will have to involve a renewed commitment to integrated approaches that prioritize non-chemical means of weed control.[41]

Weed resistance is an evolutionary phenomenon. Frequent, repeated use of an herbicide selects for the preferential survival of those initially rare individuals with the genetic predisposition to survive its application. Over time, the resistant individuals propagate and gradually supplant susceptible weeds, resulting in a resistant weed population. The rate of evolution is critically dependent on the "selection pressure." The more frequently an herbicide is used, the more rapidly a resistant weed population will evolve.

Weeds have evolved many different mechanisms for surviving the application of herbicides. The best studied are so-called "target-site" alterations in the enzyme whose activity is normally blocked by the herbicide.[42] Disablement of the enzyme, which performs some critical function in the plant, results in the death of the normal weed. The target-site alteration makes the enzyme immune to the herbicide, conferring resistance on the weed. If the herbicide is regarded as a key and the target enzyme as a lock, the normal susceptible weed is killed when the key fits and opens the lock; the resistant weed has evolved an altered lock that the herbicidal key no longer opens. Target-site alterations normally confer resistance only to herbicides (one to many) that have the same "mode of

action."[43] Each "mode of action" (corresponding to a family or class of herbicides) represents a key that opens a particular lock.[44] Use of another herbicide with a different mode of action is usually effective in killing these types of weed.

A weed may also become resistant by evolving the ability to generate many-fold more copies of the target enzyme than are normally produced. In this case, the usual dose of the herbicide is only able to shut down a certain small proportion of the much more numerous enzyme molecules, while the others continue to function, allowing the thereby resistant weed to survive.[45] In terms of the key-lock analogy, the herbicide still fits the lock, but there are not enough herbicidal keys to open the more numerous locks.

Weeds may also evolve the ability to prevent or minimize internal movement of the herbicide, once absorbed by the plant, to the tissues (e.g. roots) it must reach to exert its killing effect, a mechanism known as reduced translocation. Still another mechanism involves reduced absorption of the herbicide, for instance via leaves with a thicker or tougher cuticle.[46] In these cases, the herbicide is unable to reach the lock (or not in sufficient quantities) to open it and so kill the weed.

In all of these cases, switching to an herbicide with a different mode of action will often provide control, at least for a time, though as discussed further below there are complications.

Another different class of resistance mechanisms is called "metabolic degradation" or "enhanced metabolism." Weeds with this form of resistance have the ability to degrade or metabolize the herbicide into a form that is not toxic to the plant. Interestingly, this mechanism often utilizes the plant's natural repertoire of detoxification enzymes, and involves several classes of enzyme that are quite similar to those present in the livers and other tissues of mammals, where they perform a similar detoxification function. Weeds that evolve resistance via metabolic degradation often have the ability to detoxify herbicides from several different families with different modes of action, making them particularly difficult to control. Powles and Yu (2010), in the paper already cited, note that the P450 class of detoxification enzymes represent "a very threatening resistance mechanism, because P450 enzymes can simultaneously metabolize herbicides of different modes of action, potentially including never-used herbicides."

---

[43] For weeds resistant to different modes of action, see links under "Herbicide site of action" at http://www.weedscience.org/In.asp. Note that weeds highlighted in red with "Multiple – 2, 3, 4 or more MOAs" indicate multiple herbicide resistant weed populations that withstand herbicides from the specified number of herbicide families (MOAs = modes of action).

[44] The reality is more complicated. Each herbicide family, corresponding to a distinct mode of action, is actually comprised of several to dozens of active ingredients with slightly differing versions of the same basic key which all open the same lock. Resistant weeds may have resistance to all or in some cases only some members of herbicide family. In terms of our analogy, the lock may be altered such that none of the keys in a particular family open it, or in such a way that some keys do and others do not fit it.

[45] A population of the most damaging glyphosate-resistant weed, Palmer amaranth, recently evolved this mode of resistance. See: Gaines, T.A. et al (2010). "Gene amplification confers glyphosate resistance in Amaranthus palmeri," PNAS 107: 1029-34.

[46] For a recent review, see: Powles & Yu (2010), op. cit.

It is extremely important to observe that in most cases of weed resistance, the mechanism involved remains unknown. It requires extremely sophisticated molecular analysis as well and lengthy greenhouse testing to ascertain the mechanism of resistance in any particular case. And weed scientists are rapidly discovering that some weed populations possess two or more mechanisms of resistance to a single herbicide family, each lending only limited resistance, but together offering higher and more threatening levels.[47] Nature's evolution of weed resistance to herbicides takes quite ingenious turns,[48] and has far outpaced our technical capacities to ascertain the causes. This becomes clearer when one considers the vast numbers of resistant weeds in the world today.

According to the latest counts, over 400,000 fields in the world are infested with 348 herbicide-resistant biotypes of 194 different weed species.[49] A biotype is a particular weed species-herbicide family combination. The number of resistant biotypes exceeds the number of resistant species because a particular weed species can have various populations resistant to different herbicide families. Thus, separate tall waterhemp populations with resistance to glyphosate alone, or to ALS inhibitors alone, represent two distinct herbicide-resistant biotypes of a single weed species. The considerable excess of biotypes to species indicates that a number of weed species have different populations that are resistant to different herbicide modes of action.

The U.S. is by far the world leader in herbicide-resistant weeds, with 132 confirmed resistant biotypes infesting roughly 30 million acres.[50] Second place belongs to Australia, with just 54 resistant biotypes.[51] The most extensive populations of resistant weeds in the U.S. involve three major herbicide modes of action: resistance to photosystem II inhibitor class herbicides (chiefly the triazine class), which emerged chiefly in the 1970s; resistance to ALS inhibitor family herbicides, which evolved mainly in the 1980s and early 1990s when these herbicides were most heavily used; and resistance to glyphosate, which has evolved in dramatic fashion over just the past decade.[52]

[50] Based on Center for Food Safety's compilation of data on herbicide-resistant weeds in the U.S. from the International Survey of Herbicide-Resistant Weeds (ISHRW), at www.weedscience.org, on November 30, 2010. 30 million acres is near the upper-bound estimate of 32.3 million acres, which is closer to reality than the lower bound estimate of 9.4 million acres. One indication of this is that a recent point estimate for acreage infested by glyphosate-resistant weeds alone, made by Dr. Ian Heap, who manages the ISHRW website, is 10.4 milllion acres, exceeding the lower-bound estimate for acreage infested by ***all*** herbicide-resistant weeds.
[51] http://www.weedscience.org/summary/CountrySummary.asp.
[52] Benbrook, C. (2009). Impacts of Genetically Engineered Crops on Pesticide Use in the United States: The First Thirteen Years," The Organic Center, November 2009, pp. 12-13 and Figure 2.4. Note that acreage infested with glyphosate-resistant weeds as well as ALS inhibitor-resistant weeds has increased greatly since February of 2009, which is when the figures upon which the figure is based were compiled from ISHRW.

There are two basic pathways for weeds to evolve multiple herbicide resistance. In one pathway, weed populations ***accumulate*** resistance mechanisms, one by one, to different families of herbicides over years, while the other pathway (enhanced metabolism) involves resistance to several families of herbicides all at once.

The one-by-one pathway is made possible by the fact that weed populations, once they evolve resistance to a particular type of herbicide, often retain that resistance trait indefinitely. This is not necessarily the case, but it is often so. Weed scientists once assumed that an herbicide-resistant weed population would gradually disappear if farmers stopped applying the pertinent herbicide. This notion was based on the theoretical idea that in the absence of herbicide use, weeds ***without*** the resistance trait would always be more vigorous – grow faster and bigger, produce more seed and pollen – than resistant weeds. Thus, the latter would thrive only when the herbicide was used, but would be "outcompeted" by normal weeds in its absence. The theoretical underpinning of this idea is that the resistance trait imposes a "metabolic cost" or "fitness cost." That is, the resistant weed expends energy and resources to generate the resistance mechanism, and consequently has less to devote to growth and reproduction. According to this theory, the resistant weed, though of course favored when the herbicide is used, is less vigorous and fecund when not the herbicide is not applied.

As it turns out, this theory fits reality in some cases, but not in others. While some resistant weeds are indeed less "fit" in the absence of the pertinent herbicide's use, others are as just as fit or even more vigorous than their herbicide-susceptible brethren. As with mechanisms of resistance, weed scientists simply have not determined the fitness of the great majority of herbicide-resistant biotypes. Based on what little is known, however, we can make the following cautious generalizations about resistance to the three major modes of action presented above.

In general, weeds resistant to triazines tend to be less fit.[53] Some weeds resistant to ALS inhibitors exhibit lesser fitness, but others appear to have equivalent or even greater fitness than susceptible weeds.[54] Since glyphosate-resistant biotypes have emerged rapidly over just the past decade, in most cases their fitness has not been tested, and remains unknown. Given the importance of glyphosate in world agriculture, and the rapid emergence of glyphosate-resistant (GR) biotypes, elucidation of the fitness of GR weeds should be a top research priority.[55] Below, we discuss recent research that addresses this question.

The fitness of a resistant weed population helps determine how well it thrives in situations where farmers stop using the pertinent herbicide. Where fitness costs obtain, the resistant weed population will subside. Where there is no fitness cost, or indeed the resistant weed

---

[53] Gronwald, J.W. (1994). "Resistance to photosystem II inhibiting herbicides," in: Powles, S.B. & J.A.M. Holtum, eds., *Herbicide Resistance in Plants: Biology and Biochemistry,* Ann Arbor, MI, Lewis, 1994.

[55] Vila-Aiub, M.M. et al (2009). "Fitness costs associated with evolved herbicide resistance alleles in plants," New Phytologist 184: 751-767.

is more vigorous, ending use of the pertinent herbicide will do nothing to reduce resistant populations. In these cases, resistant weed populations may will persist indefinitely or perhaps even increase in scope even when the herbicide is not used.

Another important factor is the herbicide regime used by farmers. While we often think simplistically of farmers switching to a new mode of action when afflicted with weeds resistant to a particular herbicide, the reality is more complex. Often, herbicide A to which one or several weeds have evolved resistance will still be effective in controlling other troublesome weed species. In these cases, a common response of farmers is to supplement herbicide A with herbicide B rather than stop using A altogether. Thus, weed populations that have evolved resistance to A will continue to be exposed to it, and will continue to have an advantage over their susceptible brethren. Even if there is a fitness cost to herbicide A resistance, weeds resistant to it will continue to be favored.

The hope, of course, is that herbicide B will save the day by killing off weeds resistant to A. This forms the basis of the agrichemical -biotechnology industry's strategy of introducing multiple-herbicide resistant crops. And this will sometimes be an effective strategy. However, here too the reality is more complex. In those cases where the population of weeds resistant to A is small, the supplementation (or switching) strategy has a greater chance of success. However, this strategy is more likely to fail with larger resistant weed populations, for the following reason.

The larger the population of weeds resistant to herbicide A, the more likely that there exists among them individual weeds that have the rare genetic predisposition that confers resistance to herbicide B. Suppose that a small population of herbicide A-resistant weeds numbers 1,000, while a large population has 1 million individual plants. If on average only one in a million weeds are resistant, it is unlikely that the small population harbors one, while quite likely that the larger one does. It's essentially a numbers game, equivalent to tickets in a lottery. The small weed population is equivalent to buying just a few lottery tickets, while a large population corresponds to buying many tickets. The likelihood that the A-resistant population has a "winning ticket" (an individual with resistance to B as well as A) increases with its size. Winning the lottery, of course, is precisely what one wants to avoid in this case.[56]

What this means is that when a farmer either switches from herbicide A to herbicide B, or supplements A with B, he may well select for weeds that have resistance to ***both*** herbicides. This is the pathway by which weed populations accumulate resistance, one by one, to different herbicide modes of action.

This is the theory, and of course theory (as we have seen above with fitness) can be wrong. What do the facts on the ground tell us? One fact is that multiple herbicide-resistant weed populations are on the rise in the U.S., and have increased sharply over just the past three years. This is depicted in the table below, which is based on data compiled by Center for

[56] This lottery analogy is borrowed (and adapted) from Iowa State University weed scientist Bob Hartzler. See http://www.weeds.iastate.edu/mgmt/2004/twoforone.shtml.

Food Safety on resistant weeds from the best available source, the International Survey of Herbicide-Resistant Weeds (ISHRW).[57] The ISHRW is an online database that records populations of herbicide-resistant weeds, and is supported by agrichemical-biotechnology companies and academic weed scientists. Note that both the number of sites and acreage infested figures are given in ranges due to the difficulty of estimating the precise geographic extent of resistant weed populations. While most weed biotypes in the U.S. and the world today still have confirmed resistance to just one mode of action, the table below demonstrates a disturbing trend to proliferation of multiple herbicide-resistant (MHR) weed populations.

Data on Populations of Multiple Herbicide-Resistant Weeds in the U.S Over the Past Three Years

Date Compiled	No. of Species	No. of Populations	No. of States	Sites (min.)	Sites (max.)	Acreage (min.)	Acreage (max.)
11/21/07	11	20	12	679	1,459	25,829	245,755
11/30/10	14	32	15	1,016	3,078	127,799	1,258,605
% increase	27%	60%	25%	50%	111%	395%	412%

As the table shows, the number of MHR populations has increased by 60%, from 20 to 32, since November 2007. More concerning is the increase in the aggregate number of sites and acreage infested by these MHR populations. The number of sites infested has increased by half to more than double over the past three years, while the acreage infested has increased by a still more troubling 400%.

Two populations of MHR weeds that have emerged since November 2007 are resistant to glyphosate and paraquat. However, the most prevalent MHR weeds resist applications of ALS inhibitors and/or glyphosate. ALS inhibitor-resistant weeds emerged primarily in the 1980s and early 1990s following the introduction of herbicides with this mode of action in 1982. The fact that many weeds resistant to this mode of action have no loss of fitness (and in some cases have enhanced fitness) means that their populations have tended to persist or increase even as farmers made a large scale switch from reliance on them to use of glyphosate in tandem with the adoption of glyphosate-resistant Roundup Ready crops beginning in 1996. Many populations of ALS inhibitor-resistant weeds are also extremely large, infesting from hundreds of thousands to millions of acres. Two populations (in Missouri and Illinois) infest anywhere from 2 to 5 million acres each.

Over the past 14 years, glyphosate has largely displaced ALS inhibitors on the three crops – soybeans, cotton, and to a lesser extent corn – where Roundup Ready varieties have become predominant. These are also the three crops that receive the bulk of herbicides applied in U.S. agriculture as a whole. Consequently, it is no surprise that the majority of weeds evolving resistance over the past decade have become resistant to glyphosate. As with ALS inhibitors, glyphosate-resistant weed populations are often large, with several infesting hundreds of thousands to millions of acres.

As noted above, there has been a sharp rise in populations resistant to both ALS inhibitors and glyphosate. In November 2007, ISHRW recorded just 3 populations of two species of

[57] www.weedscience.org.

weed infesting at most 10,600 acres that were dual resistant to glyphosate and ALS inhibitors. By November 2010, just three years later, there were 7 populations of five species of weeds with dual resistance to these two modes of action, and they infested hundreds of thousands to as much as 1 million acres. This represents from 10-fold to 100-fold more infested acreage. The most extensive population of these weeds (tall waterhemp in Missouri) also resists a third mode of action, PPO inhibitors,[58] that are otherwise being relied upon by growers to combat resistance to glyphosate and ALS inhibitors. Tall waterhemp has a demonstrated ability to evolve resistance to two, three or more herbicide modes of action, and is for that and other reasons particularly feared.[59] University of Illinois weed scientists recently sounded the alarm about multiple herbicide-resistant tall waterhemp (*Amaranthus tuberculatus*) in their state and in Missouri:

> "Herbicide resistance in *A. tuberculatus* appears to be on the threshold of becoming an unmanageable problem in soybean."[60]

Noting that glufosinate is one of the few remaining options for control of late season waterhemp, they fear its loss to resistance as well:

> "Furthermore, on the basis of *A. tuberculatus's* history, there is no reason to expect it will not evolve resistance to glufosinate if this herbicide is widely used. If this happens, and no new soybean postemergence herbicides are commercialized, ***soybean production may not be practical in many Midwestern fields***." (emphasis added)

The emergence of dual resistance to glyphosate and ALS inhibitors fits the model of one-by-one accumulation of resistances presented above. Weeds initially evolved ALS inhibitor resistance in the 1980s and 1990s. Because many of these populations have no apparent loss of fitness, they have persisted into this decade; because they tend to be large, there existed among them weeds which had the rare genetic predisposition to survive glyphosate application. Massive use of glyphosate with Roundup Ready crops beginning in 1996 then fostered evolution of the dual-resistant biotypes.

To make matters still worse, a recent study of the most prevalent glyphosate-resistant weed species, horseweed, suggests that it has fitness equal to or greater than glyphosate-susceptible horseweed (at least in California), and that the glyphosate-resistant populations appear to be expanding whether or not glyphosate is applied to them.

> "In a survey conducted in 2006 and 2007, the majority of horseweed plants sampled in the southern SJV [San Joaquin Valley] were GR [glyphosate-resistant], regardless of nearby cropping systems (Hanson et al. 2009), suggesting the possibility that increased fitness may have contributed to the very rapid expansion in the range of

[58] See http://www.weedscience.org/Case/Case.asp?ResistID=5269.
[59] Tranel,P.J. (2010). "Introducing QuadStack waterhemp," Agronomy Day 2010, University of Illinois Extension.
[60] Tranel, P.J. et al (2010). "Herbicide resistances in Amaranthus tuberculatus: a call for new options," Journal of Agricultural and Food Chemistry, DOI: 10.1021/jf103797n.

> the GR biotype. ... Observations of vigorous and productive GR horseweed, regardless of whether it is growing in treated or untreated areas, suggests that the GR horseweed in California may be more competitive than the glyphosate-susceptible (GS) biotype in addition to being resistant to the most commonly used herbicide in orchards, vineyards, and adjacent noncrop areas (Shrestha, personal observation)."[61]

Still more troubling are the results of recent research on horseweed populations in Indiana and Ohio variously resistant to glyphosate alone, to ALS inhibitors alone, or to both classes of herbicides. The authors of this study reported that all three types of resistant horseweed displayed equal fitness to susceptible horseweed, as measured by "growth and seed production potential." They further warn that these populations are likely to persist and even increase in range with continued use of glyphosate and ALS inhibitors – and would be unlikely to "disappear" even if the growers were to stop using them. This latter possibility is unlikely, given the fact that these two modes of action are very commonly used to control many different weed species beyond horseweed in their region.

> "…. we conclude that horseweed populations composed of biotypes with single resistance to glyphosate and ALS-inhibiting herbicides, or multiple resistance to glyphosate + ALS-inhibiting herbicides have similar growth and seed production potential. Furthermore, the variation within these herbicide-resistant populations following exposure to herbicides would suggest that repeated applications will only increase the ability of these populations to compete and reproduce following repeated applications of the same herbicide or combination of herbicides. ... To control these herbicide-resistant horseweed populations, and to offset the evolution of more herbicide-resistant weeds, multiple integrated weed management practices need to be implemented with the idea that resistant biotypes will not just disappear after growers stop the application of these herbicide modes of action."[62]

Authors from the same team have also done several studies showing the clear potential for horseweed to evolve resistance to 2,4-D.[63] They note that:

> "Multiple-resistant and cross-resistant horseweed populations have evolved to various combinations of the previous herbicide modes of action in Israel, Michigan, and Ohio (Heap 2009), providing evidence for the plasticity of this weed."[64]

Importantly, their studies of potential 2,4-D resistance in horseweed have been driven by concern over the advisability of relying on some of the new herbicide-resistant crops, such

as the 2,4-D and dicamba-resistant varieties mentioned above. Note that 2,4-D and dicamba are both "growth regulator" type herbicides:

> "With the impending commercialization of 2,4-D- and dicamba-resistant crops, it appears that additional options for control of glyphosate-resistant annual broadleaf weeds will be available. However, growth regulator herbicide-resistant technologies ***may not provide long-term solutions*** if resistant or tolerant populations currently exist or if populations become resistant under selection pressure from overreliance on growth regulators for broadleaf weed management."[65]

The implications of these various studies and data are clear. Weeds – including some of the most agronomically damaging and costly species like horseweed and tall waterhemp – have demonstrated the ability to evolve resistance to single modes of action as well as multiple herbicides. The single-resistant and in some cases dual-resistant weeds often suffer no "fitness cost," and thus their populations are likely to persist indefinitely, rather than conveniently "disappear" if farmers were to stop using them. The persistence of single- and multiple herbicide-resistant weed populations means that switching to, or supplementation with, new modes of action like 2,4-D and dicamba – in association with crops engineered with resistance to them – may backfire. While short-term relief is possible, these new 2,4-D and dicamba-resistant crops "may not provide long-term solutions..." if growers rely excessively on them. Rather, the introduction of multiple-herbicide resistant crops is quite likely to foster increasingly costly and damaging populations of weeds resistant to ever more herbicides.

The all-at-once pathway of herbicide-resistance is also concerning. As noted above, metabolic degradation mechanisms employing the plant's natural detoxification systems can evolve to confer resistance to multiple herbicides at one time – and potentially even to herbicides that have never before been used. At present, this mechanism of weed resistance has been observed mostly in grass-type weeds in Europe and Australia. Powles and Yu (2010) report 11 weed species that have the P450-mediated herbicide degradation mechanism alluded to above. Of these species, populations of blackgrass (*Alopecurus myosuroides*) and rigid ryegrass (*Lolium rigidum*) are among the worst, with resistance to multiple herbicides from three and four different herbicide families, respectively.[66] There have thus far been few reports of weeds with this mechanism of resistance in the U.S.,[67] though further investigations may reveal others.

The rapid increase in the number of weed populations resistant to glyphosate and to multiple herbicides as well as the acreage they infest poses serious problems for U.S. agriculture. Agronomists are wary of the agrichemical-biotechnology industry's preferred response to this problem – introduction of new crops resistant to older, more toxic herbicides, often in stacked versions conferring resistance to multiple herbicides. While

new technologies may provide some short-term relief, it will come only at the cost of increased herbicidal pollution of the environment, harm to human health, and greatly increased weed control costs for farmers. In the medium to longer term, Nature is likely to win this chemical arms resistance race between crops and weeds.

Do you know of any specific health threats presented by any of the herbicide resistant crop systems under development?

As noted above, two of the leading herbicide-resistant crop systems involve resistance to 2,4-D and dicamba. According to Pennsylvania State University weed scientist Dr. Dave Mortensen, widespread deployment of these crop systems will likely lead to a substantial increase in the use of these herbicides in U.S. agriculture. In testimony before this Subcommittee on July 28, 2010, Dr. Mortensen estimated that herbicide use on soybeans would increase by 70% within three years of introduction of 2,4-D and dicamba-resistant soybeans, assuming rapid adoption,[68] an increase of roughly 55 million lbs.[69]

Increased use of these herbicides, especially at that magnitude, would have adverse impacts on the environment, public health, and in particular the health of farmers.

The toxicity of 2,4-D (dichlorophenoxyacetic acid) has been exhaustively reviewed in a petition by public interest scientists to EPA requesting that the herbicide's registration be cancelled.[70] Ingestion or inhalation of 2,4-D has adverse effects on the nervous system – loss of coordination, limb stiffness, stupor, coma. A growing body of evidence points to 2,4-D as a carcinogen. Studies in the U.S., Italy, Canada, and several other countries link 2,4-D exposure to non-Hodgkin's lymphoma, a cancer of the immune system. Studies of farm workers exposed to 2,4-D revealed higher than normal rates of birth defects in their children. 2,4-D is also a mutagen and an endocrine disruptor, and can be contaminated during the production process with the even more toxic compound dioxin, which is highly carcinogenic, weakens the immune system, decreases fertility, and causes birth defects.[71] 2,4-D is banned in Norway.

Dicamba is a chlorinated benzoic acid herbicide similar in structure and mode of action to 2,4-D, and is used in both agriculture (e.g. corn, wheat) and on lawns.[72] In 1992, the National Cancer Institute (NCI) found that farmers exposed to dicamba were twice as likely

to contract non-Hodgkin's lymphoma.[73] A subsequent NCI study reported associations between dicamba exposure and higher incidence of lung and colon cancer in pesticide applicators.[74] Researchers have also found a 20% percent inhibition of the nervous system enzyme acetylcholinesterase in a group of certified pesticide applicators whose only common pesticide used was dicamba.[75] Exposure to organophosphate insecticide residues in food has recently been linked to increased rates of attention-deficit/hyperactivity disorder in children, and the presumed mechanism is inhibition of acetylcholinesterase, an enzyme essential for normal brain development.[76] Dicamba is moderately persistent in soil and water, and is frequently found contaminating ground water supplies.[77] Pregnant mice that ingested drinking water spiked with low doses of a commercial herbicide product containing dicamba, 2,4-D and mecoprop had reduced litter size, suggesting that this herbicide mixture may have developmental toxicity.[78] A study of the frequency of sister chromatid exchanges (SCEs) and cell-cycle progression assays revealed that high doses of dicamba can damage DNA, leading the study authors to warn that dicamba is a "potentially hazardous compound to humans."[79]

Dicamba is also highly volatile, and under the right conditions (hot days, no rainfall) can revolatilize after application and drift to damage neighboring crops or plants bordering fields.[80] This drift can cause significant economic damage to other farmers, and also destroy habitat for pollinators and other beneficial insects.[81] The greatly increased use of dicamba to be expected with dicamba-resistant crops will likely exacerbate these adverse impacts. South Africa completely prohibited use of dicamba in some districts, and banned aerial application in others.[82]

2,4-D-resistant crops may pose a new food safety risk beyond the risks attributable to the increased use of 2,4-D to be expected with its adoption. First, one must understand that monocot plants (cereal crops like corn) have a natural tolerance to low levels of 2,4-D, facilitating the use of this pesticide on major field crops like wheat and corn. Numerous

studies have examined precisely how 2,4-D is metabolized by non-genetically engineered plants so as to render it non-toxic to the plant. 2,4-D-resistant plants incorporate a bacteria-derived gene that metabolizes 2,4-D in a different way, transforming it into 2,4-dichlorophenol (2,4-DCP). 2,4-DCP is not produced, or only in very small amounts, when naturally tolerant plants metabolize 2,4-D.

2,4-DCP is a chlorophenol compound that is individually listed by EPA in its toxics release inventory of toxic chemicals.[83] The European Union also lists 2,4-DCP as a hazardous substance. Animals dosed with high levels of chlorophenols in their food or drinking water experienced adverse liver and immune system effects, and did not gain as much weight as control animals. Some studies have shown increased risk of cancer, as well as acne and liver damage, among workers in pesticide plants that make chlorophenols, though it is not clear whether the effects were due to chlorophenols or other chemicals.[84]

Dow AgroSciences uses 2,4-DCP as a raw material to manufacture pesticides. In a material safety data sheet for 2,4-DCP,[85] Dow notes that exposure of just 1% of a worker's body (an area the size of the palm of a hand) to molten 2,4-DCP may cause death. Dow's industrial hygiene guideline for 2,4-DCP is 1 part per million, skin. Dow reports that animal testing has revealed that 2,4-DCP has adverse effects on blood forming organs (bone marrow & spleen), kidney and liver; that 2,4-DCP may be contaminated by the more toxic 2,4,6-trichlorophenol (known to the State of California to cause cancer); and that this contaminant (present at a level of 0.1% in current samples) may explain the inconclusive results in carcinogenicity tests on animals. Dow further notes that in-vitro genetic toxicity (mutagenicity) studies with 2,4-DCP were negative in some cases and positive in other cases, and that it found no relevant information with respect to possible reproductive effects from 2,4-DCP exposure. Dow found that 2,4-DCP is moderately toxic to aquatic organisms on an acute basis (LC50 or EC50 between 1 and 10 mg/L in most sensitive species tested).

French scientists conducted experiments to determine whether the 2,4-DCP generated by transgenic, 2,4-D-resistant plants after spraying with 2,4-D would be broken down into less toxic compounds. They found that the basic structure of the 2,4-DCP molecule remained intact. The French team concluded that 2,4-D-resistant plants sprayed with 2,4-D "may not be acceptable for human consumption."[86] They further point to the potential for 2,4-DCP

residues in foods derived from 2,4-D resistant plants to be transformed *in vivo* into more highly chlorinated compounds that have greater toxicity.[87]

BASF is awaiting USDA deregulation of genetically engineered, imidazolinone-resistant soybeans (BPS-CV127-9).[88] Imazethapyr, one of the most widely used of the imidazolinone class of herbicides (a form of heterocyclic aromatic amine), has been associated with increased risk of bladder and colon cancers in farmers who use this herbicide.[89]

Could you elaborate on the external costs imposed on growers and the environment caused by the cultivation of herbicide-resistant crops?

As explained by Steve Smith in testimony before this Subcommittee on September 30, 2010, herbicide-resistant crops make it possible to apply large quantities of herbicides much later in the growing season than is possible otherwise. This facilitation of postemergence herbicide use means that neighboring growers will be vulnerable to crop injury from herbicide drift to a much greater extent than they were before HR crops were introduced. Costs incurred from crop injury by growers whose crops are not resistant to the pertinent herbicide are difficult to estimate, but could be substantial, especially in the case of a volatile herbicide like dicamba.

In order to defend their crops from herbicide drift damage, some and perhaps very many growers will purchase seed that is herbicide-resistant for defensive purposes, not because they want to make use of the trait and associated herbicide for weed control. In fact, this has already happened with Roundup Ready technology, and is happening now with Clearfield.

According to Arkansas weed consultant Ford Baldwin:

> "A lot of growers planted Roundup Ready corn in the beginning out of self defense. I looked at enough glyphosate drift on conventional corn to understand why. Most growers initially used conventional herbicides in the Roundup Ready corn. Over time though the progression was to glyphosate-based programs and we lost a lot of the benefit of what could have been a great resistance management tool."[90]

Growers who bought Roundup Ready corn "out of self defense" paid a substantial premium (technology) fee for a trait they did not want. This is an external cost imposed by the Roundup Ready crop system, as it is used in the real world. Mr. Baldwin's article, however, focuses on an analogous situation with another herbicide-resistant crop, Clearfield rice.

[90] Baldwin, F.L. (2010). "Herbicide drift damaging rice," Delta Farm Press, June 7, 2010. http://deltafarmpress.com/rice/herbicide-drift-damaging-rice-0607/.

Clearfield is a non-GE type HR crop, resistant to the imidazolinone class of herbicides of the ALS inhibitor family. Newpath is BASF's formulation of imazethapyr.

> "My university counterparts have received more Newpath drift calls than normal as well. At present, four out of every five requests to come to a field involve some problem with Newpath on conventional rice. Most involve drift, but there have also been several cases of miscommunication between neighbors, and also between farmers and applicators on whether a particular field was Clearfield or conventional rice.
>
> These situations are never good. They have led to more talk of "defensive" planting of Clearfield rice. While it is easy for the good doctor to sit at his desk and say that is a bad idea, I have looked at several fields this year where I must admit I couldn't blame the farmer for his thinking."

Baldwin is clearly sympathetic to the crop injury and losses incurred by growers of conventional corn (due to Roundup drift from Roundup Ready fields) and conventional rice (due to Newpath drift from Clearfield rice fields). Yet he is no enemy of either technology. On the contrary, he regards them as useful tools for farmers, but tools that are having unfortunate and costly impacts on those who choose not to use them.

But the real thrust of the article has to do with the difficulty of using these herbicide-resistant crop systems in a ***sustainable*** manner, which is exacerbated by the drift issue. Growers initially bought Roundup Ready corn for defensive reasons: "Over time though the progression was to glyphosate-based programs ***and we lost a lot of the benefit of what could have been a great resistance management tool.***" What is the "great resistance management tool" that was lost? First, it was growing conventional corn with "conventional" [non-glyphosate] herbicides. That is, growers who planted Roundup Ready soybeans or cotton and then rotated to conventional corn were practicing "resistance management" by not using glyphosate for at least one year in their rotations. When they began switching to Roundup Ready corn for defensive reasons, they continued at first to use non-glyphosate herbicides with it, retaining the resistance management benefit. However, eventually they switched over to glyphosate with RR corn, increasing selection pressure for glyphosate-resistant weeds.

While Baldwin does not elaborate, it was probably economics that drove this decision. When a farmer pays a hefty technology fee for an RR traited seed, it makes economic sense to make use of it through using inexpensive glyphosate, rather than mostly more expensive "conventional" herbicides. If they hadn't been forced for "defensive" reasons to buy more expensive Roundup Ready corn, they probably would have continued planting cheaper conventional corn, which entails using conventional herbicides, and provides a resistance-managing "break" from continual glyphosate use.

Baldwin sees the same thing happening with Clearfield rice.

> "Most weed scientists I know feel we are growing more Clearfield rice now than is sustainable over time – unless we get a breakthrough in new technology. As we

> continue to increase the acres, most likely we are shortening the life of the technology. ... If you plant every acre to Clearfield and continue to pound it with Newpath and Beyond, resistant barnyardgrass will be the most likely end result."

When adoption of these two HR crops – RR corn and Newpath rice – reached a certain tipping point, the crop-damaging drift that is a consistent feature of these HR technologies forced many other growers to unwillingly adopt them. This led to massive overreliance on the HR crop-associated herbicides, loss of the resistance management benefits provided by retaining a conventional crop in the rotation, and a spate of new herbicide-resistant weeds. The resistant weeds drive the demand for "new technology" in the form of a new herbicide or new herbicide-resistant crop – spurring yet another turn in the vicious spiral of increasing herbicide use and weed resistance. It's hard to imagine a more unsustainable technology than herbicide-resistant crop systems, at least as they are used in the real world, in the absence of regulation.

The only way to get off this pesticide treadmill is through integrated weed management that prioritizes non-chemical weed control measures. Unfortunately, mainstream American agriculture has been so thoroughly fixated on the chemical-only approach that most farmers, extension agents, and weed scientists have no clue where to begin. The silver lining in the HR weed epidemic may perhaps be that it is opening minds like that of Dr. Stanley Culpepper, weed scientist at the University of Georgia.

Culpepper is in the midst of a glyphosate-resistant pigweed epidemic that is rapidly making cotton-growing an impossible task in Georgia. In 2009, half of Georgia's one million acres of cotton had to be weeded by hand to remove this GR weed, at a cost of $11 million. Growers who until recently spent $25 per acre on weed control are now forced to spend $60 to $100 per acre. According to Culpepper: "We're talking survival, at least economically speaking, in some areas, because some growers aren't going to survive this."[91]

While Culpepper does not advocate giving up herbicides, he understands that the old approach of relying upon them exclusively is doomed to fail. Culpepper now recommends deep tillage to bury the resistant pigweed seed so that it will not sprout, which can reduce seed germination by up to 50%. He also recommends the planting of heavy cover crops like rye to provide a thick mat between crop rows that likewise reduces weed seed germination by as much as 50%. Together, the two techniques reduce the emergence of resistant pigweed that actually emerges, but up to 80%. The much reduced populations of weeds (resistant or not) that do emerge can then be managed with much lesser quantities of herbicides.

While Dr. Culpepper appears to be a recent convert to the virtues of cover cropping and other non-chemical modes of weed control, other scientists have been working to improve and encourage adoption of such practices for many years, mostly without recognition and

---

with far too little support from our pesticide-friendly U.S. Dept. of Agriculture. Dr. Adam Davis recently published a study showing the effectiveness of the "cover crop roller-crimper" for use in no-till soybean cultivation.[92] The roller-crimper is a heavy, flanged cylinder that is attached to a tractor and rolled over a cover crop like rye in the spring to kill it. The killed cover crop forms a heavy mat into which soybeans can be drilled, and which physically suppresses weed emergence, as discussed above. Some cover crops also exude allelopathic compounds into the soil that also inhibit the emergence of weeds.

Dr. Matt Liebman at Iowa State University has shown the great benefits to farmers from adopting more complex rotations involving three or more crops (including a winter cover crop or alfalfa), rather than the standard corn-soybean rotation.[93] In addition to decreasing use of (and expenditures on) synthetic nitrogen fertilizers by half to three-fourths, the more complex three- and four-year rotations reduced herbicide use by 76% and 82%, respectively, with weed suppression equivalent to the herbicide-intensive, conventional corn/soybean rotation, and yields that were equal or higher. These "low-external input" (LEI) systems were also more profitable than the conventional rotation, especially when considered in the absence of subsidies. Our perverted subsidy system, however, reduce the differences between the systems, and act as an impediment to adoption of such beneficial systems by American growers. A perhaps even more important factor, however, is the paucity of support to truly sustainable weed management systems such as this on the part of the U.S. Dept. of Agriculture, which like the major agrichemical-biotechnology firms is fixated on chemical-only approaches to weed control and farming in general.

We conclude by citing a very recent paper by Illinois agronomists, who are at ground zero of an extremely threatening outbreak of multiple herbicide-resistant tall waterhemp (*Amaranthus tuberculatus*). Patrick Tranel and colleagues have recently surveyed fields in Illinois and Missouri, and found a startingly high proportion of tall waterhemp populations to be resistant to glyphosate as well as one, two or in some cases even three additional herbicide modes of action.[94] Tall waterhemp is regarded as one of the most threatening weeds to soybean and to a lesser extent corn cultivation in the Midwest, particularly in Illinois and Missouri. Waterhemp populations with individuals resistant to only one herbicide mode of action are practically a thing of the past. The majority of populations now contain multiple-herbicide resistant plants. Tranel and colleagues state that:

> "Herbicide resistance in A. tuberculatus appears to be on the threshold of becoming an unmanageable problem in soybean."

They further warn that these weed populations will likely evolve resistance to glufosinate, one of the few postemergence herbicidal options available to growers afflicted with these multiple herbicide-resistant populations. This would occur with widespread deployment

of glufosinate-resistant, LibertyLink soybeans, which at present are very little grown. If this happens, they warn, and no new soybean postemergence herbicides are commercialized:

> "Soybean production may not be practical in many Midwest U.S. fields."

The inability to economically cultivate the second most widely grown crop in America, a mainstay of Midwestern agriculture, would represent a huge cost imposed by unregulated use of HR crop systems on American farmers and U.S. agriculture as a whole. Clearly, USDA and land grant university agronomists must begin devoting serious attention to the sorts of sustainable, integrated weed control practices described above, which make non-chemical approaches a priority, and deemphasize the use of herbicides.

October 15, 2010

Mr. Jay Vroom
President and CEO
CropLife America
1156 15th St. NW
Washington, DC 20005

Dear Mr. Vroom:

In connection with the September 30, 2010 hearing of the Domestic Policy Subcommittee, entitled, "Are "Superweeds" an Outgrowth of USDA Biotech Policy? (Part II)", I hereby request that you provide answers in writing to the following questions for the hearing record.

1. Does the industry believe USDA has authority under the Plant Protection Act (codified at 7 U.S.C. § 7701 *et. seq.*) and its regulations to regulate GE crops so as to prevent pesticide-resistant pests (including herbicide-resistant weeds)?
2. Does the industry believe that U.S.E.P.A. has that authority under a different statute?
3. Can the industry point to any purely voluntary stewardship practices that have successfully prevented or contained the spread of glyphosate resistance in weeds on a broad basis involving many individual farmers?
4. What regulatory schemes are supported by the industry that would prevent harm to horticultural crops and landscapes growing in proximity to soybean fields, if Dicamba-resistant soy is deregulated by USDA?
5. What is the extent of glyphosate-resistance in weeds outside of the United States? Please provide a country-by-country assessment, in tabular form, of glyphosate-resistant weeds, in terms of glypohsate-resistant species by name and date of discovery, estimated number of acres of infestation, and date of commercialization of Roundup-Ready corn, soy or cotton (as is applicable).

Ranking member Jordan submits the following additional questions:

1. Do you think that introducing multiple modes of action that control weeds in different ways and appropriate herbicide management techniques can help address the challenge of herbicide-resistant weeds?

2. How quickly will the issue of herbicide-resistant weeds worsen in the absence of new technologies entering the marketplace?

The Oversight and Government Reform Committee is the principal oversight committee in the House of Representatives and has broad oversight jurisdiction as set forth in House Rule X.

We request that you provide written answers to these questions as soon as possible, but in no case later than **5:00 p.m. on October 30, 2010**.

If you have any questions regarding this request, please contact Jaron Bourke, Staff Director at (202) 225-6427.

Sincerely,

Dennis J. Kucinich
Chairman
Domestic Policy Subcommittee

cc: Jim Jordan
Ranking Minority Member

CropLife ☆AMERICA☆

November 5, 2010

The Honorable Dennis J. Kucinich
Chairman, Domestic Policy Subcommittee
Committee on Oversight and Government Reform
U. S. House of Representatives

Dear Congressman Kucinich:

CropLife America (CLA) thanks you for the opportunity to provide testimony on September 30, 2010 during the Domestic Policy Subcommittee hearing entitled, "Are "Superweeds" an Outgrowth of USDA Biotech Policy? (Part II)". CropLife America is the leading trade association representing the U.S. crop protection industry and our members supply virtually all of the crop protection products used by American farmers. CropLife America's member companies, and members of our counterpart association at RISE[1], proudly discover, manufacture, register and distribute crop protection products for American agriculture, and specialty use products outside of agriculture, such as those used for public health protection and commercial pest management inside of homes and commercial buildings.

During the first hearing, CLA emphasized three major points that are essential to understanding weed resistance to herbicides and the need for best management practices to minimize the potential for resistance development:

- Herbicide resistance occurs naturally, and best management practices need to be applied at the farm level in ensuring that resistance development is avoided or delayed. Resistance is a scientific reality in virtually all biological systems.
- The market can and will facilitate the development and adoption of solutions to combat weed resistance in crop production to ensure production of safe, affordable, and plentiful food.
- The current regulatory framework for herbicides is robust.

As requested, below are our responses to questions for the hearing record.

1. **Does the industry believe USDA has authority under the Plant Protection Act (codified at 7 U.S.C. § 7701 *et. seq.*) and its regulations to regulate GE crops so as to prevent pesticide-resistant pests (including herbicide-resistant weeds)?**

Recognizing that CLA does not represent the crop protection industry on the specific matter of regulations for genetically engineered (GE) crops, CLA would consult the affected agencies for their interpretation of the laws granting them specific authorities. However, USDA has the authority under Part 340 of the Plant Protection Act to regulate

[1] Responsible Industry for a Sound Environment (RISE) – www.pestfacts.org

the introduction (importation, interstate movement, or release into the environment) of GE crops. Unlike crops genetically engineered to produce Bt proteins to control insects, herbicide-tolerant (HT) crops do not control weeds or any other pests. In addition to examining potential risks to plant health under the Plant Protection Act, APHIS assesses the potential effects of its actions on the quality of the environment under the authority of the National Environmental Policy Act.

Regulation of the herbicides that accomplish weed control is under the jurisdiction of EPA (see next question.) USDA and EPA work cooperatively as necessary to identify, develop, and approve best management practices for avoiding and mitigating pest resistance to pesticides.

2. Does the industry believe that U.S.E.P.A. has that authority under a different statute?

Recognizing that CLA does not represent industry on regulations for GE crops, CLA would consult the affected agencies for their interpretation of the laws granting them specific authorities. However, the safe use of pesticidal substances is regulated by the Environmental Protection Agency (EPA). GE insect-resistant crops may contain an introduced pesticidal substance also known as a plant-incorporated protectant (PIP) that is subject to review by EPA. EPA's regulatory process for PIPs includes rigorous environmental assessment. As mentioned earlier, USDA and EPA work cooperatively as necessary to identify, develop, and approve best management practices for avoiding and mitigating pest resistance to pesticides.

The use of pesticides in the U.S. is regulated by EPA under the Federal Insecticide, Fungicide, & Rodenticide Act (FIFRA; codified at 7 USC §136 *et seq.*) and selected provisions of the Federal Food, Drug, & Cosmetic Act (FFDCA; codified at 21 USC §301 *et seq.*; specifically 21 USC §346a). Implementing regulations are published in 40 CFR Parts 150 to 189. This authority can and does extend to resistance mitigation strategies. EPA reviews, approves, and regulates every statement and instruction that goes on the label of every pesticide and herbicide product, according to these laws and regulations. This responsibility is taken very seriously by EPA and pesticide registrants. State regulators and enforcement personnel are EPA's close partners in seeing that pesticide products carry the correct, valid labels and that farmers use them correctly.

3. Can the industry point to any purely voluntary stewardship practices that have successfully prevented or contained the spread of glyphosate resistance in weeds on a broad basis involving many individual famers?

In Arkansas, extension, academic, and government personnel, together with grower organizations have developed a strong program for management of glyphosate-resistant weed populations, focusing on "zero tolerance." Education and outreach efforts are extensive, and industry is fully cooperating. Member companies represented by the Industry's Herbicide Resistance Action Committee (HRAC) and CropLife America have monitored and researched the herbicide resistance issue on a global basis for 20 years,

cooperating closely with academia and government authorities in developing and implementing resistance management strategies. HRAC has been very active in the recent developments concerning glyphosate-resistant weeds.

In Arkansas, farmers are strongly encouraged to closely monitor all fields, acre by acre, row by row, following all herbicide treatments including glyphosate. Any weeds escaping control are to be removed, by spot treatment with other herbicides, by hoe, or by hand, if necessary. Other herbicides must be used in combination with or in place of glyphosate to control the resistant weeds. Other crops may be grown in rotation in subsequent growing seasons to facilitate a diversity of weed control practices. Harvesting equipment should be cleaned carefully before it leaves a field where resistant weeds are known or suspected, to avoid spreading them to other fields. Registrants are offering financial incentives to convince growers to employ best management practices, including using a competitor's product, when necessary.

Such extensive efforts are an example of progress in the fight against glyphosate-resistant weeds in Arkansas. Similar efforts tailored to local needs are in practice and under development in other affected Southern states. States not yet affected are watching closely and learning the lessons that can be implemented to avert losses.

4. **What regulatory schemes are supported by the industry that would prevent harm to horticultural crops and landscapes growing in proximity to soybean fields, if Dicamba-resistant soy is deregulated by USDA?**

EPA evaluates the potential off-site movement of an herbicide when deciding whether to register a product for a particular use and will require label instructions designed to minimize off-site movement. EPA-registered herbicides have been used successfully in agriculture for decades and farmers have extensive experience in managing off-site movement by strict adherence to label instructions and the application of best management practice. Industry supports pesticide applicator efforts to minimize off-site movement by providing education and training resources, and continued research and development of technologies to further reduce such movement.

5. **What is the extent of glyphosate-resistance in weeds outside of the United States? Please provide a country-by-country assessment, in tabular form, of glyphosate-resistant weeds, in terms of glyphosate-resistant species by name and date of discovery, estimated number of acres of infestation, and date of commercialization of Roundup-Ready corn, soy or cotton (as is applicable).**

CropLife America does not have the information requested on the global status of glyphosate resistance. However, CLA supports efforts by HRAC to compile reports of herbicide resistance to all herbicides worldwide.

Additional questions from Ranking Member Jordan are addressed below:

1. **Do you think that introducing multiple modes of action that control weeds in different ways and appropriate herbicide management techniques can help address the challenge of herbicide-resistant weeds?**

Yes, use of best management practices in concert with herbicides that have different modes of action is a component of integrated pest management broadly supported by public and private sector scientists. Use of multiple modes of action will reduce the impact of herbicide-resistant weeds. To avoid or delay the onset of resistance, growers need to be aware of and adopt best management practices. Information regarding best management practices and integrated weed management is available from multiple reliable sources including websites sponsored by the Weed Science Society of America (WSSA) and HRAC.

2. **How quickly will the issue of herbicide-resistant weeds worsen in the absence of new technologies entering the marketplace?**

Using a diversity of weed management options is important for managing weed resistance. New technologies provide growers with more options that make is easier to implement effective weed management in all cropping systems across the U.S. Adoption of biotechnology has not caused the rapid onset of resistance in weed species; appropriate use of a diversity of technologies is fundamental for reducing the impact of resistance.

The market can and will adopt solutions to combat weed resistance in crop production to ensure production of safe, affordable and plentiful food. Farming is a long-term investment, and growers will adapt their operations to succeed. They need the flexibility to manage their farm operations for the current season and for the future. That flexibility requires access to the tools that enable them to take care of their business interests and sufficient latitude in terms of how and when they are used. Growers are in the best position to know their fields, the weeds growing in them, and how to best manage their farm inputs. Such knowledge will enable them to make the best decisions on what tools to use, including crop protection products and biotech crop seed, considering relevant economic factors and their future management plans.

Weed control options will continue to be developed. Crop protection is a competitive business. If a weakness in a particular weed control option emerges, there will be other new or existing technologies that will seek to fill that void. The market favors maximization of the tools currently available. The development of new herbicides is an involved and expensive process. To make that investment worthwhile requires that the useful life of a product be extended as long as possible with available means. Some recent marketing programs have included manufacturer rebates for use of competitive products in combination with the manufacturer's product, in order to stem the onset of resistance. This is one example of how the market addresses the issue.

Thank you for the opportunity to provide this information. If we can be of further assistance, please contact Beau Greenwood, Executive Vice President, Federal Affairs (bgreenwood@croplifeamerica.org).

Sincerely,

Jay J. Vroom
President and CEO

Dear Mr. Smith:

In connection with the September 30, 2010 hearing of the Domestic Policy Subcommittee, entitled, "Are "Superweeds" an Outgrowth of USDA Biotech Policy? (Part II)", Representative Jim Jordan, Ranking Member, requests that you provide answers in writing to the following questions for the hearing record.

1. You testified that your company and growers faced over $1 million in cropping losses from glyphosate drift. Can you describe specifically what caused those alleged losses?
2. What losses have your growers experienced as a result of dicamba drift and revolatilization?

The Oversight and Government Reform Committee is the principal oversight committee in the House of Representatives and has broad oversight jurisdiction as set forth in House Rule X.

We request that you provide written answers to these questions as soon as possible, but in no case later than **5:00 p.m. on October 30, 2010**.

If you have any questions regarding this request, please contact Jaron Bourke, Staff Director at (202) 225-6427.

Sincerely,

Dennis J. Kucinich
Chairman
Domestic Policy Subcommittee

Honorable Dennis J. Kucinich
Chairman
Domestic Policy Subcommittee
2157 Rayburn House Office Building
Washington, DC 20515-6143

Dear Chairman Kucinich,

Thank you for the opportunity to reply to questions concerning my recent testimony about the effects to the Midwestern tomato industry by the release of dicamba tolerant soybeans during the Part II hearing entitled, "Are Superweeds an Outgrowth of USDA Biotech Policy?"

Question #1 referred to my testimony asserting over $1 million in cropping losses from glyphosate drift. I have attached a spreadsheet outlining our exact crop losses from all forms of drift and volatization for the last four cropping seasons and the eventual outcome of the losses. As you will see, several are still in litigation which is the reasoning behind my comments and requests that the makers of dicamba and the registrants of dicamba tolerant soybeans to immediately be financially responsible for losses.

Question #2 asks about our actual experiences as a result of dicamba drift and revolatization. As you will notice from the spreadsheet, we have had only one dicamba volatility issue in the last four years and it occurred early enough in the growing cycle that the field could be replanted, so the large losses to us the processor of not having fruit available and big yield losses to the grower were mitigated to a great degree. However, as my testimony said, the use of dicamba in our area is nearly non-existent because of the potential losses to soybeans. The important point is that revolatization is a known characteristic of dicamba and when sensitive crops are present, damage will occur, and as listed, we have had an actual case even with very little actual exposure.

I would be more than pleased to answer any further questions or explain any other statements that may arise.

Sincerely,

Steve Smith
(sent electronically)

Red Gold Drift Loss Summary 1997-2010

Year	Grower	Loss Total	Cause of loss	settlement outcome
2007	Gelfius Farms	$ 18,934.00	Acetochlor	still in litigation
2008	Janssen Brothers Farms	$ 24,915.13	glyphosate	still in litigation
	Morrin Farms	$ 14,570.44	glylphosate	still in litigation
	Lievens Brothers Farms	$ 702,197.77	glyphosate	still in litigation
	Keesling Farms	$ 18,660.00	2,4 d	settled in full
	Triple S Smith Farms	$ 137,126.57	glyphosate	settled in full
	Daily Farms	$ 63,085.82	glyphosate	settled at about 90%
	Associated Growers	$ 4,725.00	dicamba	no settlement, sprayer denied claim, able to replant
	Detling Farms	$ 3,306.09	glyphosate	settled in full
2009	Howell Farms	$ 40,951.82	glyphosate	settled in full
	Steve Busch	$ 15,907.25	glyphosate	settled in full
	King Farms	$ 34,370.71	glyphosate	settled in full *grower portion estimated
	Plank Farms	$ 13,990.29	glyphosate	settled in full
2010	Prible Farms	$ 50,000.00	glyphosate	estimated loss, awaiting settlement
		$ 1,142,740.89

October 15, 2010

Mr. Phil Miller
Vice President, Global Regulatory
Monsanto Company
800 North Lindbergh Blvd.
St. Louis, MO 63167

Dear Mr. Miller:

In connection with the September 30, 2010 hearing of the Domestic Policy Subcommittee, entitled, "Are "Superweeds" an Outgrowth of USDA Biotech Policy? (Part II)", I hereby request that you provide answers in writing to the following questions for the hearing record.

1. You say in your written testimony that genetically engineered crops increase farmer profits, yields and carbon sequestration. As you know, the scope of the hearing was limited to herbicide-resistant crops. Please provide the Subcommittee with all documents that provide a basis for those three claims as they would relate to herbicide-resistant crops.
2. At what point was glyphosate-resistance in weeds first predicted and when was it first documented by the Company or Company-funded scientists? Please provide all citations for published research.
3. Are voluntary stewardship measures sufficient to prevent and/or mitigate glyphosate resistance in weeds? Please provide specific examples of purely voluntary stewardship practices that have successfully prevented or contained the spread of glyphosate resistance in weeds on a broad basis involving many individual farmers.
4. Given that including in a rotation non-glyphosate-resistant crops can be important to preventing glyphosate resistance in weeds, what varieties of non-glyphosate-resistant corn, cotton and soy does Monsanto and its affiliated seed companies offer to farmers?
5. Concerning the development of other herbicide-resistant resistant crops, including dicamba-resistant soybeans, what is the scale of Monsanto Company's research and development efforts to create other herbicide resistant crops?

6. Is Dicamba-resistance in weeds currently predicted by the Company or any Company-funded scientist in fields that will be growing Dicamba-resistant soybeans?
7. What lessons has the Company taken from glyphosate-resistance in weeds to apply to preventing or mitigating Dicamba resistance in weeds?
8. Does the Company believe that voluntary stewardship measures alone will be sufficient to prevent Dicamba resistance in weeds from occuring after Dicamba-resistant crops are planted?
9. In light of producer concerns for horticultural crops once Dicamba gains more widespread use after Dicamba-resistant crops are deregulated, what measures does the Company believe will prevent producer concerns from being realized?
10. In the hearing, we received testimony expressing concern that Dicamba/Roundup tolerant soybean will cause collateral injury to fruit and vegetable farmers and backyard gardeners. In fact, your testimony acknowledges that concern. In the event that such injury should materialize, who will be liable for the economic costs of the affected farmers? Will it be Monsanto or another party?
11. Concerning USDA regulation of biotech crops: Specifically, does the Company believe USDA has authority under the Plant Protection Act (codified at 7 U.S.C. § 7701 *et. seq.*) and its regulations to regulate GE crops so as to prevent herbicide-resistant weeds? Has the Company ever taken a position on that question? Please provide all documents expressing a legal opinion on that question.

Ranking member Jordan submits the following additional questions:

1. Who is responsible for addressing the issue of herbicide-resistant weeds?

2. The advertorial you received during the September 30, 2010 hearing contained a recommendation for growers to use two modes of action. Can you explain what that means?

The Oversight and Government Reform Committee is the principal oversight committee in the House of Representatives and has broad oversight jurisdiction as set forth in House Rule X.

We request that you provide written answers to these questions as soon as possible, but in no case later than **5:00 p.m. on October 30, 2010**.

If you have any questions regarding this request, please contact Jaron Bourke, Staff Director at (202) 225-6427.

Sincerely,

Dennis J. Kucinich
Chairman
Domestic Policy Subcommittee

The Hon. Dennis J. Kucinich
Chairman
Domestic Policy Subcommittee
House Committee on Oversight and Government Reform

Dear Chairman Kucinich:

On behalf of Monsanto, thank you for the opportunity to respond to questions submitted for the record following your hearing on September 30th. I hope the information provided assists the Subcommittee in its analysis of the issues surrounding biotechnology regulatory policy and the development of herbicide resistant weeds.

This is an important topic for not only our industry but also for our Nation and farmers around the world as we seek to feed an ever-growing global population.

Please do not hesitate to contact me if I can be of further assistance.

Sincerely,

Philip Miller
Vice President, Regulatory
Monsanto Company

Cc: The Hon. Jim Jordan, Ranking Member

QUESTIONS FROM CHAIRMAN KUCINICH

1. **You say in your written testimony that genetically engineered crops increase farmer profits, yields and carbon sequestration. As you know, the scope of the hearing was limited to herbicide-resistant crops. Please provide the Subcommittee with all documents that provide a basis for those three claims as they would relate to herbicide-resistant crops.**

   Provided below is a list of publications that establish that GE crops increase farmer profits, yields and carbon sequestration. Because the benefits of herbicide-tolerant and insect-resistant crops are additive when these traits are combined in the same crop, researchers often assess the cumulative benefits of these traits. The list of publications provided includes analysis of the benefits of herbicide-tolerant and insect-resistant crops separately and combined. In a recent comprehensive analysis, the National Research Council Committee on the Impact of Biotechnology on Farm-Level Economics and Sustainability concluded, "In general, the committee finds that genetic-engineering technology has produced substantial net environmental and economic benefits to U.S. farmers compared with non-GE crops in conventional agriculture."

2. **At what point was glyphosate-resistance in weeds first predicted and when was it first documented by the Company or Company-funded scientists? Please provide all citations for published research.**

   Weeds and other organisms can adapt to their environments. The development of weed populations resistant to any herbicide is in theory an eventual outcome of its use and is influenced by inherent characteristics of the chemistry and application of agricultural practices. In that sense, from a scientific perspective, the eventual discovery of weed populations resistant to any herbicide including glyphosate can be theoretically anticipated based on the principles of population biology and selection; however it is not possible to anticipate with any specificity or probability when, under what circumstances, in what geographies or in what species resistance will occur.

   The first known and documented case of glyphosate resistance was a population of weeds in Australia discovered in 1996 in conventional (non-biotech) cropping systems (reference www.weedscience.org) after 15 years of successful glyphosate use in those systems. (Attached is the original publication). Monsanto did not "predict" this development. Upon discovery of this population that was potentially resistant, Monsanto collaborated with the public sector scientists who made the discovery. Attached is a Monsanto authored publication using seed from this first glyphosate resistant population, regarding efforts to understand the mechanism of resistance.

   Powles, S. B., D.F. Lorraine-Colwill, J.J. Dellow, and C. Preston. 1998. Evolved resistance to glyphosate in rigid ryegrass (Lolium rigidum) in australis. Weed Science, 46: 604-607.

   Feng, Paul C.C., James E. Pratley and Josephe A Bohn. 1999. Reistance to glyphosate in Lolium rgidum. II. Uptake, translocation and metabolism. Weed Sceince, 47: 412-415.

3. **Are voluntary stewardship measures sufficient to prevent and/or mitigate glyphosate resistance in weeds? Please provide specific examples of purely voluntary stewardship practices that have successfully prevented or contained the spread of glyphosate resistance in weeds on a broad basis involving many individual farmers.**

   To be clear, neither the scientific community nor any other community of experts can identify any

practice or product that will prevent resistance to any herbicide. However, the conscientious implementation of agronomic best management practices (BMPs) can delay or mitigate the development of resistance. Such BMPs can and should be established in market-driven voluntary stewardship programs.

Specific to herbicide tolerant crops, market research, as described in the following reference, indicates that growers are increasingly adopting best management practices to manage weed resistance. These practices are being implemented voluntarily by growers. As an example, in the 2007 market research study approximately 50 % of Roundup Read corn growers use other herbicides in addition to glyphosate. More recent market research indicates that the percentage of RR corn growers using other herbicides has increased significantly in 2010.

Frisvold, G. B., T. M. Hurley, and P.D. Mitchell. 2009. Adoption of Best management Practices to control Weed Resistance by Corn, Cotton, and Soybean Growers. AgBioForun, 12(3&4): 370-381.

4. **Given that including in a rotation non-glyphosate-resistant crops can be important to preventing glyphosate resistance in weeds, what varieties of non-glyphosate-resistant corn, cotton and soy does Monsanto and its affiliated seed companies offer to farmers?**

As previously mentioned, neither the scientific community nor any other community of experts can identify any practice or product that will prevent resistance to any herbicide. However, the conscientious implementation of agronomic best management practices (BMPs) can delay or mitigate the development of resistance. Such BMPs can and should be established in market-driven voluntary stewardship programs.

Best practices for managing weed resistance involve the use of a diversified weed management program that can include the use of multiple herbicide modes of action in mixtures, sequences or in rotation with or without the use of tillage and cultural practices such as crop rotation. Importantly, it is not the trait present in the crop but rather the herbicide(s) used in the system that provides the diversity of weed management practices that are important to minimize the chance of the development of resistant populations. Using herbicide mixtures and sequences even if repeated over multiple years can be more effective than rotating herbicides across years as highlighted in the following research papers. Thus, rotating to non-transgenic or transgenic non-glyphosate-tolerant crops is not critical for implementing a successful, diversified weed management program.

To address your question regarding non-glyphosate tolerant varieties, Monsanto commercially offers 44 non-glyphosate tolerant corn hybrids, seven cotton varieties and seven soybean varieties. Non-glyphosate tolerant hybrids and varieties are also offered by other seed companies.

Beckie, H.J. and Xavier Reboud. 2009. Selecting for Weed Resistance: Herbicide Rotation and Mixture. Weed Technology 23:363-370.

Diggle, A.J., P.B. Neve, and F.P. Smith. 2003. Herbicides used in combination can reduce the probability of herbicide resistance in finite weed populations. Weed Research 43: 371-382.

Maxwell B.D., M.L. Roush and S.R. Radosevich. 1990. Predicting the evolution and dynamics of herbicide resistance in weed populations. Weed Technology 4, 2-13.

5. **Concerning the development of other herbicide-resistant resistant (sic) crops, including dicamba-resistant soybeans, what is the scale of Monsanto Company's research and development efforts to create other herbicide resistant crops?**

   Monsanto's research and development pipeline includes the following projects: dicamba-glufosinate tolerant cotton, dicamba tolerant soybeans, dicamba-glufosinate tolerant corn, and FOPS tolerant corn.

6. **Is Dicamba-resistance in weeds currently predicted by the Company or any Company funded scientist in fields that will be growing Dicamba-resistant soybeans?**

   Weeds and other organisms can adapt to their environments. The development of weed populations resistant to any herbicide is in theory an eventual outcome of its use and is influenced by inherent characteristics of the chemistry and application of agricultural practices. In that sense, from a scientific perspective, the eventual discovery of weed populations resistant to any herbicide including glyphosate can be theoretically anticipated based on the principles of population biology and selection; however it is not possible to anticipate with any specificity or probability when, under what circumstances, in what geographies or in what species resistance will occur.

   To date there are two species with known resistance to dicamba in the U.S. after over 40 years of use; kochia (Kochia scoparia) and prickly lettuce (Lactuca serriola) (www weedscience.org). The use of dicamba in dicamba tolerant (DT) soybeans is not expected to result in an increase in resistant populations of species known to be dicamba resistant nor to increase the total number of dicamba resistant species. In DT soybeans, dicamba will predominantly be used in combination with other herbicides with different modes of action, principally glyphosate, but also with other soil-active herbicides (Johnson et al. 2010). The presence of multiple herbicides in the weed management system greatly diminishes the chance that weed resistance will occur as noted in the references listed for question 4, above.

   Johnson, B., Young, B., Matthews, J., Marquardt, P., Slack, C., Bradley, K., York, A., Culpepper, S., Hager, A., Al-Khatib, K., Steckel, L., Moechnig, M., Loux, M., Bernards, M., and Smeda, R. 2010. Weed control in dicamba-resistant soybeans. Online. Crop Management doi:10.1094/CM-2010-0920-01-RS.

7. **What lessons has the Company taken from glyphosate-resistance in weeds to apply to preventing or mitigating Dicamba resistance in weeds?**

   Neither the scientific community nor any other community of experts can identify any practice or product that will prevent resistance to any herbicide. However, the conscientious implementation of agronomic best management practices (BMPs) can delay or mitigate the development of resistance. Such BMPs can and should be established in market-driven voluntary stewardship programs.

   We and other scientists have learned that where diversity in weed management systems is maintained, the use of glyphosate (and other herbicides) for weed control can be sustained (Powles, 2008). A diverse weed management program will be implemented for dicamba-tolerant crop systems. As noted above in question 6, use of dicamba in dicamba tolerant (DT) soybeans will predominantly be used in combination with other herbicides with different modes of action,

principally glyphosate, but also with other soil-active herbicides (Johnson et al. 2010). In addition, farmer recommendations will be in place for surveillance and the early identification of dicamba resistance, should it occur, and for ways to manage the occurrence and to limit the spread of potential dicamba-resistant weeds in soybeans and crops rotated with soybeans.

Powles, Stephen B. 2008. Evolution in Action: glyphosate-resistant weeds threaten world crops. Outlooks on Pest Management, December 2008.

8. **Does the Company believe that voluntary stewardship measures alone will be sufficient to prevent Dicamba resistance in weeds from occurring after Dicamba-resistant crops are planted?**

   Yes, however, and again to be clear, neither the scientific community nor any other community of experts can identify any practice or product that will prevent resistance to any herbicide. However, the conscientious implementation of agronomic best management practices (BMPs) can delay or mitigate the development of resistance. Such BMPs can and should be established in market-driven voluntary stewardship programs.

   As noted in the answer to question 3, voluntary stewardship measures have been effective for managing weed resistance in agriculture and will be effective for managing weed resistance in dicamba-tolerant crop systems. As noted above in questions 6-7, in DT soybeans, dicamba will predominantly be used in combination with other herbicides with different modes of action, principally glyphosate, but also with other soil-active herbicides (Johnson et al. 2010). Thus the use of dicamba in dicamba tolerant (DT) soybeans is not expected to result in an increase in resistant populations of species known to be dicamba resistant nor to increase the number of dicamba resistant species. The presence of multiple herbicides in the weed management system greatly diminishes the chance that weed resistance to dicamba will occur.

9. **In light of producer concerns for horticultural crops once Dicamba gains more widespread use after Dicamba-resistant crops are deregulated, what measures does the Company believe will prevent producer concerns from being realized?**

   The potential off-site movement of herbicides is not new or unique to dicamba-tolerant crops. The EPA regulates the use of herbicides, including off-site movement. The EPA-approved label will include provisions designed to minimize drift. Farmers are required to follow herbicide labels and are aware of the importance of following BMPs to minimize off-target movement of herbicides.

   Monsanto is working with multiple stakeholders, including soybean growers as well as growers of crops that may be grown nearby, to design appropriate stewardship measures to address the potential off-site movement of dicamba when used with dicamba-tolerant crops. We are also working with other companies to develop improved dicamba formulations that reduce the potential for off-site movement.

10. **In the hearing, we received testimony expressing concern that Dicamba/Roundup tolerant soybean will cause collateral injury to fruit and vegetable farmers and backyard gardeners. In fact, your testimony acknowledges that concern. In the event that such injury should materialize, who will be liable for the economic costs of the affected farmers? Will it be Monsanto or another party?**

To clarify, it is the application of herbicides (regulated by the EPA), not the soybeans, that has raised the concern regarding potential off-site movement and injury to neighboring crops. The soybeans have no characteristics that would result in injury of any kind, including to farmers or gardeners. Liability for economic costs of persons affected by offsite movement from the application of pesticides depends on the facts of the situation and the applicable state law. To the extent offsite movement results from the use of a pesticide in a manner that is not in accordance with the product's EPA-approved label, such use would be a violation of federal law. EPA's registration of a pesticide is a determination that when used in accordance with label directions, the pesticide will cause no unreasonable adverse effects on the environment, a concept comparable to the analysis under NEPA.

11. **Concerning USDA regulation of biotech crops: Specifically, does the Company believe USDA has authority under the Plant Protection Act (codified at 7 U.S.C. 7701 et. seq.) and its regulations to regulate GE crops so as to prevent herbicide-resistant weeds? Has the Company ever taken a position on that question? Please provide all documents expressing a legal opinion on that question.**

No.

As Dr. Miller provided in his written statement, weed resistance is an herbicide issue, not a biotech crop issue, and is dependent on how herbicides are used. Under the Federal Insecticide, Fungicide and Rodenticide Act (FIFRA) and the Federal Government's Coordinated Framework for regulating biotechnology-derived products, EPA is the agency charged with analyzing the potential environmental impacts from the use of herbicides and other pesticides. The EPA's determinations are the functional equivalent of a NEPA analysis.

In complying with the National Environmental Policy Act (NEPA), USDA evaluates potential impacts to the human environment related to its decision to deregulate a biotech crop. The use of herbicides in conjunction with an herbicide-tolerant crop, and any associated impact on the potential development of weed resistance, is considered by USDA as part of its NEPA evaluation. USDA does not, however, have the authority to regulate herbicides or weed resistance to herbicides under the Plant Protection Act, which regulates plant pests and noxious weeds.

The Company's position on this question is aligned with the industry as expressed by BIO (the Biotechnology Industry Organization) and CLA (CropLife America). The opinion of Monsanto in-house counsel is reflected in these responses.

QUESTIONS FROM RANKING MEMBER JORDAN

1. **Who is responsible for addressing the issue of herbicide-resistant weeds?**

There is not just one reason why resistance develops, nor is there just one way to best manage it. Monsanto has a shared responsibility with farmers, university researchers, extension scientists and others in industry to provide the best possible advice, options and recommendations for how to

proactively and reactively manage resistance. The U.S. EPA regulates use of herbicides and its regulatory position on resistance is set forth in PR Notice 2001-5. Industry, the public sector and farmers also have the responsibility to monitor for resistance and to provide early identification of herbicide resistant weeds for farmers. The farmer and/or land owner ultimately decides what weed management practices are best and most appropriate for use on his crops. Green and Owen, 2010, provide an overview of key concepts and management programs that need to be considered in herbicide resistant crops to ensure sustainability of the herbicides used in these crops.

Green, J.M. and M.D.K. Owen. 2010. Herbicide-resistant crops: utilities and limitation for herbicide-resistant weed management. Online: J. Agric. Food Chem. Doi:10.102/jf101286h.

2. **The advertorial you received during the September 30, 2010 hearing contained a recommendation for growers to use two modes of action. Can you explain what that means?**

Each herbicide is defined in large part by its mode of action for controlling weeds. This provides information about what plant mechanisms are disrupted when the herbicide is sprayed on a weed. The mechanism of weed resistance and the associated naturally occurring genes that can confer resistance to a herbicide is often related to the mode of action of the herbicide. Estimates of the frequency of resistance genes within weed populations differ by herbicide but are typically very low for weed populations that remain susceptible to the herbicides. When two herbicides, with different modes of action, both effective for controlling a weed are used in combination, the likelihood that herbicide resistant genes for both herbicides occur together in the same plant is very low. From a management standpoint, the use of mixtures of two or more herbicides with different modes of action is predicted by model simulations to delay resistance much longer than the use of either herbicide alone or by rotating herbicides in successive crops. The principle of using multiple modes of action is also a basic component of resistance management of insects and fungi to insecticides and fungicides. Global Impact of Biotech Crops: Environmental Effects, 1996-2008

Graham Brookes and Peter Barfoot
PG Economics Ltd, Dorchester, UK

This article updates the assessment of the impact commercialized agricultural biotechnology is having on global agriculture from an environmental perspective. It focuses on the impact of changes in pesticide use and greenhouse gas emissions arising from the use of biotech crops. The technology has reduced pesticide spraying by 352 million kg (-8.4%) and, as a result, decreased the environmental impact associated with herbicide and insecticide use on these crops (as measured by the indicator the environmental impact quotient) by 16.3%. The technology has also significantly reduced the release of greenhouse gas emissions from this cropping area, which, in 2008, was equivalent to removing 6.9 million cars from the roads.

Key words: pesticide, active ingredient, environmental impact quotient, carbon sequestration, biotech crops, no tillage.

Introduction

This study presents the findings of research into the global environmental impact of biotech crops since their commercial introduction in 1996. It updates the findings of earlier analyses presented by the authors in *AgBioForum* 8(2&3), 9(3), and 11(1).[1]

The environmental impact analysis undertaken focuses on the impacts associated with changes in the amount of insecticides and herbicides applied to the biotech crops relative to conventionally grown alternatives. The analysis also examines the contribution of biotech crops towards reducing global greenhouse gas (GHG) emissions.

The analysis is mostly based on that of existing farm-level impact data from biotech crops. Primary data for impacts of commercial biotech cultivation on both pesticide usage and greenhouse gas emissions is, however, limited and is not available for every crop, in every year and for each country. Nevertheless, all identified, representative, previous research has been utilized. This has been used as the basis for the analysis presented, although, where relevant, primary analysis has been undertaken from base data.

Environmental Impacts from Insecticide and Herbicide Use Changes

Methodology

Assessment of the impact of biotech crops on insecticide and herbicide use requires comparisons of the respective weed- and pest-control measures used on biotech versus the 'conventional alternative' form of production. This presents a number of challenges relating to availability and representativeness. Comparison data ideally derives from farm-level surveys, which collect usage data on the different forms of production. A search of literature on biotech crop impact on insecticide or herbicide use at the trait, local, regional, or national level shows that the number of studies exploring these issues is limited (e.g., Pray, Huang, Hu, & Rozelle, 2002; Qaim & De Janvry, 2005; Qaim & Traxler, 2002) with even fewer (e.g., Brookes, 2003, 2005), providing data to the pesticide (active ingredient) level. Second, national-level pesticide usage survey data is also extremely limited; in fact, there are no published annual pesticide usage surveys conducted by national authorities in any of the countries currently growing biotech traits, and the only country in which pesticide usage data is collected (by private market-research companies) on an annual basis and which allows a comparison between biotech and conventional crops to be made is the United States.[2]

1. *Readers should note that some data presented in this article are not directly comparable with data presented in previous articles because the current article takes into account the availability of new data and analysis (including revisions to data for earlier years).*

2. *The US Department of Agriculture also conducts pesticide-usage surveys, but these are not conducted on an annual basis (e.g., the last time corn was included was 2005) and do not disaggregate usage by production type (biotech versus conventional).*

Unfortunately, even where national survey data is available on usage, the data on conventional crop usage may fail to be reasonably representative of what herbicides and insecticides might be expected to be used in the absence of biotechnology. When biotech traits dominate total production (e.g., for soybeans, corn, cotton, and canola in the United States since the early 2000s), the conventional cropping dataset used to identify pesticide use relates to a relatively small share of total crop area and therefore is likely to underestimate what usage would probably be in the absence of biotechnology. The reasons why this conventional cropping dataset is unrepresentative of the levels of pesticide use that might reasonably be expected to be used in the absence of biotechnology include the following.

- While the levels of pest and weed problems/damage vary by year, region, and within region, farmers who continue to farm conventionally are often those with relatively low levels of pest or weed problems, and hence see little, if any, economic benefit from using the biotech traits targeted at these agronomic problems. Their pesticide usage levels therefore tend to be below the levels that would reasonably be expected to be used to control these weeds and pests on an average farm. A good example to illustrate this relates to the US cotton crop where, for example, in 2008, nearly half of the conventional cotton crop was located in Texas. Here, levels of bollworm pests (the main target of biotech insect-resistant cotton) tend to be consistently low, and cotton farming systems are traditionally of an extensive, low input nature (e.g., the average cotton yield in Texas was about 82% of the US average in 2008).
- Some of the farms continuing to use conventional (non-biotech) seed traditionally use extensive, low-intensity production methods (including organic) in which limited (below average) use of pesticides is a feature (see, for example, the Texas cotton example above). The usage pattern of this subset of growers is therefore likely to understate usage for the majority of farmers if all crops were conventional.
- Many of the farmers using biotech traits have experienced improvements in pest and weed control from using this technology relative to the conventional control methods previously used. If these farmers were to now switch back to using conventional techniques—based wholly on pesticides—it is likely that most would wish to maintain the levels of pest/weed control delivered with use of the biotech traits and therefore would use higher levels of pesticide than they did in the pre-biotech crop days.

To overcome these problems in the analysis of pesticide use changes arising from the adoption of biotech crops (i.e., where biotech traits account for the majority of total plantings), presented in this article,[3] actual recorded usage levels for the biotech crops are used (based on survey data), with the conventional alternative (counterfactual situation) identified based on opinion from extension advisors and industry specialists as to what farmers might reasonably be expected to use in terms of crop protection practices and usage levels of pesticide.[4] This methodology has been used by others, for example Johnson and Strom (2007). Details of how this methodology has been applied to the 2008 calculations, sources used for each trait/country combination examined and examples of typical conventional versus biotech pesticide applications are provided in Appendices A and B.

The most common way in which changes in pesticide use with biotech crops has been presented in the literature has been in terms of the volume (quantity) of pesticide applied. While comparisons of total pesticide volume used in biotech and conventional crop production systems are a useful indicator of associated environmental impacts, amount of active ingredient used is an imperfect measure because it does not account for differences in the specific pest-control programs used in biotech and conventional cropping systems. For example, different specific products used in biotech versus conventional crop systems, differences in the rate of pesticides used for efficacy, and differences in the environmental characteristics (mobility, persistence, etc.) are masked in general comparisons of total pesticide volumes used.

In this article, the pesticide-related environmental impact changes associated with biotech crop adoption

3. *Also see earlier work by the authors (Brookes & Barfoot, 2006, 2007, 2008, 2009b).*
4. *In other words, Brookes and Barfoot draw on the findings of work by various researchers at the National Center for Food and Agriculture Policy (Carpenter & Gianessi, 1999; Johnson & Strom, 2007; Sankula & Blumenthal, 2003, 2006; also see http://www.ncfap.org). This work consults with in excess of 50 extension advisors in almost all of the states growing corn, cotton, and soybeans and therefore provides a reasonably representative perspective on likely usage patterns.*

Table 1. Impact of changes in the use of herbicides and insecticides from growing biotech crops globally 1996-2008.

Trait	Change in volume of active ingredient used (million kg)	Change in field EIQ impact (in terms of million field EIQ/ha units)	% change in ai use on biotech crops	% change in environmental impact associated with herbicide & insecticide use on biotech crops	Area biotech trait 2008 (million ha)
GM HT soybeans	-50.45	-5,314.8	-3.0	-16.6	62.47
GM HT maize	-111.58	-2,724.2	-7.5	-8.5	22.40
GM HT canola	-13.74	-437.2	-17.6	-24.3	5.83
GM HT cotton	-6.29	-188.4	-3.4	-5.5	2.41
GM IR maize	-29.89	-1,007.0	-35.3	-29.4	36.04
GM IR cotton	-140.6	-6,555.7	-21.9	-24.8	13.20
GM HT sugar beet	+0.13	-0.46	+10	-2	0.26
Totals	**-352.42**	**-16,227.76**	**-8.4**	**-16.3**	**142.61**

are examined in terms of changes in the volume (amount) of active ingredient applied but supplemented by the use of an alternative indicator, developed at Cornell University in the 1990s: the environmental impact quotient (EIQ). The EIQ indicator, developed by Kovach, Petzoldt, and Degni, and Tette (1992) and updated annually, effectively integrates the various environmental impacts of individual pesticides into a single 'field value per hectare.' The EIQ value is multiplied by the amount of pesticide active ingredient (ai) used per hectare to produce a field EIQ value. For example, the EIQ rating for glyphosate is 15.33. By using this rating multiplied by the amount of glyphosate used per hectare (e.g., a hypothetical example of 1.1 kg applied per ha), the field EIQ value for glyphosate would be equivalent to 16.86/ha.

The EIQ indicator used is therefore a comparison of the field EIQ/ha for conventional versus biotech crop production systems, with the total environmental impact or load of each system, a direct function of respective field EIQ/ha values and the area planted to each type of production (biotech versus conventional). The use of environmental indicators is commonly used by researchers, and the EIQ indicator has been, for example, cited by Brimner, Gallivan, and Stephenson (2004)—in a study comparing the environmental impacts of biotech and conventional canola—and by Kleiter et al. (2005).

The EIQ indicator provides an improved assessment of the impact of biotech crops on the environment when compared to only examining changes in volume of active ingredient applied, because it draws on some of the key toxicity and environmental exposure data related to individual products, as applicable to impacts on farm workers, consumers, and ecology. Readers should, however, note that the EIQ is an indicator only and does not take into account all environmental issues and impacts. It is therefore not a comprehensive indicator. Detailed examples of the relevant amounts of active ingredient used and their associated field EIQ values for biotech versus conventional crops for the year 2008 are presented in Appendix B.

Results

Biotech traits have contributed to a significant reduction in the environmental impact associated with insecticide and herbicide use on the areas devoted to biotech crops (Table 1). Since 1996, the use of pesticides on the biotech crop area was reduced by 352 million kg of active ingredient (8.4% reduction), and the environmental impact associated with herbicide and insecticide use on these crops—as measured by the EIQ indicator—fell by 16.3%. In absolute terms, the largest environmental gain has been associated with the adoption of GM IR cotton and reflects the significant reduction in insecticide use that the technology has allowed, in what has traditionally been an intensive user of insecticides. The volume of herbicides used in biotech soybean crops also decreased by 50 million kg (1996-2008), a 3% reduction, while the overall environmental impact associated with herbicide use on these crops decreased by a significantly larger 16.6%. This highlights the switch in herbicides used with most GM HT crops to active ingredients with a more environmentally benign profile than the ones generally used on conventional crops.

Important environmental gains have also arisen in the maize and canola sectors. In the maize sector, herbicide and insecticide use decreased by 141.5 million kg and the associated environmental impact of pesticide use on this crop area decreased due to a combination of reduced insecticide use (29.4%) and a switch to more environmentally benign herbicides (8.5%). In the canola sector, farmers reduced herbicide use by 13.7 million kg (a 17.6% reduction) and the associated environmental

Table 2. Biotech crop environmental benefits from lower insecticide and herbicide use 1996-2008: Developing versus developed countries.

	Change in field EIQ impact (in terms of million field EIQ/ha units): Developed countries	Change in field EIQ impact (in terms of million field EIQ/ha units): Developing countries
GM HT soybeans	3,692.8	1,622.0
GM HT maize	2,674.9	49.3
GM HT cotton	153.5	34.9
GM HT canola	437.2	0
GM IR corn	983.8	23.2
GM IR cotton	443.3	6,112.4
GM HT sugar beet	0.46	0
Total	**8,385.96**	**7,841.8**

impact of herbicide use on this crop area fell by 24.3% due to a switch to more environmentally benign herbicides.

In terms of the division of the environmental benefits associated with less insecticide and herbicide use for farmers in developing countries relative to farmers in developed countries, Table 2 shows roughly a 50% split of the environmental benefits (1996-2008) in developed and developing countries. Three quarters of the environmental gains in developing countries have been from the use of GM IR cotton.

Impact on Greenhouse Gas Emissions

Methodology

The methodology used to assess impact on greenhouse gas emissions combines reviews of literature relating to changes in fuel and tillage systems and carbon emissions coupled with evidence from the development of relevant biotech crops and their impact on both fuel use and tillage systems. Reductions in the level of GHG emissions associated with the adoption of biotech crops is acknowledged in a wide body of literature (CTIC, 2002; Fabrizzi, Morónc, & García, 2003; Jasa, 2002; Johnson et al., 2005; Lazarus & Selley, 2005; Liebig et al., 2005; Reicosky, 1995; Robertson, Paul, & Harwood, 2000; West & Post, 2002). First, biotech crops contribute to a reduction in fuel use due to less frequent herbicide or insecticide applications and a reduction in the energy use in soil cultivation. For example, Lazarus and Selley (2005) estimated that one pesticide spray application uses 1.045 liters of fuel, which is equivalent to 2.87 kg/ha of carbon dioxide emissions. In this analysis, we used the conservative assumption that only GM IR crops reduced spray applications with the number of spray applications of herbicides remaining the same for conventional production systems.[5]

In addition, there has been a shift from conventional tillage to reduced/no till. This has had a marked impact on tractor fuel consumption due to energy-intensive cultivation methods being replaced with no/reduced tillage and herbicide-based weed control systems. The GM HT crop where this is most evident is GM HT soybeans. Here, adoption of the technology has made an important contribution to facilitating the adoption of reduced or no-tillage farming.[6] Before the introduction of GM HT soybean cultivars, no-tillage (NT) systems were practiced by some farmers using a number of herbicides and with varying degrees of success. The opportunity for growers to control weeds with a non-residual foliar herbicide as a "burndown" pre-seeding treatment followed by a post-emergent treatment when the soybean crop became established has made the NT systems more reliable, technically viable, and commercially attractive. These technical advantages combined with the cost advantages have contributed to the rapid adoption of GM HT cultivars and the near doubling of the NT soybean area in the United States (also more than a five-fold increase in Argentina). In both countries, GM HT soybeans are estimated to account for more than 95% of the NT soybean crop area in 2007/8.

Substantial growth in NT production systems have also occurred in Canada, where the NT canola area increased from 0.8 million ha to 2.6 million ha (equal to about half of the total canola area) between 1996 and 2005 (95% of the NT canola area is planted with GM HT cultivars). Similarly the area planted to NT in the US cotton crop increased from 0.2 million ha to 1 million ha over the same period (of which 86% is planted to GM HT cultivars) and has remained at this share of the total crop in 2007 and 2008.

The fuel savings resulting from changes in tillage systems used in this article are drawn from estimates from studies by Jasa (2002), CTIC (2002), and the University of Illinois (2006). The adoption of NT farming systems is estimated to reduce cultivation fuel usage by 32.3 liters/ha compared with traditional conventional

5. *Evidence from different countries varies, with some countries exhibiting on average no change and others showing a small net reduction in the number of spray runs.*
6. *See, for example, CTIC (2002) and American Soybean Association (2001).*

tillage (CT; which has an average usage of 43.7 liters/ha) and by 19.33 liters/ha compared with (the average of) reduced tillage (RT) cultivation methods (which has an average usage of 30.72 liters/ha). In turn, this results in reductions of carbon dioxide emissions of 88.81 kg/ha for NT relative to CT and 35.66 kg/ha for RT relative to CT.[7]

Secondly, the use of 'no-till' and 'reduced-till' farming systems that utilize less ploughing increase the amount of organic carbon in the form of crop residue that is stored or sequestered in the soil. This carbon sequestration reduces carbon dioxide emissions into the environment. Rates of carbon sequestration have been calculated for cropping systems using normal tillage and reduced tillage and these were incorporated in the analysis on how GM crop adoption has played an important facilitating role in increasing carbon sequestration, and ultimately, on reducing the release of carbon dioxide into the atmosphere. Of course, the amount of carbon sequestered varies by soil type, cropping system, and eco-region. In North America, the Intergovernmental Panel on Climate Change (IPCC, 2006) estimates that the conversion from conventional-tillage to no-tillage systems stores between 50 kg carbon/ha^{-1} yr and 1,300 kg carbon/ha^{-1} yr (average 300 kg carbon/ha^{-1} yr). In the analysis presented below, a conservative saving of 300 kg carbon/ha^{-1} yr was applied to all NT agriculture and 100 kg carbon/ha^{-1} yr was applied to RT agriculture. Where some countries aggregate their no- and reduced-till data (e.g., Argentina), the reduced-tillage saving value of 100 kg carbon/ha^{-1} yr was used. One kg of carbon sequestered is equivalent to 3.67 kg of carbon dioxide. These assumptions were applied to the reduced pesticide spray applications data on GM IR crops, derived from separate analysis and reviews of farm income literature impacts by the authors (see Brookes & Barfoot, 2009a) and the GM HT crop areas using no/reduced tillage (limited to the GM HT soybean crops in North and South America and GM HT canola crop in Canada).[8]

Results

Herbicide-tolerant Soybeans

The United States: Over the 1996-2008 period, the area of soybeans cultivated in the United States increased rapidly from 25.98 million ha to 30.21 million ha. Over the same period, the area planted using conventional tillage is estimated to have fallen by 21.3% (from 7.5 million ha to 5.9 million ha), while the area planted using NT has increased by 62.3% (from 7.7 million ha to 12.5 million ha).

The most rapid rate of adoption of the GM HT technology has been by growers using NT systems (GM HT cultivars accounting for an estimated 99% of total NT soybeans in 2008). This compares with conventional-tillage systems for soybeans, where GM HT cultivars account for about 79% of total conventional-tillage soybean plantings. The importance of GM HT soybeans in the adoption of a NT system has also been confirmed by an American Soybean Association study (ASA, 2001) of conservation tillage. This study found that the availability of GM HT soybeans has facilitated and encouraged farmers to implement reduced-tillage practices; a majority of growers surveyed indicated that GM HT soybean technology had been the factor of *greatest* influence in their adoption of RT practices.

Based on the soybean crop area planted by tillage system, type of seed planted (GM and conventional) and applying the fuel usage consumption rates referred to in the methodology section,[9] the total consumption of tractor fuel has increased by only 2.1% (15.9 million liters)—from 746.4 to 762.4 million liters (1996 to 2008)—while the area planted increased by 16.3%, some 4.3 million ha. Over the same period, the average fuel usage fell 12.2%—from 28.7 liters/ha to 25.2 liters/ha. A comparison of biotech versus conventional pro-

7. *Based on one-liter fuel results in a carbon dioxide saving of 2.75 kg/ha from Lazarus and Selly (2005).*

8. *Due to the likely small-scale impact and/or lack of tillage-specific data relating to GM HT maize and cotton crops (and the US GM HT canola crop), analysis of possible GHG emission reductions in these crops have not been included. The no/reduced-tillage areas to which these soil carbon reductions were applied were limited to the increase in the area planted to no/reduced tillage in each country since GM HT technology has been commercially available. In this way, the authors have tried to avoid attributing no/reduced-tillage soil carbon sequestration gains to GM HT technology on cropping areas that were using no/reduced-tillage cultivation techniques before GM HT technology became available. Also, the development of the no-tillage soybean crops have not been attributed to the plantings of GM HT crops in Brazil due to the rapid development of this production system before GM HT soybean technology was permitted in 2003.*

9. *Our estimates are based on the following average fuel consumption rates: NT 11.4 liter/ha, RT 30.73 liters/ha (the average of fuel consumption for chisel ploughing and disking) and conventional tillage 43.7 liters/ha.*

Table 3. US soybeans: Permanent reduction in tractor fuel consumption and CO_2 emissions 1996-2008.

2008	4,348.85	144.0

duction systems shows that in 2008, the average tillage fuel consumption on the biotech planted area was 24.3 liters/ha compared to 36.5 liters/ha for the conventional crop (primarily because of differences in the share of NT plantings).

The cumulative permanent reduction in tillage fuel use in US soybeans is summarized in Table 3. This amounted to a reduction in tillage fuel usage of 834.7 million liters, which equates to a reduction in carbon dioxide emission of 2,295.3 million kg.

Based on the crop area planted by tillage system and type of seed planted (biotech and conventional) and using estimates of the soil carbon sequestered by tillage system for corn and soybeans in continuous rotation (the NT system is assumed to store 300 kg of carbon/ha/year, the RT system assumed to *store* 100 kg carbon/ha/year, and the CT system assumed to *release* 100 kg carbon/ha/year),[10] our estimates of total soil carbon sequestered are (Table 4):

- an increase of 1,707.9 million kg carbon/year (from 2,641 million kg in 1996 to 4,349 million kg carbon/year in 2008 due to increases in both crop area planted and the NT soybean area);
- the average level of carbon sequestered per ha increased by 42.3 kg carbon/ha/year (from 101.7 to 144 kg carbon/ha/year).

Cumulatively, since 1996 the increase in soil carbon due to the increase in NT and RT in US soybean production systems has been 10,370 million kg of carbon which, in terms of carbon dioxide emission equates to a saving of 38,057 million kg of carbon dioxide that would otherwise have been released into the atmosphere (Table 5). This estimate does not, however, take into consideration the potential loss in carbon sequestration that arises when some farmers return to conventional

10. The actual rate of soil carbon sequestered by tillage system is, however dependent upon soil type, soil organic content, quantity, and type of crop residue, so these estimates are indicative averages.

Table 5. US soybeans: Potential additional soil carbon sequestration attributable to NT/RT systems (1996 to 2008).

tillage and therefore should be treated as a maximum potential rather than an achieved level.

Argentina: Since 1996, the area planted to soybeans in Argentina has increased by 188% (from 5.9 to 17 million ha). Over the same period, the area planted using NT and RT practices also increased by an estimated 672%, from 2.07 to 15.98 million ha, while the area planted using CT decreased 73%, from 3.8 to 1.02 million ha.

As in the United States, a key driver for the growth in NT soybean production has been the availability of GM HT soybean cultivars, which, in 2008, accounted for 97.8% of the total Argentine soybean area.

Between 1996 and 2008 total fuel consumption associated with soybean cultivation increased by an estimated 169.6 million liters (80.2%), from 211.6 to 381.2 million liters/year. However, during this period the average quantity of fuel used per ha fell 37.34% from 35.8 to 22.4 liters/ha, due predominantly to the widespread use of GM HT soybean cultivars and NT/RT systems. If the

Total			**11,927.7**	**43,775.07**

Assumption: NT = +150 kg carbon/ha/yr; CT = -100 kg carbon/ha/yr.

proportion of NT/RT soybeans in 2008 (applicable to the total 2008 area planted) had remained at the 1996 level, an additional 1,635.9 million liters of fuel would have been used. At this level of fuel usage, an additional 4,498.79 million kg of carbon dioxide would have otherwise been released into the atmosphere (Table 6).

Applying a conservative estimate of soil carbon retention of 150 kg/carbon/ha/yr for NT/RT soybean cropping in Argentina (tillage data in Argentina does not differentiate between NT and RT), a cumulative total of 11,927.8 million kg of carbon—which equates to a saving of 43,775.1 million kg of carbon dioxide—has been retained in the soil that would otherwise have been released into the atmosphere (Table 7).

Paraguay and Uruguay: NT/RT systems have also become important in soybean production in both Paraguay and Uruguay, where the majority of production in both countries are reported by industry sources to use NT/RT systems.

Using the findings and assumptions applied to Argentina (see above), the savings in fuel consumption for soybean production between 1996 and 2008 (associated with changes in NT/RT systems, the adoption of GM HT technology and comparing the proportion of NT/RT soybeans in 2008 relative to the 1996 level) has possibly amounted to 195.9 million liters. At this level of fuel saving, the reduction in the level of carbon dioxide released into the atmosphere has probably been 538.7 million kg. Applying the same rate of soil carbon retention for NT/RT soybeans as Argentina, the cumulative increase in soil carbon since 1996—due to the increase in NT/RT in Paraguay and Uruguay soybean production systems—has been 2,163.2 million kg of carbon. In terms of carbon dioxide emission, this equates to a saving of 7,938.94 million kg of carbon dioxide that may otherwise have been released into the atmosphere.

Herbicide-tolerant Canola

The analysis presented below relates to Canada only and does not include the US GM HT canola crop. This reflects the lack of information about the level of NT/RT in the US canola crop. Also, the area devoted to GM HT canola in the United States is relatively small by comparison to the corresponding area in Canada (0.39 million ha in the United States in 2008 compared to 5.4 million ha in Canada).

Since 1996 the cumulative permanent reduction in tillage fuel use in Canadian canola is estimated at 347.5 million liters, which equates to reduction in carbon dioxide emission of 955.39 million kg (Table 8).

In terms of the increase in soil carbon associated with the increase in NT and RT in Canadian canola production, the estimated values are summarized in Table 9. The cumulative increase in soil carbon equals 3,227 million kg of carbon, which in terms of carbon dioxide emission equates to a saving of 11,842 million kg of carbon dioxide that would otherwise have been released into the atmosphere.

Herbicide-tolerant Cotton and Maize

The contribution to reduced levels of carbon release arising from the adoption of GM HT maize and cotton is likely to have been marginal, and hence no assessments are presented. This conclusion is based on the following.

- Although the area of NT/RT cotton has increased significantly in countries such as the United States, it still only represented an estimated 21%[11] of the total cotton crop in 2007.
- As the soybean-maize rotation system is commonplace in the United States, the benefits of switching to a NT system have largely been examined above for soybeans.
- No significant changes to the average number of spray runs under a GM HT production system rel-

Note: Assumptions: 4 tractor passes per ha; 1.045 liters/ha of fuel per insecticide application.

ative to a conventional production system have been reported.

Insect-resistant Cotton

The cultivation of GM IR cotton has resulted in a significant reduction in the number of insecticide spray applications (e.g., Gianessi & Carpenter, 1999). During the period 1996 to 2008, the global cotton area planted with GM IR cultivars (excluding China and India)[12] has increased from 0.86 million ha to 3.94 million ha in 2006 before falling back to 2.41 million ha in 2008.[13] Based on a conservative estimate of four fewer insecticide sprays being required for the cultivation of GM IR cotton relative to conventional cotton and applying this to the global area (excluding China and India) of GM IR cotton over the period 1996-2008 suggests that there has been a reduction of 119.6 million ha of cotton being sprayed. The cumulative saving in tractor fuel consumption has been 124.99 million liters. This represents a permanent reduction in carbon dioxide emissions of 344 million kg (Table 10).

Insect-resistant Maize

No analysis of the possible contribution to reduced level of carbon sequestration from the adoption of GM IR maize (via fewer insecticide spray runs) and the adoption of corn rootworm (CRW) resistant maize is presented. This is because the impact of using these technologies on carbon sequestration is likely to have been small for the following reasons.

- In some countries (e.g., Argentina), insecticide use for the control of pests such as the corn borer has traditionally been negligible.
- Even in countries where insecticide use for the control of corn-boring pests has been practiced (e.g., the United States), the share of the total crop treated has been fairly low (under 10% of the crop) and varies by region and year according to pest pressure.
- Nominal application savings have occurred in relation to the adoption of GM CRW maize where more than 13.7 million ha were planted in 2008. The adoption of the GM CRW may become increasingly important with wider adoption of NT cultivation systems due to the potential increase in soil-borne pests.

12. These are excluded because all spraying in these two countries is assumed to be undertaken by hand.

13. This is in line with the general fall in total cotton plantings.

Table 11. Summary of carbon sequestration impact 1996-2008.

Crop/trait/country	Permanent fuel saving (million liters)	Potential additional carbon dioxide saving from fuel saving (million kg)	Potential additional carbon dioxide saving from soil carbon sequestration (million kg)

Argentina: GM HT soybeans	1,636	4,499	43,775
Other countries: GM HT soybeans	196	539	7,939
Canada: GM HT canola	347	955	11,842
Global GM IR cotton	125	344	0
Total	3,139	8,632	101,613

Note: Other countries: GM HT soybeans Paraguay and Uruguay (applying US carbon sequestration assumptions). Brazil not included because of NT/RT adoption largely in the absence of GM HT technology.

Discussion and Conclusions

The analysis of pesticide use changes arising from the adoption of biotech crops shows that there have been important environmental benefits, amounting to 352 million kg less pesticide use by growers (an 8.4% reduction in the amount of active ingredient applied). As weight of active ingredient applied is a fairly crude measure of environmental impact, the analysis considered impacts using an alternative (more rounded) measure, known as the EIQ. Based on this, the environmental benefits have been more significant at a 16.3% reduction in the environmental impact associated with insecticide and herbicide use on the global crop area planted to biotech traits (1996-2008). The most significant environmental benefits derived have been associated with the adoption of GM IR cotton, which has resulted in a substantial reduction in insecticide applications on cotton. There have also been important environmental gains associated with the adoption of GM HT technology, which has seen a switch to the use of more environmentally benign active ingredients.

The analysis also shows that biotechnology trait adoption has made important contributions to reducing GHG emissions associated with cropping agriculture, and a summary of the total carbon sequestration impact of GM crops is presented in Table 11. This shows that the permanent savings in carbon dioxide emissions (arising from reduced fuel use of 3,137 million liters of fuel) since 1996 have been about 8,632 million kg and the additional amount of soil carbon sequestered since 1996 has been equivalent to 101,613 million tonnes of carbon dioxide that has not been released into the global atmosphere.[14] The reader should, however, note that these soil carbon savings are based on saving arising from the rapid adoption of NT/RT farming systems in North and South America for which the availability of GM HT technology has been cited by many farmers as an important facilitator. GM HT technology has therefore probably been an important contributor to this increase in soil carbon sequestration but is not the only factor of influence. Other influences, such as the availability of relatively cheap generic glyphosate (the real price of glyphosate fell threefold between 1995 and 2000 once patent protection for the product expired), have also been important, as illustrated by the rapid adoption of NT/RT production systems in the Brazilian soybean sector, largely in the absence of the GM HT technology.[15] Cumulatively the amount of carbon sequestered may be higher than these estimates due to year-on-year benefits to soil quality; however, equally with only an estimated 15-25% of the crop area in continuous NT systems, it is likely that the total cumulative soil sequestration gains have been lower. Nevertheless, it is not possible to estimate cumulative soil sequestration gains that take into account reversions to conventional tillage because of the lack of detailed, disaggregated farm- and field-level tillage data for the

14. *These estimates are based on fairly conservative assumptions and therefore the true values could be higher. Also, some of the additional soil carbon sequestration gains from RT/NT systems may be lost if subsequent ploughing of the land occurs. Estimating the possible losses that may arise from subsequent ploughing would be complex and difficult to undertake. This factor should be taken into account when using the estimates presented in this section of the report.*

15. *The reader should note that the estimates of soil carbon sequestration savings presented do not include any for soybeans in Brazil because we have assumed that the increase in NT/RT area has not been primarily related to the availability of GM HT technology in Brazil.*

Table 12. Context of carbon sequestration impact 2008: Car equivalents.

Crop/trait/country	Permanent carbon dioxide savings arising from reduced fuel use (million kg of carbon dioxide)	Average family car equivalents removed from the road for a year from the permanent fuel savings	Potential additional soil carbon sequestration savings (million kg of carbon dioxide)	Average family car equivalents removed from the road for a year from the potential additional soil carbon sequestration
US: GM HT soybeans	290	129	4,691	2,085
Argentina: GM HT soybeans	624	277	6,290	2,795
Other countries: GM HT soybeans	82	37	1,214	539
Canada: GM HT canola	179	80	2,223	988
Global GM IR cotton	28	12	0	0
Total	1,205	534	14,417	6,408

Note: Assumption: An average family car produces 150 grams of carbon dioxide of km. A car does an average of 15,000 km/year and therefore produces 2,250 kg of carbon dioxide/year.

1996-2008 period. Consequently, the estimate provided above of 101,613 million tonnes of carbon dioxide not released into the atmosphere should be treated with caution and clearly represents a potential maximum rather than a realized level.

Further examining the context of the carbon sequestration benefits, Table 12 shows the carbon dioxide equivalent savings associated with planting of biotech crops for the latest year (2008) in terms of the number of car-use equivalents. This shows that in 2008, the permanent carbon dioxide savings from reduced fuel use was the equivalent of removing nearly 0.534 million cars from the road for a year, and the additional soil carbon sequestration gains were equivalent to removing nearly 6.4 million cars from the roads. In total, biotech crop-related carbon dioxide emission savings in 2008 were equal to the removal from the roads of nearly 6.9 million cars, equal to about 26% of all registered private cars in the United Kingdom.

The impacts identified in this article are, however, probably conservative, reflecting the limited availability of relevant data and conservative assumptions used. In addition, the analysis examines only a limited number of environmental indicators. As such, subsequent research of the environmental impact might usefully include additional environmental indicators such as impact on soil erosion.

Appendix A: Details of Methodology as Applied to 2008 Calculations of Environmental Impact Associated with Pesticide Use Changes

Table A1. GM IR corn (targeting corn-boring pests) 2008.

Country	Area of trait ('000 ha)	Maximum area treated for corn boring pests: Pre GM IR ('000 ha)	Average ai use GM crop (kg/ha)	Average ai use if conventional (kg/ha)	Average field EIQ/ ha GM crop	Average field EIQ/ha if conventional	Aggregate change in ai use ('000 kg)	Aggregate change in field EIQ/ha units
US	18,140	3,182	0.23	0.83	12.8	32.8	-1,909	-63.6
Canada	750	60.2	0.04	0.64	4.8	24.8	-36.12	-1.25
Argentina	1,150	0	0	0	0	0	0	0
Philippines	280	Very low - assumed zero	0	0	0	0	0	0
South Africa	1,668	1,768	0	0.094	0	3.42	-156.8	-5.71
Spain	79.3	36.3	0.36	1.32	0.9	26.9	-34.9	-0.94
Uruguay	110	Assumed to be zero: as Argentina	0	0	0	0	0	0
Brazil	1,450	Not known	Not known	Not known	Not known	Not known	None applied	None applied

Note: Brazil: *2008 was first year of use of GM IR corn technology. Insufficient data currently available to make an assessment.* Other countries: *Honduras and EU countries: Areas planted to GM IR corn under 10,000 ha in each country: not examined.*

Table A2. GM IR corn (targeting corn rootworm) 2008.

Country	Area of trait ('000 ha)	Maximum area treated for corn boring pests: Pre GM IR ('000 ha)	Average ai use GM crop (kg/ha)	Average ai use if conventional (kg/ha)	Average field EIQ/ha GM crop	Average field EIQ/ha if conventional	Aggregate change in ai use ('000 kg)	Aggregate change in field EIQ/ha units
US	13,689	9,543	0.234	0.45	12.8	20.43	-2,063	-72.8

Note: There are no Canadian-specific data available. Analysis has therefore not been included for the Canadian crop of 119,000 ha planted to seed containing GM IR traits targeted at corn rootworm pests.

Table A3. GM IR cotton 2008.

Country	Area of trait ('000 ha)	Average ai use GM crop (kg/ha)	Average ai use if conventional (kg/ha)	Average field EIQ/ha GM crop	Average field EIQ/ha if conventional	Aggregate change in ai use ('000 kg)	Aggregate change in field EIQ/ha units
US	1,930	0.92	1.06	29.1	38.0	-276.6	-17.1
China	3,828	1.84	2.80	83.22	127.96	-3,675	-171.3
Australia	121.2	2.2	11.0	39	220	-1,066.9	-21.94
Mexico	70	3.6	5.22	120.4	177.0	-113.5	-3.96
Argentina	213	0.64	1.15	21.0	53.0	-108.6	-6.82
India	6,973	1.06	1.86	34.43	70.07	-5,565.1	-248.5
Brazil	170	0.64	1.15	21.0	53.0	-86.7	-5.44

Note: Due to the widespread and regular nature of bollworm and budworm pest problems in cotton crops, GM IR areas planted are assumed to be equal to the area traditionally receiving some form of conventional insecticide treatment.
South Africa (7,700 ha), Burkino Faso (8,500 ha), and Columbia (28,000 ha) not included in analysis due to lack of data and small size of plantings relative to total area of trait.
Brazil: due to a lack of data, usage patterns from Argentina have been assumed.

Table A4. GM HT soybeans 2008.

Country	Area of trait ('000 ha)	Average ai use GM crop (kg/ha)	Average ai use if conventional (kg/ha)	Average field EIQ/ha GM crop	Average field EIQ/ha if conventional	Aggregate change in ai use ('000 kg)	Aggregate change in field EIQ/ha units
US	27,790	1.63	1.62	26.29	36.16	+277.9	-274.3
Canada	880	1.32	1.43	20.88	34.20	-96.8	-11.73
Argentina	16,830	2.68	2.53	41.38	43.64	+2,524	-38.05
Brazil	13,320	2.37	1.94	36.34	32.96	+5,705	+45.0
Paraguay	2,430	1.16	0.99	18.8	20.05	+413.1	-3.04
South Africa	184	1.89	1.556	28.97	32.08	+61.4	-0.57
Uruguay	569	2.68	2.53	41.38	43.64	+85.4	-1.29
Mexico	7.3	1.62	1.76	24.83	41.02	-1	-0.12
Bolivia	454	1.16	0.99	18.8	20.05	+77.11	-0.57

Note: Due to lack of country-specific data, usage patterns in Paraguay assumed for Bolivia and usage in Argentina assumed for Uruguay.

Table A5. GM HT corn 2008.

Country	Area of trait ('000 ha)	Average ai use GM crop (kg/ha)	Average ai use if conventional (kg/ha)	Average field EIQ/ha GM crop	Average field EIQ/ha if conventional	Aggregate change in ai use ('000 kg)	Aggregate change in field EIQ/ha units
US glyphosate tolerant	18,847	2.06	3.48	43.08	77.15	-26,802	-642.0
US glufosinate tolerant	1,203	2.04	3.48	44.76	77.15	-1.738	-39.0
Canada glyphosate tolerant	477	1.83	2.71	37.01	61.10	-418.9	-11.44
Canada glufosinate tolerant	136	1.64	2.71	36.01	61.01	-145.3	-3.41
Argentina	805	2.36	2.77	43.80	57.82	-330.0	-11.3
South Africa	646	2.754	3.103	46.17	65.87	-225.3	-12.7

Note: The Philippines is not included due to lack of data on weed-control methods and product use.

Table A6. GM HT cotton 2008.

Country	Area of trait ('000 ha)	Average ai use GM crop (kg/ha)	Average ai use if conventional (kg/ha)	Average field EIQ/ha GM crop	Average field EIQ/ha if conventional	Aggregate change in ai use ('000 kg)	Aggregate change in field EIQ/ha units
US	2,082.8	2.83	3.26	50.6	60.08	-896	-19.74
South Africa	11.0	1.80	1.81	27.59	31.86	-0.11	-0.05
Australia	122.5	4.0	6.29	67.28	113.50	-281.4	-5.66
Argentina	210	1.80	3.48	27.60	68.04	-358.7	-8.6

Note: Mexico is not included due to lack of data on herbicide use.

Table A7. GM HT canola 2008.

Country	Area of trait ('000 ha)	Average ai use GM crop (kg/ha)	Average ai use if conventional (kg/ha)	Average field EIQ/HA GM crop	Average field EIQ/ha if conventional	Aggregate change in ai use ('000 kg)	Aggregate change in field EIQ/ha units
US glyphosate tolerant	180.1	0.649	1.12	9.95	25.71	-84.8	-2.84
US glufosinate tolerant	200.1	0.383	1.12	7.78	25.71	-147.5	-3.59
Canada glyphosate tolerant	2,943	0.7	0.56	10.68	11.52	+403.2	-2.47
Canada glufosinate tolerant	2,681	0.35	0.56	7.07	11.52	-569.1	-11.93

Table A8. GM herbicide-tolerant sugar beet 2008.

Country	Area of trait ('000 ha)	Average ai use GM crop (kg/ha)	Average ai use if conventional (kg/ha)	Average field EIQ/ha GM crop	Average field EIQ/ha if conventional	Aggregate change in ai use ('000 kg)	Aggregate change in field EIQ/ha units
US	258	1.90	1.40	29.13	30.89	+129	-0.45

Appendix B: Examples of EIQ Calculations

Table B1. Estimated typical herbicide regimes for conventional reduced/no till soybean production systems that will provide an equal level of weed control to the GM HT system in Argentina 2008.

	Active ingredient	Field eiq/ha
	Option 1	
Glyphosate	0.864	13.25
Metsulfuron	0.03	0.50
2 4 d amine	0.3	6.21
Imazethapyr	0.08	1.57
Diflufenican	0.05	0.88
Clethodim	0.144	2.45
Total	**1.468**	**24.85**
	Option 2	
Glyphosate	1.35	20.70
Dicamba	0.0576	1.46
Acetochlor	1.08	21.49
haloxifop *	0.096	2.13
Sulfentrazone	0.0875	1.02
Total	**2.67**	**46.80**
	Option 3	
Glyphosate	1.62	24.83
Atrazine	0.384	8.79
Bentazon	0.6	11.22
2 4 db ester	0.04	0.61
Imazaquin	0.024	0.37
Total	**2.67**	**45.83**
	Option 4	
Glyphosate	1.8	27.59
2 4 d amine	0.384	7.95
Flumetulam	0.06	0.94
Fomesafen	0.25	6.13
Chlorimuron	0.015	0.29
Fluazifop	0.12	3.44
Total	**2.63**	**46.34**
	Option 5	
Glyphosate	1.8	27.59
Metsulfuron	0.05	0.84
2 4 d amine	0.75	15.53
Imazethapyr	0.1	1.96
haloxifop	0.096	2.13
Total	**2.80**	**48.05**
	Option 6	
Glyphosate	1.8	27.59
Metsulfuron	0.05	0.84
2 4 d amine	0.75	15.53
Imazethapyr	0.1	1.96
Clethodim	0.24	4.08
Total	2.94	49.99
Average all	**2.53**	**43.64**

Table B7. Data sources (for pesticide usage data).

	Sources of data for assumptions
US	Gianessi and Carpenter (1999) Carpenter and Gianessi (2002) Sankula and Blumenthal (2003, 2006) Johnson and Strom (2007) All of the above mainly for conventional regimes (based on surveys of extension advisors across the United States) DMR Kynetec—private market research data on pesticide usage. Is the most comprehensive dataset on crop pesticide usage at the farm level and allows for disaggregation to cover biotech versus conventional crops. This source primarily used for usage on biotech traits.
Argentina	AMIS Global—private market research data on pesticide use. Is the most detailed dataset on crop pesticide use. Global Impact of Biotech Crops: Income and Production Effects, 1996-2007

Graham Brookes and Peter Barfoot
PG Economics, Ltd., Dorchester, UK

This article updates the assessment of the impact of commercialized agricultural biotechnology on global agriculture from an economic perspective. It examines specific global economic impacts on farm income, indirect (non-pecuniary) farm-level income effects and impacts on the production base of the four main crops—soybeans, corn, cotton, and canola. The analysis shows that there have been substantial net economic benefits at the farm level, amounting to $10.1 billion in 2007 and $44.1 billion for the 12-year period (in nominal terms). The non-pecuniary benefits associated with the use of the technology have also had a positive impact on adoption (in the US accounting for the equivalent of 25% of the total direct farm income benefit). Biotech crops have also made important contributions to increasing global production levels of the four main crops—adding, for example, 68 million tonnes and 62 million tonnes respectively to global production of soybeans and corn.

Key words: yield, cost, income, non-pecuniary benefit, production, biotech crops.

Introduction

This article presents the findings of research on the global economic impact of GM crops since their commercial introduction in 1996. It updates part of the findings of earlier analysis presented by the authors in *AgBioForum* 8(2&3), 9(3), and 11(1).[1]

The analysis concentrates on farm income effects because this is a primary driver of adoption amongst farmers (both large commercial and small-scale subsistence). It also considers more indirect farm income or non-pecuniary benefits, and quantifies the (net) production impact of the technology.

Methodology

The report is based largely on extensive analysis of existing farm-level impact data for biotech crops. While primary data for impacts of commercial cultivation were not available for every crop, in every year, and for each country, a substantial body of representative research and analysis is available, and this has been used as the basis for the analysis presented.

Since the economic performance and impact of this technology at the farm level varies widely—both between, and within regions/countries (as applies to any technology used in agriculture)—the measurement of performance and impact is considered on a case-by-case basis in terms of crop and trait combinations. The analysis presented is based on the average performance and impact recorded in different crops by the studies reviewed; the average performance is the most common way in which the identified literature has reported impact. Where several pieces of relevant research (e.g., on the impact of using a GM trait on the yield of a crop in one country in a particular year) have been identified, the findings used have been based largely on the average of these findings.

This approach may both overstate and understate the real impact of GM technology for some trait, crop, and country combinations, especially in cases where the technology has provided yield enhancements. However, since impact data for every trait, crop, location, and year is not available, the authors have had to extrapolate available impact data from identified studies to years for which no data are available. Therefore, the authors acknowledge that this represents a weakness in the research. To reduce the possibilities of over/understating impact, the analysis:

- directly applies impacts identified from the literature to the years that have been studied. As a result, the impacts used vary in many cases according to the findings of literature covering different years.[2] Hence, the analysis takes into account variation in the impact of the technology on yield according to its effectiveness in dealing

1. *Readers should note that some data presented in this article are not directly comparable with data presented in the previous three articles because the current articles takes into account the availability of new data and analysis (including revisions to data for earlier years).*

with (annual) fluctuations in pest and weed infestation levels as identified by research;
- uses current farm-level crop prices and bases any yield impacts on (adjusted—see below) current average yields. In this way some degree of dynamics has been introduced into the analysis that would otherwise be missing if constant prices and average yields indentified in year-specific studies had been used;
- includes some changes and updates to the impact assumptions identified in the literature based on consultation with local sources (analysts, industry representatives) so as to better reflect prevailing/changing conditions (e.g., pest and weed pressure, cost of technology);
- includes some sensitivity analysis in which the impacts based on average performance are supplemented by a range incorporating 'below average' and 'above average' performance assumptions (see Appendix 2 for details); and
- adjusts downward the average base yield (in cases where GM technology has been identified as having delivered yield improvements) on which the yield enhancement has been applied. In this way, the impact on total production is not overstated.

Detailed examples of how the methodology has been applied to the calculation of the 2007 year results are presented in Appendix 1. Appendix 2 also provides details of the impacts and assumptions applied and their sources.

Other aspects of the methodology used to estimate the impact on direct farm income are as follows.

- Impact is quantified at the trait and crop level, including where stacked traits are available to farmers. Where stacked traits have been used, the individual trait components were analyzed separately to ensure estimates of all traits were calculated.
- All values presented are nominal for the year shown and the base currency used is the US dollar. All financial impacts in other currencies have been converted to US dollars at prevailing annual average exchange rates for each year.
- The analysis focuses on changes in farm income in each year arising from impact of GM technology on yields, key costs of production (notably seed cost and crop protection expenditure, but also impact on costs such as fuel and labor),[3] crop quality (e.g., improvements in quality arising from less pest damage or lower levels of weed impurities, which result in price premia being obtained from buyers), and the scope for facilitating the planting of a second crop in a season (e.g., second crop soybeans in Argentina following wheat that would, in the absence of the GM herbicide-tolerant [HT] seed, probably not have been planted). Thus, the farm income effect measured is essentially a gross margin impact (impact on gross revenue less variable costs of production) rather than a full net cost of production assessment. Through the inclusion of yield impacts and the application of actual (average) farm prices for each year, the analysis also indirectly takes into account the possible impact of biotech crop adoption on global crop supply and world prices.

The article also examines some of the more intangible (more difficult to quantify) economic impacts of GM technology. The literature in this area is much more limited and, in terms of aiming to quantify these impacts, largely restricted to the US-specific studies. The findings of this research are summarized[4] and extrapolated to the cumulative biotech crop planted areas in the United States in the 1996-2007 period.

Lastly, the article includes estimates of the production impacts of GM technology at the crop level. These have been aggregated to provide the reader with a global perspective of the broader production impact of the technology. These impacts derive from the yield impacts (where identified), but also from the facilitation of addi-

2. *Examples where such data is available include the impact of GM insect-resistant cotton: in India, see Bennett, Ismael, Kambhampati, and Morse (2004) and IMRB (2006, 2007); in Mexico, see Traxler, Godoy-Avilla, Falck-Zepeda, and Espinoza-Arellano (2001) and Monsanto Mexico (2005, 2007); and in the US, see Sankula and Blumenthal (2003, 2006) and Mullins and Hudson (2004).*

3. *Impacts on these categories of cost are, however, more limited than the impacts on seed and crop protection costs because only a few of the papers reviewed have included consideration of such costs in their analyses. Therefore, in most cases the analysis relates to impact of crop protection and seed cost only.*

4. *Notably relating to the US—Marra and Piggott (2006).*

Table 1. Global farm income benefits from growing biotech crops, 1996-2007 (US $ million).

Trait	2007 increase in farm income	1996-2007 increase in farm income	2007 farm income benefit as % of total value of production of these crops in biotech adopting countries	2007 farm income benefit as % of total value of global production of crop
GM HT soybeans	3,935.5	21,814.1	7.2	6.4
GM HT maize	442.3	1,507.6	0.7	0.4
GM HT cotton	24.5	848.2	0.1	0.1
GM HT canola	345.6	1,438.6	7.65	1.4
GM IR maize	2,075.3	5,673.6	3.2	1.9
GM IR cotton	3,204.0	12,576.2	16.5	10.2
Others	54.4	208.8	n/a	n/a
Totals	**10,081.6**	**44,067.1**	**6.9**	**4.4**

Note. All values are nominal. Others = Virus-resistant papaya and squash. Totals for the value shares exclude "other crops" (i.e., relate to the four main crops of soybeans, maize, canola, and cotton). Farm income calculations are net farm income changes after inclusion of impacts on yield, crop quality, and key variable costs of production (e.g., payment of seed premia, impact on crop protection expenditure).

tional cropping within a season (notably in relation to soybeans in South America). Details of how these values were calculated (for 2007) are shown in Appendix 1.

Results

GM technology has had a significant positive impact on farm income derived from a combination of enhanced productivity and efficiency gains (Table 1). In 2007, the direct global farm income benefit from biotech crops was $10.1 billion. This is equivalent to having added 4.4% to the value of global production of the four main crops of soybeans, maize, canola, and cotton. Since 1996, farm incomes have increased by $44.1 billion.

The largest gains in farm income have arisen in the soybean sector, largely from cost savings. The $3.9 billion additional income generated by GM HT soybeans in 2007 has been equivalent to adding 7.2% to the value of the crop in biotech-growing countries, or adding the equivalent of 6.4% to the $60 billion value of the global soybean crop in 2007. These economic benefits should, however be placed within the context of a significant increase in the level of soybean production in the main biotech-adopting countries. Since 1996, the soybean area in the leading soybean-producing countries—United States, Brazil, and Argentina—increased by 58%.

Substantial gains also have arisen in the cotton sector through a combination of higher yields and lower costs. In 2007, cotton farm income levels in the biotech-adopting countries increased by $3.2 billion, and since 1996, the sector has benefited from an additional $12.6 billion. The 2007 income gains are equivalent to adding 16.5% to the value of the cotton crop in these countries, or 10.2% to the $27.5 billion value of total global cotton production. This is a substantial increase in value-added terms for two new cotton seed technologies.

Significant increases to farm incomes have also occurred in the maize and canola sectors. The combination of GM insect-resistant (GM IR) and GM HT technology in maize has boosted farm incomes by $7.2 billion since 1996. In the North American canola sector, an additional $1.4 billion has been generated.

Table 2 summarizes farm income impacts in key biotech-adopting countries. This highlights the important farm income benefit arising from GM HT soybeans in South America (Argentina, Brazil, Paraguay, and Uruguay), GM IR cotton in China and India, and a range of GM cultivars in the United States. It also illustrates the growing level of farm income benefits being obtained in South Africa, the Philippines, and Mexico.

In terms of the division of the economic benefits obtained by farmers in developing countries relative to farmers in developed countries, Table 3 shows that in 2007, 58% of the farm income benefits were earned by developing-country farmers. The vast majority of these income gains for developing-country farmers have been from GM IR cotton and GM HT soybeans.[5] Over the twelve years—1996-2007—the cumulative farm income gain derived by developing country farmers was $22.1 billion (50.1% of the total).

Examining the cost farmers pay for accessing GM technology, Table 4 shows that across the four main bio-

5. *The authors acknowledge that the classification of different countries into developing or developed country status affects the distribution of benefits between these two categories of country. The definition used in this article is consistent with the definition used by James (2007).*

Table 2. GM crop farm income benefits in selected countries, 1996-2007 ($ million).

	GM HT soybeans	GM HT maize	GM HT cotton	GM HT canola	GM IR maize	GM IR cotton	Total

Note. All values are nominal. Farm income calculations are net farm income changes after inclusion of impacts on yield, crop quality, and key variable costs of production (e.g., payment of seed premia, impact on crop protection expenditure). n/a = not applicable. US figures exclude benefits from virus-resistant crops.

Table 3. GM crop farm income benefits in developing versus developed countries, 2007 ($ million).

	Developed	Developing
GM HT soybeans	1,375.1	2,560.5
GM IR maize	1,773.4	301.9
GM HT maize	401.6	40.8
GM IR cotton	285.8	2,918.1
GM HT cotton	16.3	8.2
GM HT canola	345.6	0
GM virus-resistant papaya and squash	54.4	0
Total	**4,252.2**	**5,829.5**

Note. Developing countries = all countries in South America, Mexico, India, China, the Philippines, and South Africa.

tech crops, the total cost in 2007 was equal to 24% of the total technology gains (inclusive of farm income gains plus the cost of the technology payable to the seed supply chain).[6]

For farmers in developing countries the total cost was equal to 14% of total technology gains, while for farmers in developed countries the cost was 34% of the total technology gains. While circumstances vary between countries, the higher share of total technology gains accounted for by farm income gains in developing countries relative to the farm income share in developed countries reflects factors such as weaker provision and enforcement of intellectual property rights in developing countries and the higher average level of farm income gain on a per-hectare basis derived by developing country farmers relative to developed country farmers.

As indicated in the methodology section, the analysis presented above is largely based on estimates of average impact in all years. Recognizing that pest and weed pressure varies by region and year, additional sensitivity analysis was conducted for the crop/trait combinations where yield impacts were identified in the literature. This sensitivity analysis (see Appendix 2 for details) was undertaken for two levels of impact assumption: one in which all yield effects in all years were assumed to be 'lower than average' (levels of impact that reflected yield impacts in years of low pest/weed pressure), and one in which all yield effects in all years were assumed to be 'higher than average' (levels of impact that reflected yield impacts in years of high pest/weed pressure). The results of this analysis suggest a range of positive direct farm income gains in 2007 of +$8.5 to +$12.9 billion and, over the 1996-2007 period, a range of +$38.2 to +$52.2 billion (Table 5). This range

6. *The cost of the technology accrues to the seed supply chain, including sellers of seed to farmers, seed multipliers, plant breeders, distributors, and the GM technology providers.*

Table 4. Cost of accessing GM technology relative to the total farm income benefits, 2007 ($ million).

	Cost of technology: All farmers	Farm income gain: All farmers	Total benefit of technology to farmers and seed supply chain	Cost of technology: Developing countries	Farm income gain: Developing countries	Total benefit of technology to farmers and seed supply chain: Developing countries
GM HT soybeans	930.8	3,935.5	4,866.3	326	2,560.5	2,886.5
GM IR maize	714.3	2,075.3	2,789.6	79.1	301.9	381
GM HT maize	530.8	442.3	973.1	20.2	40.8	61
GM IR cotton	670.4	3,204.0	3,874.4	535.1	2,918.1	3,453.2
GM HT cotton	226.4	24.5	250.9	8.5	8.2	16.7

Total	**3,174.9**	**10,027.2**	**13,202.1**	**968.9**	**5,829.5**	**6,798.4**

Note. n/a = not applicable. Cost of accessing technology based on the seed premia paid by farmers for using GM technology relative to its conventional equivalents. Total farm income gain excludes $54.4 million associated with virus-resistant crops in the United States.

Table 5. Direct farm income benefits 1996-2007 under different impact assumptions ($ million).

Crop	Consistent below average pest/weed pressure	Average pest/weed pressure (main study analysis)	Consistent above average pest/weed pressure
Soybeans	21,796.0	21,814.1	21,829.0
Corn	4,571.0	7,181.2	12,152.0
Cotton	10,920	13,424.4	15,962.0
Canola	818.7	1,438.6	2,013.0
Others	101.4	208.8	224.3
Total	**38,207.1**	**44,067.1**	**52,180.3**

Note. No significant change to soybean production under all three scenarios as almost all gains due to cost savings and second crop facilitation.

is broadly within 85% to 120% of the main estimates of farm income presented above.

Indirect (Non-Pecuniary) Farm-Level Impacts

In addition to the tangible and quantifiable impacts on farm profitability presented above, there are other important, more intangible (difficult to quantify) impacts of an economic nature.

Many of the studies[7] of the impact of biotech crops have identified the following reasons as being important influences for adoption of the technology.

Herbicide Tolerant Crops

- HT crops allow for increased management flexibility and convenience that comes from a combination of the ease of use associated with broad-spectrum, post-emergent herbicides like glyphosate and the increased/longer time window for spraying. This not only frees up management time for other farming activities but also allows additional scope for undertaking off-farm, income-earning activities.
- In a conventional crop, post-emergent weed control relies on herbicide applications before the weeds and crop are well established. As a result, the crop may suffer 'knock-back' to its growth from the effects of the herbicide. In the GM HT crop, this problem is avoided because the crop is both tolerant to the herbicide and spraying can occur at a later stage when the crop is better able to withstand any possible "knock-back" effects.
- These crops facilitate the adoption of conservation or no-tillage systems. This provides for additional cost savings such as reduced labor and fuel costs associated with plowing, additional moisture retention, and reductions in soil erosion levels.
- Improved weed control has contributed to reduced harvesting costs—cleaner crops have resulted in reduced times for harvesting. It has also improved harvest quality and led to higher levels of quality price bonuses in some regions and years (e.g., HT soybeans and HT canola in the early years of adoption, respectively, in Romania and Canada).
- Elimination of potential damage caused by soil-incorporated residual herbicides in follow-on

7. *For example, relating to HT soybeans, USDA (1999), Gianessi and Carpenter (1999), and Qaim and Traxler (2002); relating to IR maize, Rice (2004) and Brookes (2008); relating to IR cotton, Ismael, Bennett, Morse, and Buthelezi (2002) and Pray et al. (2002).*

crops and less need to apply herbicides in a follow-on crop because of the improved levels of weed control;
- HT crops also contribute to a general improvement in human safety (as manifest in greater peace of mind about own and worker safety) from reduced exposure to herbicides and a switch to more environmentally benign products.

Insect Resistant Crops

- IR crops offer benefits in the areas of production risk management and insurance. The technology takes away much of the worry of significant pest damage occurring and is, therefore, highly valued. Although not applicable in 2007 (piloted in 2008 and likely to be more widely operational from 2009), US farmers using stacked corn traits (containing IR and HT traits) are being offered discounts on crop insurance premiums equal to $7.41/hectare.
- These crops have a 'convenience' benefit derived from having to devote less time to crop walking and/or applying insecticides.
- IR crops offer savings in energy use—mainly associated with less use of aerial spraying and less tillage.
- Planting IR crops can produce savings in machinery use (for spraying and possibly reduced harvesting times).
- IR crops produce a higher quality of crop. There is a growing body of research evidence relating to the superior quality of GM IR corn relative to conventional and organic corn from the perspective of having lower levels of mycotoxins. Evidence from Europe (as summarized in Brookes [2008]) has shown a consistent pattern in which GM IR corn exhibits significantly reduced levels of mycotoxins compared to conventional and organic alternatives. In terms of revenue from sales of corn, however, no premia for delivering product with lower levels of mycotoxins have been reported to date; however, where the adoption of the technology has resulted in reduced frequency of crops failing to meet maximum permissible fumonisin levels in grain maize (e.g., in Spain), this delivers an important economic gain to farmers selling their grain to the food-using sector. In one study (Yorobe, 2004), GM IR corn farmers in the Philippines have also been reported to have obtained price premia of 10% relative to conventional corn because of better quality, less damage to cobs, and lower levels of impurities.
- They also offer improved health and safety for farmers and farm workers—from reduced handling and use of pesticides, especially in developing countries where many apply pesticides with little or no use of protective clothing and equipment.
- Shorter growing seasons (e.g., for some cotton growers in India) allow some farmers to plant a second crop in the same season.[8] Also, some Indian cotton growers have reported benefits for bee keepers, as fewer bees are now lost to insecticide spraying.

Some of the economic impact studies have attempted to quantify some of these benefits. For example, Qaim and Traxler (2002) quantified some of these in Argentina—a $3.65/hectare saving (-7.8%) in labor costs and a $6.82/ha (-28%) saving in machinery/fuel costs associated with the adoption of GM HT soybeans. Where identified, these cost savings have been included in the analysis presented above. Nevertheless, it is important to recognize that these largely intangible benefits are considered by many farmers as a primary reason for adoption of GM technology, and in some cases farmers have been willing to adopt for these reasons alone, even when the measurable impacts on yield and direct costs of production suggest marginal or no direct economic gain.

Since the early 2000s, a number of farmer-survey-based studies in the United States have also attempted to better quantify these non-pecuniary benefits. These studies have usually employed contingent valuation techniques[9] to obtain farmer valuations of non-pecuniary benefits.

- A 2002 survey of 600 US corn farmers explored opinions and valuations of the then new IR corn trait resistant to corn rootworm, which was introduced in the following year (2003). Respondents were asked to value any potential time and equipment savings, additional farmer and worker

8. *Notably maize in India.*
9. *Survey-based method of obtaining valuations of non-market goods that aim to identify willingness to pay for specific goods (e.g., environmental goods, peace of mind, etc.) or willingness to pay to avoid something being lost.*

safety, additional environmental benefits, and production risk management benefits (from more consistent control of rootworm) that they thought might arise from use of the technology relative to existing corn rootworm control methods. The production risk management benefit was mostly highly valued by farmers, followed by operator/worker safety and environmental gains. The average value of all the non-pecuniary benefits was $17.89/hectare for likely adopters, $9.54/hectare for unlikely adopters, and an overall average of $16.33/hectare across all farmers surveyed.

- A 2002 survey of 610 US soybean farmers sought farmers' views on the benefits associated with their use (since 1996) of GM HT soybeans. Respondents were asked to value additional farmer and worker safety, the environmental impact of the technology and the additional convenience and flexibility the technology provided for weed control relative to the conventional alternatives. All of these benefits were valued by the soybean farmers, with convenience given the highest value. Overall, the average benefit attributed to these three categories of non-pecuniary benefits was $27/hectare (58% of which came from the convenience benefit).
- A 2003 survey of nearly 300 farmers of GM HT crops (soybeans, corn, and cotton) asked respondents to value additional farmer and worker safety, the environmental impact of the technology, and the additional convenience and flexibility the technology provided for weed control relative to the conventional alternatives. Results obtained were similar to those in the 2002 soybean farmer survey referred to above. In terms of valuations, the average benefit attributed to these three categories of non-pecuniary benefits were, respectively, $32/hectare for HT corn farmers, $35.70/hectare for HT soybean farmers, and $39.40/hectare for HT cotton farmers.

The values for non-pecuniary benefits identified in these surveys are, however, usually subject to bias due to factors such as the hypothetical nature of the contingent valuation technique, the framing of questions, and what is referred to as part-whole bias.[10] Marra and Piggott (2006) examined bias (notably part-whole bias) in the three surveys referred to above and found most respondents tended to overstate the value of parts by more than 60% compared with the separately stated total values for all non-pecuniary benefits. They subsequently rescaled[11] the sum of the values given by respondents to each separate non-pecuniary benefit and identified revised average (median) values for the non-pecuniary benefits in each survey (Table 6). This suggests that US farmers who make widespread use of biotech HT traits value the non-pecuniary benefits of the technology at between $12.35/hectare and $24.71/hectare, with cotton farmers valuing the non-pecuniary aspects highest and corn farmers having the lowest valuation. In terms of attributes most valued, convenience is perceived to provide between 50% and 66% of the total non-pecuniary benefit of the HT technology. It is also interesting to note that the most recent survey of cotton farmers using HT (flex) technology have valued this technology as delivering an additional $12/hectare in tterms of benefit from extra convenience relative to the first generation of biotech HT cotton technology. Corn producers value the non-pecuniary benefits of the IR ((rootworm resistance) technology at about $7.40/hectare, of which the risk reduction component accounted for the largest single share (about a third).

Table 6. Re-scaled values of non-pecuniary benefits.

Survey	Median value ($/hectare)
2002 IR (to rootworm) corn growers survey	7.41
2002 soybean (HT) farmers survey	12.35
2003 HT cropping survey (corn, cotton & soybeans)—North Carolina	24.71
2006 HT (flex) cotton survey	12.35 (relative to first generation HT cotton)

Aggregating the Impact to US Crops 1996-2007

The approach used to estimate the non-pecuniary benefits derived by US farmers from biotech crops over the period 1996-2007 has been to draw on the re-scaled values identifed by Marra and Piggot (2006, 2007, Table 6) and to apply these to the biotech-crop planted areas during this 12-year period. Figure 1 summarizes the values for non-pecuniary benefits derived from biotech crops

10. In the case of non-pecuniary benefits, the sum of values given by farmers to individual categories of benefit is greater than their stated total value of all non-pecuniary benefits (farmers being asked to value each type of benefit separately in addition to separately valuing total non-pecuniary benefits).

11. See Marra and Piggott (2006).

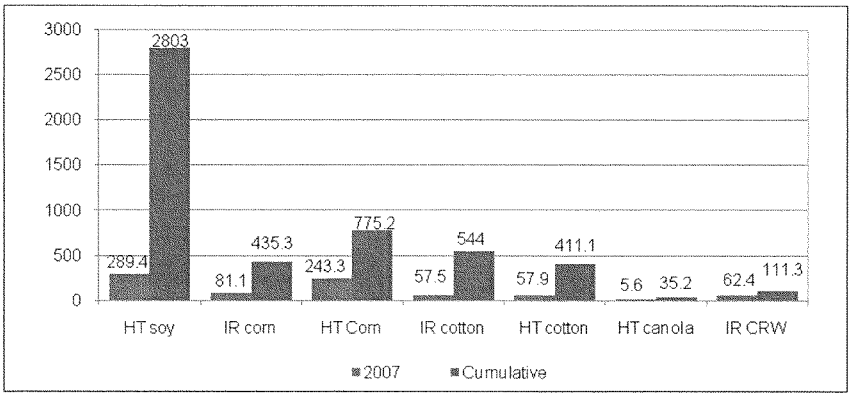

Figure 1. Non-pecuniary benefits derived by US farmers by trait, 1996-2007 ($ million).

in the United States (1996-2007) and shows an estimated (nominal value) benefit of $792 million in 2007 and a cumulative total benefit (1996-2007) of $5.11 billion. Relative to the value of direct farm income benefits presented above, the non-pecuniary benefits were equal to 21% of the total direct income benefits in 2007 and 25% of the total cumulative (1996-2007) direct farm income. This highlights the important contribution this category of benefit has had on biotech trait adoption levels in the United States, especially where the direct farm income benefits have been identfied to be relatively small (e.g., HT cotton).

Estimating the Impact in Other Countries

It is evident from the literature review that GM technology-using farmers in other countries also value the technology for a variety of non-pecuniary/intangible reasons. The most appropriate methodology for identifying these non-pecuniary benefit valuations in other countries would be to repeat the type of US farmer surveys in other countries. Unfortunately, the authors are not aware of any such studies undertaken to date.

Production Effects of the Technology

Based on the yield assumptions used in the direct farm income benefit calculations presented above (see Appendix 1) and taking into account the second soybean crop facilitation in South America, biotech crops have added important volumes to global production of corn, cotton, canola, and soybeans since 1996 (Table 7).

Table 7. Additional crop production arising from positive yield effects of biotech crops.

	1996-2007 additional production (million tonnes)	2007 additional production (million tonnes)
Soybeans	67.80	14.46
Corn	62.42	15.08
Cotton	6.85	2.01
Canola	4.44	0.54

The biotech IR traits—used in the corn and cotton sectors—have accounted for 99% of the additional corn production and almost all of the additional cotton prodduction. Positive yield impacts from the use of this technology have occurred in all user countries (except GM IR cotton in Australia)[12] when compared to average yields derived from crops using conventional technology (such as application of insecticides and seed treatments). Since, 1996 the average yield impact across the total area planted to these traits over the 12 year period has been +6.1% for corn traits and +13.4% for cotton traits (Figure 2).

Although the primary impact of biotech HT technology has been to provide more cost-effective (less expensive) and easier weed control—versus improving yields

12. This reflects the levels of Heliothis pest control previously obtained with intensive insecticide use. The main benefit and reason for adoption of this technology in Australia has arisen from significant cost savings (on insecticides) and the associated environmental gains from reduced insecticide use.

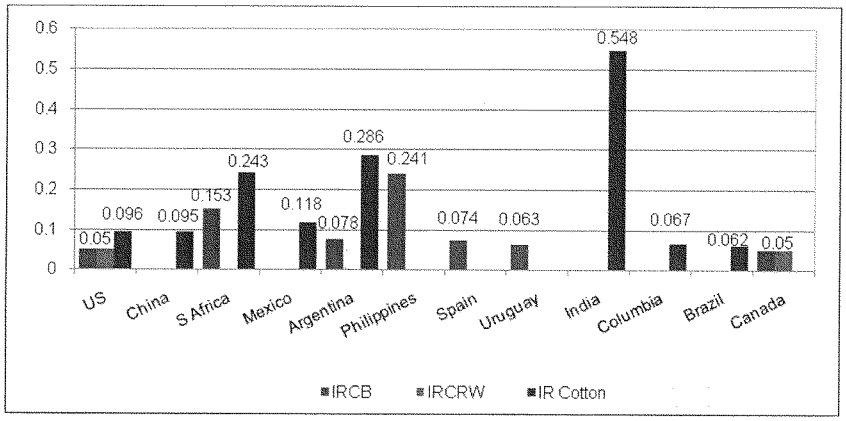

Figure 2. Average yield impact of biotech IR traits by country and trait, 1996-2007.
Note. IRCB = resistant to corn-boring pests. IRCRW = resistant to corn rootworm.

Table 8. Additional crop production arising from positive yield effects of biotech crops under different pest/weed pressure assumptions and impacts of the technology, 1996-2007 (million tonnes).

Crop	Consistent below average pest/weed pressure	Average pest/ weed pressure (main study analysis)	Consistent above average pest/weed pressure
Corn	46.0	62.42	109.5
Cotton	4.61	6.86	9.03
Canola	2.09	4.44	6.26

Note. No significant change to soybean production under all three scenarios as 99% of production gain due to second cropping facilitation of the technology.

from better weed control (relative to weed control obtained from conventional technology)—improved weed control has, nevertheless occurred, delivering higher yields in some countries. Specifically, HT soybeans in Romania improved the average yield by more than 30%, and biotech HT corn in Argentina and the Philippines delivered yield improvements of +9% and +15%, respectively.

Biotech HT soybeans have also facilitated the adoption of no-tillage production systems, shortening the production cycle. This advantage enables many farmers in South America to plant a crop of soybeans immediately after a wheat crop in the same growing season. This second crop, additional to traditional soybean production, has added 67.5 million tonnes to soybean production in Argentina and Paraguay between 1996 and 2006—accounting for 99% of the total biotech-related additional soybean production.

Using the same sensitivity analysis as applied to the farm income estimates presented above to the production impacts (one scenario of consistent lower-than-average pest/weed pressure and one of consistent higher-than-average pest/weed pressure), Table 8.

Concluding Comments

This study quantified the cumulative global impact of GM technology between 1996 and 2007 on farm income and production. The analysis shows that there have been substantial direct economic benefits at the farm level, amounting to a cumulative total of $44.1 billion; half of this has been derived by farmers in developing countries. Important non-pecuniary benefits have also been derived by many farmers, which in the case of US farmers added a further $5.1 billion to the farm income benefits derived from the technology. GM technology has also resulted in additional production of important crops, equal to an extra 68 million tonnes of soybeans and 62 million tonnes of corn (1996-2007).

The impacts identified are based on estimates of average impact, reflecting the limitations of the methodologies used and the limited availability of relevant data.

Applying alternative assumptions that reflect the extremes of low weed and pest pressure in all years and high weed and pest pressure in all years suggests that the impact on farm income probably falls within a range of -15% to +20% around the cumulative estimate of $44.1 billion referred to above. Subsequent research at the trait- and country-level might usefully extend this analysis to incorporate more sophisticated consideration of dynamic economic impacts and broader (outside the United States) examination of the less tangible (non-pecuniary) economic impacts.

Appendix 1: Details of Methodology as Applied to 2007 Farm Income Calculations

Table A1. GM IR corn (targeting corn boring pests), 2007.

Country	Area of trait ('000 ha)	Yield assumption % change	Base yield (tonnes/ ha)	Farm level price ($/ tonne)	Cost of technology ($/ha)	Impact on costs, net of cost of technology ($/ha)	Change in farm income ($/ha)	Change in farm income at national level ('000 $)	Production impact ('000 tonnes)
United States	18,561	+5	9.25	135.4	-17.3	-1.42	61.22	+1,136,212	+8,584.4
Canada	831	+5	8.29	165.44	-19.3	+1.68	+70.26	+58,382	+344.4
Argentina	2,509	+5.5	6.8	113.0	-19.9	-19.9	+22.41	+56,220	+938.4
Philippines	194	+24.15	2.52	215.12	-36.2	-22.14	+108.78	+21,091	+118
South Africa	1,234	+15	4.0	304.47	-16.19	-2.29	+180.39	+222,601	+740.4
Spain	75.1	+10	9.34	283.77	-47.75	+9.55	+274.59	+20,634	+70.2
Uruguay	105	+5.5	5.61	125	-19.9	-19.9	+18.63	+1,956.6	+32.4
France	22.1	+10	9.4	256.48	-54.57	+13.64	+254.73	+5,638.5	+20.8
Germany	2.7	+4	9.09	285.13	-54.57	+13.64	+117.32	+315	+1
Portugal	4.3	+12.5	5.51	278.31	-47.75	-47.75	+143.95	+613.6	+2.9
Czech Republic	5	+10	5.75	294.68	-47.75	-23.19	+146.25	+713.2	+2.9
Slovakia	0.9	+12.3	4.28	285.13	-47.75	-47.75	+102.35	+97.1	+0.5
Poland	0.3	+12.5	5.28	259.21	-47.75	-47.75	+123.33	+40	+0.2
Romania	0.3	+7.1	3.50	315.14	-43.66	-43.66	+34.66	+12	+0.1

Note. Impact on costs net of cost of technology = cost savings from reductions in pesticide costs, labor use, fuel use, etc., from which the additional cost (premium) of the technology has been deducted. For example (above), US cost savings from reduced expenditure on insecticides, etc. = +$15.88/ha, from which cost of technology (-$17.3/ha) is deducted to leave a net impact of costs of -$1.42.

There are no Canadian-specific studies available, so we have applied US study findings to the Canadian context (since it is the nearest country for which relevant data is available).

Table A2. GM IR corn (targeting corn rootworm), 2007.

Country	Area of trait ('000 ha)	Yield assumption % change	Base yield (tonnes/ha)	Farm level price ($/tonne)	Cost of technology ($/ha)	Impact on costs, net of cost of technology ($/ha)	Change in farm income ($/ha)	Change in farm income at national level ('000 $)	Production impact ('000 tonnes)
US	8,417.6	+5	9.25	135.4	-35	+2.47	+65.10	+547,991	+3,893.2

Note. Where no positive yield effect due to this technology is applied, the base yields shown are the indicative average yields for the crops and differ (are higher) than those used for the GM IR base yield analysis, which have been adjusted downwards to reflect the impact of the yield enhancing technology (see below).

Argentina: 20% of area assumed to use certified seed with 80% farm-saved seed.

Table A7. GM HT canola, 2007.

Country	Area of trait ('000 ha)	Yield assumption % change	Base yield (tonnes/ ha)	Farm level price ($/tonnes)	Cost of technology ($/ha)	Impact on costs, net of cost of technology ($/ha)	Change in farm income ($/ha)	Change in farm income at national level ('000 $)	Production impact ('000 tonnes)
US glyphosate tolerant	271.9	+4	1.65	359.36	-12.36	+27.73	+51.45	+13,990.1	+5.2
US glufosinate tolerant	182.9	+10	1.65	359.36	-12.36	+22.28	+81.57	+14,918.4	+8.7
Canada glyphosate tolerant	2,840.9	+4	1.41	508.27	-34.01	+6.82	+35.49	+100,823.3	+160.2
Canada glufosinate tolerant	2,588.4	+10	1.41	508.27	0	+11.72	+83.38	+215,830.1	+365.0

Note. Baseline (conventional) comparison in Canada with HT (non GM) 'Clearfield' varieties.

Table A8. GM virus-resistant crops.

Country	Area of trait (ha)	Yield assumption % change	Base yield (tonnes/ ha)	Farm level price ($/tonne)	Cost of technology ($/ha)	Impact on costs, net of cost of technology ($/ha)	Change in farm income ($/ha)	Change in farm income at national level ('000 $)	Production impact ('000 tonnes)
US papaya	778	+15	22.86	864.36	-148	-148	+2,816.1	+2,190	+2.7
US squash	3002	+100	31.4	566.90	-398	-398	+17,402.9	+52,252.3	+94.3

Second Soybean Crop Benefits: Argentina

An additional farm income benefit that many Argentine soybean growers have derived comes from the additional scope for second cropping of soybeans. This has arisen because of the simplicity, ease, and weed management flexibility provided by the (GM) technology which has been an important factor facilitating the use of no- and reduced-tillage production systems. In turn, the adoption of low/no-tillage production systems has reduced the time required for harvesting and drilling subsequent crops and, hence, has enabled many Argentine farmers to cultivate two crops (wheat followed by soybeans) in one season. As such, the proportion of soybean production in Argentina using no- or low-tillage methods has increased from 34% in 1996 to 90% by 2005. Also, 30% of the total Argentine soybean crop was second crop in 2007, compared to 8% in 1996. Based on the additional gross margin income derived from second crop soybeans (see below), this has contributed a further boost to national soybean farm income of $1.1 billion in 2007 and $4.4 billion cumulatively since 1996.

Base Yields Used Where GM Technology Delivers a Positive Yield Gain

In order to avoid over-stating the positive yield effect of GM technology (where studies have identified such an impact) when applied at a national level, average (national level) yields used have been adjusted downwards (see example in Table A10). Production levels based on these adjusted levels were then cross checked with total production values based on reported average yields across the total crop.

Table A9. Farm-level income impact of using GM HT soybeans in Argentina, 1996-2007 (2): Second crop soybeans.

Year	Second crop area (million ha)	Average gross margin/ha for second crop soybeans ($/ha)	Increase in income linked to GM HT system (million $)
1996	0.45	128.78	Negligible
1997	0.65	127.20	25.4
1998	0.8	125.24	43.8
1999	1.4	122.76	116.6
2000	1.6	125.38	144.2
2001	2.4	124.00	272.8
2002	2.7	143.32	372.6
2003	2.8	151.33	416.1
2004	3.0	226.04	678.1
2005	2.3	228.99	526.7
2006	3.2	218.40	698.9
2007	4.94	229.36	1,133.6

Note. Crop areas and gross margin data based on data supplied by Grupo CEO (no data available before 2000, hence 2001 data applied to earlier years but adjusted, based on GDP deflator rates).

The second cropping benefits are based on the gross margin derived from second crop soybeans multiplied by the total area of second crop soybeans (less an assumed area of second crop soybeans that equals the second crop area in 1996—this was discontinued from 2004 because of the importance farmers attach to the GM HT system in facilitating them remaining in no-tillage production systems).

Table A10. Example: GM IR cotton (2007).

Country	Average yield across all forms of production (t/ha)	Total cotton area ('000 ha)	Total production ('000 tonnes)	GM IR area ('000 ha)	Conventional area ('000 ha)	Assumed yield effect of GM IR technology	Adjusted base yield for conventional cotton (t/ha)	GM IR production ('000 tonnes)	Conventional production ('000 tonnes)
United States	0.985	4,381.6	4,315.9	2,585.2	1,796.5	+10%	0.93	2,644.7	1,670.7
China	1.257	6,200.0	7,793.4	3,800.0	2,400.0	+10%	1.184	4,949.1	2,841.6

Note. Figures subject to rounding.

Appendix 2: Impacts, Assumptions, Rationale, and Sources for All Trait/Country Combinations

Table 1. IR corn (resistant to corn-boring pests).

Country	Yield impact assump. used	Rationale	Yield references	Sensitivity analysis applied to yield assump.	Cost of technology data/ assump.	Cost savings (excluding impact of seed premium) assump.	Cost references
GM IR corn resistant to corn boring pests							
US & Canada	+5% all years	Broad average of impact identified from several studies/ papers	Carpenter and Gianessi (2002) found yield impacts of +9.4% in 1997, +3% in 1998, +2.5% in 1999 Marra et al. (2002) average impact of +5.04% 1997-2000 based a review of five studies, James (2003) average impact of +5.2% 1996-2002, Sankula and Blumenthal (2003, 2006) range of +3.1% to +9.9% Canada—no studies identified —as US—impacts qualitatively confirmed by industry sources (personal communication, 2005, 2007).	+3% to +9%	1996 & 1997: $25 1998 & 1999: $20 2000-2004: $22 2005 & onwards: $17	All years to 2004: $15.50 2005 onwards: $15.90	The same reference sources as yield were used. Industry sources also confirmed costs of technology and estimated cost-saving values for Canada.
Argentina	+9% all years to 2004 +5.5% 2005 onwards	Average of reported impacts in first seven years, later revised downwards for more recent years to reflect professional opinion	James (2003) cites two unpublished industry survey reports; one for 1996-1999 showing an average yield gain of +10% and one for 2000-2003 showing a yield gain of +8%. Trigo, Chudnovsky, Cap, and Lopez (2002), Trigo and Cap (2006) +10%, Trigo (personal communication, 2007, 2008) estimates average yield impact since 2005 to be lower at between +5% and +6%.	+5% all years to +9% all years	Same as US to 2005 then 60 Pesos 2006 onwards	None, as maize crops not traditionally treated with insecticides for corn boring pest damage	Cost of technology drawn from Trigo et al. (2002) and Trigo and Cap (2006), i.e., costed/priced at same level as US (Trigo, personal communication, 2007, 2008).
Philippines	+24.6% all years	Average of three studies used all years	Gonsalves (2005) found average yield impact of +23% dry season crops and +20% wet season crops; Yorobe (2004) +38% dry season crops and +35% wet season crops; Ramon (2005) found +15.3% dry season crops and +13.3% wet season crops.	All years +14% to +34%	All years: 1,673 Pesos	All years: 651 Pesos	Based on Gonsalves (2005)—the only source to break down these costs. For 2006 and 2007, this level of cost and average cost savings were confirmed by industry sources.
South Africa	2000-2001: +11% 2002: +32% 2003: +16% 2004: +5% 2005 onwards: +15%	Reported average impacts used for years available (2000-2004), 2005 onwards based on average of other years.	Gouse, Pray, Kirsten, and Schimmelpfenning (2005), Gouse, Piesse, and Thirtle (2006), and Gouse, Pray, Schimmelpfenning, and Kirsten (2006) reported yield impacts as shown (range of +11% to +32%).	+5% to +32% all years	(In Rand) 2000 & 2001: 84 2002: 90 2004 & 2005: 94 2006 and onwards: 113	All years 97 Rand	Based on the same papers as used for yield, plus confirmation in 2006 and 2007 that these are representative values from industry sources.

Spain	1998-2004: +6.3% 2005 onwards: +10%	Impact based on author's own detailed, representative analysis for period 1998-2002 then updated to reflect improved technology based on industry analysis.	Brookes (2003) identified an average of +6.3% using the Bt 176 trait mainly used in the period 1998-2004 (range +1% to +40% for the period 1998-2002). From 2005, 10% used based on Brookes (2008), which derived from industry (unpublish-ed sources) commercial-scale trials and monitoring of impact of the newer, dominant trait Mon 810 in the period 2003-2007. Gomez-Barbero and Rodriguez-Cerezo (2006) reported an average impact of +5% for Bt 176 used in 2002-2004.	+3% to +15% all years	(In Euros) 1998 & 1999: 30 2000: 28 2001-2005: 18.5 2006 and onwards: 35	42 Euros all years	Based on Brookes (2003), the only source to break down these costs. The more recent cost of technology costs derive from industry sources (reflecting the use of Mon 810 technology). Industry sources also confirm value for insecticide cost savings as being representative.
Other EU	France: +10% Germany: +4% Portugal: +12.5% Czech Rep.: +10% Slovakia: +12.3% Poland: +12.5% Romania: +7.1%	Impacts based on average of available impact data in each country.	Based on Brookes (2008), which drew on a number of sources. For France, four sources with average yield impacts of +5% to +17%; for Germany the sole source had average annual impacts of +3.5% and +9.5% over a two year period; for Czech Republic, three studies identified average impacts in 2005 of an average of 10% and a range of +5% to +20%; for Portugal, commercial trial and plot monitoring reported +12% in 2005 and between +8% and +17% in 2006; in Slovakia based on trials for 2003-2007 and 2006/07 plantings with yield gains averaging between +10% and +14.7%; in Poland based on variety trial tests 2005 and commercial trials 2006 which had a range of +2% to +26%; Romania based on estimated impact by industry sources for the 2007 year.	Not applied in context of total study due to very small scale of production (i.e., would produce an insignificant impact range in the context of the whole study).	France and Germany, 40 Euros Portugal, Czech and Slovak Republics, and Poland, 35 Euros Romania, 32 Euros	France and Germany, 50 Euros; Portugal, Slovakia, Poland and Romania, 0; Czech Republic, 18 Euros	Data derived from the same sources referred to for yield.
Uruguay	Same as Argentina	Same as Argentina	No country-specific studies identified, so impact analysis from nearest country of relevance (Argentina) applied.	Same as Argentina: +5% to +9%	Same as Argentina	Same as Argentina	Same as Argentina

GM IR corn (resistant to corn rootworm)								
US & Canada	+5% all years	Based on the impact used by the references cited.	Sankula and Blumenthal (2003, 2006) used +5% in analysis, citing this as conservative, themselves having cited impacts of +12%-+19% in 2005 in Iowa, +26% in Illinois in 2005, and +4%-+8% in Illinois in 2004. Johnson and Strom (2007) used the same basis as Sankula and Blumenthal. Rice (2004) range of +1.4% to +4.5% (based on trials) Canada—no studies identified—as US—impacts qualitatively confirmed by industry sources (personal communication, 2005, 2007).	+3% to +9%	2003 & 2004: $42 2005 onwards: $35	2003: $33 2004 onwards: $37	Data derived from Sankula and Blumenthal (2006) and Johnson and Strom (2007). Canada—no studies identified — as US—impacts qualitatively confirmed by industry sources (personal communication, 2005, 2007).
GM HT cotton								
US	0%	Not relevant	Not relevant	Not relevant	$12.85 1996-2000 $21.32 2001-2003 $34.55 2004 $68.22 2005 $70.35 2006 onwards	$34.12 1996-2000 $66.59 2001-2003 $83.35 2004 $71.12 2005 $75.55 2006 onwards	Carpenter and Gianessi (2002) Sankula and Blumenthal (2003, 2006) Johnson and Strom (2007)—these are the only available studies breaking down impact into disaggregated parts.	
Australia	0%	Not relevant	Not relevant	Not relevant	Aus $50 all years	Aus $60 all years	Doyle et al. (2003) Monsanto Australia (personal communication, 2005, 2007, 2008)	
South Africa	0%	Not relevant	Not relevant	Not relevant	133 Rand 2001-2004 101 Rand 2005 165 Rand 2006 onwards	160 Rand all years	No studies identified—based on Monsanto South Africa (personal communication, 2005, 2007, 2008)	
Argentina	0% on area using farm saved seed, +17.4% on area using certified seed	Based on only available data—company monitoring of commercial plots.	No studies identified—based on personal communic-ations with Grupo CEO & Monsanto Argentina (2007, 2008).	+10% to +20% on certified seed area	122 Pesos all years	68 Pesos all years	No studies identified—based on personal communications with Grupo CEO and Monsanto Argentina (2007, 2008).	
Mexico	+3.6%	Based on only available data—company monitoring of commercial plots.	Same as source for cost data	0% to +5% all years	All years: 720 Pesos	All years: 1,150 Pesos	No studies identified—based on personal communications with Monsanto Mexico (2007).	

			IR cotton				
US	1996-2002: +9% 2003 & 2004: +11% 2005 onwards: +10%	Based on the (conserv-ative) impact used by the references cited	Sankula and Blumenthal (2003, 2006) drew on earlier work from Carpenter and Gianessi (2002) in which they estimated the average yield benefit in the 1996-2000 period was +9%. Marra et al. (2002) examined the findings of over 40 state-specific studies covering the period 1996 up to 2000, the approximate average yield impact was +11%. The lower of these two values was used for the period to 2002. The higher values applied from 2003 reflect values used by Sankula and Blumenthal (2006) and Johnson and Strom (2007) that take into account the increasing use of Bollgard II technology, and draws on work by Mullins and Hudson (2004) that identified a yield gain of +12% relative to conventional cotton. The values applied 2005 onwards were adjusted downwards to reflect the fact that some of the GM IR cotton area has still been planted to Bollgard I.	+5% to +15%	1996-2002: $58.27 2003 & 2004: $68.32 2005 onwards: $49.60	1996-2002: $63.26 2003-2005: $74.10 2006 onwards: $41.18	Data derived from the same sources referred to for yield.
China	1997-2001: +8% 2002 onwards: +10%	Average of studies used to 2001. Increase to 10% on basis of industry assess-ments of impact and reporting of unpublished work by Schuchan.	Pray, Huang, Hu, and Rozelle (2002) surveyed farm level impact for the years 1999-2001 and identified yield impacts of +5.8% in 1999, +8% in 2000, and +10.9% in 2001 Monsanto China (personal communication, 2007, 2008)	+6% to +12%	All years to 2005: $46.30 2006 onwards: 366 Yuan	2000: $261 2001: $438 average of these used all other years to 2004 2005 onwards: 1,530 Yuan	Data derived from the same sources referred to for yield.
Australia	None	Studies have usually identified no significant average yield gain.	Fitt (2001) Doyle (2005) James (2002) Commonwealth Scientific and Industrial Research Organisation (CSIRO, 2005)	None applied	(In Australian dollars) 1996 & 1997: $245 1998: $155 1999: $138 2000-2001: $155 2002: $167 2003: $190 2004: $250 2005 onwards: $300	1996: $151 1997: $157 1998: $188 1999: $172 2000-2002: $267 2003: $598 2004: $509 2005 onwards: $553	Data derived from the same sources referred to for yield (Fitt, 2001) covering earlier years of adoption, then CSIRO for later years. For 2006 and 2007 cost of technology values confirmed by personal communication from Monsanto Australia.

Argentina	+30% all years	More conservative of the two pieces of research used	Qaim and De Janvry (2002, 2005) analysis based on farm level analysis in 1999/00 and 2000/01 +35% yield gain, Trigo and Cap (2006) used an average gain of +30% based on work by Elena (2001).	+25% to +35%	All years to 2004: $86 2005 onwards: 116 Pesos	51 Pesos all years	Data derived from the same sources referred to for yield. Cost of technology in 2006 and 2007 also confirmed from industry sources.
South Africa	+24% all years	Lower end of estimates applied	Ismael et al. (2002) identified yield gain of +24% for the years 1998/99 & 1999/2000. Kirsten, Gouse, and Jenkins (2002) for 2000/01 season found a range of +14% (dry crops/large farms) to +49% (small farmers). James (2002) also cited a range of impact between +27% and +48% during the years 1999-2001.	+15% to +40%	All years to 2005: 149 Rand 2006 onwards: 345 Rand	127 Rand all years	Data derived from the same sources referred to for yield. Values for cost of technology and cost of insecticide cost savings also provided/ confirmed from industry sources.
Mexico	1996: +37% 1997: +3% 1998: +20% 1999: +27% 2000: +17% 2001: +9% 2002: +6.7% 2003: +6.4% 2004: +7.6% 2005: +9.25% 2006: +9% 2007: +9.28	Recorded yield impact data used as available for almost all years	The yield impact data for 1997 and 1998 is drawn from the findings of farm level survey work by Traxler et al. (2001). For all other years the data is based on the commercial crop monitoring reports required to be submitted to the Mexican government (Monsanto Mexico, 2005, 2007). As data from this source was not available for 2007, the yield applied in 2007 is the average for the period 2000-2006.	None applied as almost all years are crop-specific estimates	All years to 2005: 540 Pesos 2006 onwards: 760 Pesos	1996 & 1999 onwards: 985 Pesos 1997: $121 1998: $94	Data derived from the same sources referred to for yield
India	2002: +45% 2003: +63% 2004: +54% 2005: +64% 2006 & 2007: +50%	Recorded yield impact used for almost all years	Yield impact data 2002 and 2003 is drawn from Bennett et al. (2004), for 2004 the average of 2002 and 2003 was used. 2005 and 2006 are derived from IMRB (2006, 2007). 2007 impact data based on lower end of range of impacts identified in previous three years (2007 being a year of similar pest pressure to 2006—lower than average).	All years 45% to 65%	(in Rupees) 2002: 2,636 2003: 2,512 2004: 2,521 2005: $2,307 2006 & 2007: 2,211	(in Rupees) 2002: 2,032 2003: 1,767 2004: 1,900 2005: 1,362 2006: 2,308 2007: 1,857	Data derived from the same sources referred to for yield. 2007 cost of technology confirmed from industry sources and cost savings for 2007 taken as average of past three years
Brazil	+6.23%		The only data source identified (unpublished farm survey data—Monsanto Brazil, 2008) has been used covering the 2006 season. This has also been used for 2007.	All years: +4% to +8%	2006 onwards: $40	141 Real	Data derived from the same source referred to for yield.

For GM glufosinate tolerant varieties, the yield differences were +12% in 2004, +19% in 2005, and +10% for 2006 and 2007.		Same as source for cost data	+4% to +12% all years	Can $44.63 all years to 2003 2004 onwards based on difference seed premium and technology fee relative to Clearfields HT canola; $0 for GM glufosinate tolerance and Can $37 for glyphosate tolerance	(In Canadian $) **Glyphosate tolerant** $39 all years to 2003 2004 onwards: $40 **Glufosinate tolerant** All years to 2003: $39 2004 onwards: $10	Based on Canola Council of Canada (2001) to 2003, then adjusted to reflect main current non GM (HT) alternative of 'Clearfields'—data derived from personal communicatio ns with the Canola Council of Canada (2008) and Gusta et al. (2008).

Readers should note that the assumptions are drawn from the references cited, supplemented and updated by industry sources (where the authors have not been able to identify specific studies). This has been particularly of relevance for some of the HT traits more recently adopted in several developing countries. Accordingly, the authors are grateful to industry sources who have provided information on impact, notably on cost of the technology and impact on costs of crop protection. While this information is not derived from detailed studies, the authors are confident that it is reasonably representative of average impacts; in fact, in a number of cases, information provided from industry sources via personal communications has suggested levels of average impact that are lower than those identified in independent studies. Where this has occurred, the more conservative (industry source) data has been used.

GLOBAL IMPACT OF BIOTECH CROPS: SOCIO-ECONOMIC & ENVIRONMENTAL EFFECTS 1996–2007

Graham Brookes & Peter Barfoot, PG Economics Ltd, Dorchester, UK outline the benefits that have been found with the growing of GM crops globally
www.pgeconomics.co.uk

Keywords: yield, cost, income, environmental impact quotient, carbon sequestration, GM crops

Introduction

This paper summarises the findings of research into the global socio-economic and environmental impact of biotech crops in the twelve years since they were first commercially planted on a significant area in 1996. Since then the global area using this technology has grown rapidly to in excess of 100 million hectares, highlighting the popularity of the technology amongst adopting farmers. In contrast, EU farmers have had little opportunity to adopt this technology with only one trait (insect resistant maize) approved for planting and the EU accounting for less than 0.5% of the global biotech crop in 2007. The paper focuses on the farm level economic effects, the production effects, the environmental impact resulting from changes in the use of insecticides and herbicides, and the contribution towards reducing greenhouse gas (GHG) emissions of biotech trait adoption. The research is based on, and draws from, an extensive literature review of impacts globally coupled with some collection and analysis of data, notably relating to pesticide usage. More detailed information and a full list of references can be found by referring to longer papers on this topic by the authors in the peer reviewed journal Agbioforum – www.agbioforum.org or directly from the PG Economics website (see above).

Farm Income Impacts

GM technology has had a significant positive impact on the income of farmers using the technology, derived from a combination of enhanced productivity and efficiency gains (Table 1). In 2007, the direct global farm income benefit from biotech crops was $10.1 billion. This is equivalent to having added 4.4% to the value of global production of the four main crops of soybeans, maize (corn), oilseed rape (canola) and cotton. Since 1996, farm incomes have increased by $44.1 billion. The largest gains in farm income have been in the soybean sector, largely from cost savings. The $3.9 billion additional income generated by GM herbicide tolerant (GM HT) soybeans in 2007 has been equivalent to adding the equivalent of 6.4% to the $60 billion value of this crop in 2007.

Substantial gains have also arisen in the cotton sector through a combination of higher yields and lower costs. In 2007, cotton farm income levels in the biotech adopting countries increased by $3.2 billion and from 1996 to 2007, the sector has benefited from an additional $12.6 billion. In 2007 alone, income gains from GM technology added 10.2% to the $27.5 billion value of total global cotton production, a substantial increase in value added terms for two new cotton seed technologies.

Significant increases to farm incomes have also been seen in the maize and canola sectors. The combination of GM insect resistant (GM IR) and GM HT technology in maize has boosted farm incomes by $7.2 billion since 1996. In the North American canola sector, an additional $1.4 billion has been generated.

Figure 1 summarises farm income impacts in key biotech adopting countries and this highlights the important farm income benefit arising from GM technology in South American countries, China and India and the US. It also illustrates the growing level of farm income benefits being obtained in South Africa, the Philippines and Mexico.

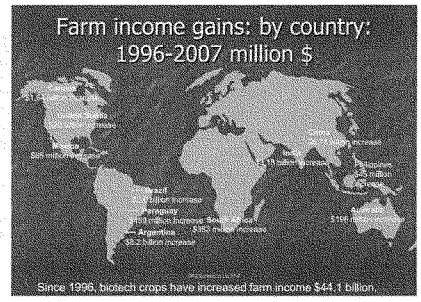

Figure 1

In terms of the division of the economic benefits obtained by farmers in less developed countries relative to farmers in developed countries, in 2007, 58% of the farm income benefits have been earned by less developed country farmers, wth the vast majority of these income gains coming from GM IR cotton and GM HT soybeans.[1] Over the twelve years,

[1] The authors acknowledge that the classification of different countries into less developed or developed country status affects the distribution of benefits between these two categories of country. The definition used in this paper is consistent with the definition used by James (2007)

Table 1. Global farm income benefits from growing biotech crops 1996–2007: million US $

Trait	Increase in farm income 2007	Increase in farm income 1996–2007	Farm income benefit in 2007 as % of total value of production of these crops in biotech adopting countries	Farm income benefit in 2007 as % of total value of global production of crop
GM herbicide tolerant soybeans	3,935.5	21,814.1	7.2	6.4
GM herbicide tolerant maize	442.3	1,507.6	0.7	0.4
GM herbicide tolerant cotton	24.5	848.2	0.1	0.1
GM herbicide tolerant canola	345.6	1,438.6	7.65	1.4
GM insect resistant maize	2,075.3	5,673.6	3.2	1.9
GM insect resistant cotton	3,204.0	12,576.2	16.5	10.2
Others	54.4	208.8	Not applicable	Not applicable
Totals	**10,081.6**	**44,067.1**	**6.9**	**4.4**

Notes: All values are nominal. Others = Virus resistant papaya and squash. Totals for the value shares exclude 'other crops' (ie, relate to the 4 main crops of soybeans, maize, canola and cotton). Farm income calculations are net farm income changes after inclusion of impacts on yield, crop quality and key variable costs of production (eg, payment of seed premia, impact on crop protection expenditure)

Table 2. Cost of accessing GM technology (million $) relative to the total farm income benefits 2007

	Cost of technology: all farmers	Farm income gain: all farmers	Total benefit of technology to farmers and seed supply chain	Cost of technology: less developed countries	Farm income gain: less developed countries	Total benefit of technology to farmers and seed supply chain: less developed countries
GM HT soybeans	930.8	3,935.5	4,866.3	326	2,560.5	2,886.5
GM IR maize	714.3	2,075.3	2,789.6	79.1	301.9	381
GM HT maize	530.8	442.3	973.1	20.2	40.8	61
GM IR cotton	670.4	3,204.0	3,874.4	535.1	2,918.1	3,353.2
GM HT cotton	226.4	24.5	250.9	8.5	8.2	16.7
GM HT canola	102.2	345.6	447.8	N/a	N/a	N/a
Total	**3,174.9**	**10,027.2**	**13,202.1**	**968.9**	**5,829.5**	**6,798.4**

N/a = not applicable. Cost of accessing technology based on the seed premia paid by farmers for using GM technology relative to its conventional equivalents. Total farm income gain excludes $54.4 million associated with virus resistant crops in the US

1996-2007, the cumulative farm income gain derived by less developed country farmers was $22.1 billion (50.1% of the total).

Examining the cost farmers pay for accessing GM technology, Table 2 shows that across the four main biotech crops, the total cost in 2007 was equal to 24% of the total technology gains (inclusive of farm income gains plus cost of the technology payable to the seed supply chain[2]). For farmers in less developed countries the total cost was equal to 14% of total technology gains, whilst for farmers in developed countries the cost was 34% of the total technology gains. These differences are accounted for by factors such as weaker provision and enforcement of intellectual property rights in less developed countries and the higher average level of farm income gain on a per hectare basis derived by less developed country farmers.

Indirect (non pecuniary) Farm Level Impacts

As well as the more tangible and quantifiable impacts on farm profitability presented above, there are other important, more intangible (difficult to quantify) impacts of an economic nature that studies have identifed. The main ones are:

For herbicide tolerant crops the main benefits are:

- increased management flexibility and convenience that comes from a combination of the ease of use associated with broad-spectrum, post emergent herbicides like glyphosate and the wider window for spraying;
- reduced damage to crops by inputs. In a conventional crop, post-emergent weed control relies on herbicide applications before the weeds and crop are well established to achieve maximum efficacy. As a result, the crop may suffer 'knock-back' to its growth from the effects of the herbicide. In a GM HT crop, this problem is avoided because the crop is both tolerant to the herbicide and spraying can occur at a later stage when the crop is better able to withstand any possible "knock-back" effects;
- facilitation of the adoption of conservation or no tillage systems. This provides additional cost saving benefits such as reduced labour and fuel costs associated with ploughing, in addition to greater moisture retention and reductions in levels of soil erosion;
- improvements in levels of weed control. This has contributed to reduced harvesting costs – cleaner crops have resulted in reduced times for harvesting. It has also improved harvest quality and led to higher levels of quality price bonuses in some regions and years (eg, HT soybeans and HT canola in the early years of adoption respectively in Romania and Canada[3]);
- elimination of potential damage caused by soil-incorporated residual herbicides in follow-on crops;
- reduced need to apply herbicides in a follow-on crop because of the improved weed control.

For insect resistant crops the main benefits are:

- improved production risk management – the technology takes away much of the worry of significant pest damage occurring and is, therefore, highly valued;
- reduced management time. A 'convenience' benefit from having to devote less time to crop walking and applying insecticides;
- savings in energy use – mainly associated with less use of aerial spraying;
- savings in machinery use (for spraying and possibly reduced harvesting times[4]);
- better crop quality. There is a growing body of research evidence[5] relating to the superior quality of GM IR corn relative to conventional and organic corn from the perspective of having lower levels of mycotoxins;
- improved health and safety for farmers and farm workers, from reduced handling and use of pesticides, especially in less developed countries where many apply pesticides with little or no use of protective clothing and equipment;
- shorter growing season (eg, for some cotton growers in India) which allows some farmers to plant a second crop in the same season[6];
- benefits to the local environment from reduced spraying. For example, Some Indian cotton growers have reported knock on benefits for bee keepers as fewer bees are now lost to insecticide spraying.[7]

Since the early 2000s, a number of farmer-survey based studies in the US have attempted to quantify these non pecuniary benefits. These studies have usually employed contingent valuation techniques.[8] Drawing on this analysis, the estimated value for non pecuniary benefits derived from biotech crops in the US (1996-2007) is $5.11 billion, equal to 26% of the total cumulative (1996-2007) direct farm income. Similar benefits are likely likely to have accrued in other countries, but have not yet been quantified.

Production Effects on the Technology

Based on the yield assumptions used in the direct farm income benefit calcuations presented above and taking account of the second soybean crop facilitation in South

[2] The cost of the technology accrues to the seed supply chain including sellers of seed to farmers, seed multipliers, plant breeders, distributors and the GM technology providers

[3] See for example Brookes (2005) relating to Romania and the Canola Council (2001) relating to Canada cited in the full Brookes & Barfoot (2009) paper

[4] For example, when there is lower incidence of crops falling over slowing the speed of harvesting equipment – a notable benefit of GM IR technology in maize – see for example Brookes (2002) relating to Spain, cited in the full Brookes & Barfoot (2009) paper

[5] See Brookes (2008) relating to the adoption of Bt maize in Europe, cited in the full Brookes & Barfoot (2009)

[6] Notably maize in India – see for example, Manjunath T (2008) cited in the full Brookes & Barfoot (2009) paper

[7] Manjunath T (2008) cited in the full Brookes & Barfoot (2009) paper

[8] Survey based method of obtaining valuations of non market goods that aim to identify willingness to pay for specific goods (eg, environmental goods, peace of mind, etc) or willingness to pay to avoid something being lost

America (see below), biotech crops have made important contributions to global production of corn, cotton, canola and soybeans since 1996 (Table 3). The biotech IR traits, used in the corn and cotton sectors, have accounted for 99% of the additional corn production and almost all of the additional cotton production and since 1996 the average yield impact across the total area planted to these traits over the 12 year period has been +6.1% for corn traits and +13.4% for cotton traits.[9]

Table 3. Additional crop production arising from positive yield effects of biotech crops

	1996–2007 additional production (million tonnes)	2007 additional production (million tonnes)
Soybeans	67.80	14.46
Corn	62.42	15.08
Cotton	6.85	2.01
Canola	4.44	0.54

Although the primary impact of biotech HT technology has been to provide more cost effective (less expensive) and easier weed control versus improving yields from better weed control (relative to weed control obtained from conventional technology), improved weed control has, nevertheless occurred, delivering higher yields in some countries. Specifically, HT soybeans in Romania improved the average yield by over 30% and biotech HT corn in Argentina and the Philippines delivered yield improvements of +9% and +15% respectively.[10]

Biotech HT soybeans have also facilitated the adoption of no tillage production systems, shortening the production cycle (eg, by not needing to plough). This advantage enables many farmers in South America to plant a crop of soybeans immediately after a wheat crop in the same growing season. This second crop, additional to traditional soybean production, has added 67.5 million tonnes to soybean production in Argentina and Paraguay between 1996 and 2006 (accounting for 99% of the total biotech-related additional soybean production).[11]

Impact on Pesticide Use and the Associated Environmental Impact

To examine the environmental impact of pesticide use with biotech crops, studies have analysed both active ingredient use and utilised the indicator known as the Environmental Impact Quotient (EIQ[12]) to assess the broader impact on the environment (plus impact on animal and human health). The EIQ distils the various environmental and health impacts of individual pesticides and agricultural practices in different production systems into a single 'field value per hectare' by drawing on all of the key toxicity and environmental exposure data related to individual products. It therefore provides a consistent and fairly comprehensive measure to compare the impact of crop protection practices in various production systems (be they GM, conventional or organic) on the environment and human health. Table 4 summarises the environmental impact over the last twelve years and shows that there have been important environmental gains associated with adoption of biotechnology. More specifically, the analysis presented in the full Brookes & Barfoot (2009) paper shows that:

- Since 1996, the quantity of herbicides and insecticides applied to the biotech crop area was reduced by 359 million kg of active ingredient (8.8% reduction). The overall environmental impact associated with their use on these crops was reduced by 17.2%;
- In absolute terms, the largest environmental gain has been associated with the adoption of GM HT soybeans, which reflects the large share of global soybean plantings accounted for by biotech varieties. The volume of herbicides used in biotech soybean crops decreased by 73 million kg (1996-2007), a 4.6% reduction, and, the overall environmental impact associated with herbicide use on these crops decreased by 20.9% (compared to the probably impact if this cropping area had been planted to conventional soybeans). However, it should be noted that in some countries, such as in South America, the adoption of GM HT soybeans coincided with increases in the volume of herbicides used relative to historic levels on a number of arable crops (both GM and conventional). This largely reflects the facilitating role of the GM HT technology in accelerating and maintaining the switch away from conventional tillage to no/low tillage production systems with their inherent other environmental benefits (notably reductions in greenhouse gas emissions and reduced soil erosion). Despite this net increase in the volume of herbicides used in some countries, the associated EIQ values still fell, as farmers switched to herbicides with a more environmentally benign profile;
- Major environmental gains have also been derived from the adoption of GM IR cotton. These gains were the largest of any crop on a per hectare basis. Since 1996, farmers have used 147.6 million kg less insecticide in GM IR cotton crops (a 23% reduction), and this has reduced the associated environmental impact of insecticide use on this crop area by 27.8%;
- Important environmental gains have also arisen in the maize and canola sectors. In maize, herbicide and insecticide use decreased by 92 million kg and the associated environmental impact on this crop area

[9] See the full Brookes & Barfoot (2009) paper for additional information

[12] Developed at Cornell University

Table 4. Impact of changes in the use of herbicides and insecticides from growing biotech crops globally 1996–2007

Trait	Change in volume of active ingredient used (million kg)	Change in field EIQ impact (in terms of million field EIQ/ha units)	% change in ai use on biotech crops	% change in environmental impact associated with herbicide & insecticide use on biotech crops
GM herbicide tolerant soybeans	–730.0	–6,283	–4.6	–20.9
GM herbicide tolerant maize	–81.8	–1,934	–6.0	–6.8
GM herbicide tolerant cotton	–37.0	–748	–15.1	–16.0
GM herbicide tolerant canola	–9.7	–443	–13.9	–25.8
GM insect resistant maize	–10.2	–528	–5.9	–6.0
GM insect resistant cotton	–147.6	–7,133	–23.0	–27.8
Totals	**–359.3**	**–17,069**	**–8.8**	**–17.2**

decreased, due to a combination of reduced insecticide use (5.9%) and a switch to more environmentally benign herbicides (6%). In canola, farmers reduced herbicide use by 9.7 million kg (a 13.9% reduction) and the associated environmental impact of herbicide use fell by 25.8% (due to a switch to more environmentally benign herbicides).

Fifty two per cent of the environmental benefits (1996-2007) associated with lower insecticide and herbicide use have been in less developed countries, the vast majority of which have been from the use of GM IR cotton and GM HT soybeans.

Impact on Greenhouse Gas (GHG) Emissions

Biotech crops contribute to lower levels of GHG emissions in two principle ways[13]:

- Reduced fuel use from less frequent herbicide or insecticide applications and a reduction in the energy use in soil cultivation. In 2007, this amounted to about 1,144 million kg of carbon dioxide savings (arising from reduced fuel use of 416 million litres). Over the period 1996 to 2007 the cumulative permanent carbon dioxide reduction is estimated at 7,090 million kg of carbon dioxide (arising from reduced fuel use of 2,578 million litres);
- Use of 'no-till' and 'reduced-till'[14] farming systems. These production systems have increased significantly with the adoption of GM HT crops because the technology has improved growers ability to control competing weeds, without the need to rely on soil cultivation and seed-bed preparation. As a result, tractor fuel use for tillage is reduced (see above), soil quality is enhanced and levels of soil erosion cut. In turn, more carbon remains in the soil and this leads to lower GHG emissions. As a result of the rapid adoption of no till/reduced tillage farming systems in North and South America, an extra 3,570 million kg of soil carbon is estimated to have been sequestered in 2007 (equivalent to 13,103 million tonnes of carbon dioxide that has not been released into the global atmosphere). Cumulatively the amount of carbon sequestered may be higher due to year-on-year benefits to soil quality.[15] However, with only an estimated 15%-25% of the crop area in continuous no-till systems it is currently not possible to estimate confidently cumulative soil sequestration gains.

[13] Additional details about how these values are calculated and associated references can be found in the full Brookes & Barfoot (2009) paper. Limited availability of space for this article means full details cannot provided here and therefore interested readers should consult the full report

[14] No-till farming means that the ground is not ploughed at all, while reduced tillage means that the ground is disturbed less than it would be with traditional tillage systems. For example, under a no-till farming system, soybean seeds are planted through the organic material that is left over from a previous crop such as corn, cotton or wheat

[15] The optimum conditions for soil sequestration are high biomass production of both surface residue and decaying roots that decompose in moist soils where aeration is not limiting

Placing these carbon sequestration benefits within the context of the carbon dioxide emissions from cars, Table 5 shows that:

- In 2007, the permanent carbon dioxide savings from reduced fuel use were the equivalent of removing nearly 495,000 cars from the road for a year;
- The additional probable soil carbon sequestration gains in 2007 were equivalent to removing nearly 5.823 million cars from the roads for a year;
- In total, the combined biotech crop-related carbon dioxide emission savings from reduced fuel use and additional soil carbon sequestration in 2007 were equal to the removal from the roads for a year of nearly 6.3 million cars, equivalent to about 24% of all registered cars in the UK;
- It is not possible to estimate confidently the soil carbon sequestration gains since 1996. If the entire biotech crop in reduced or no tillage agriculture during the last twelve years had remained in permanent reduced/no tillage then this would have resulted in a carbon dioxide saving of 83.18 million kg, equivalent to taking 36.97 million cars off the road for a year. This is, however a maximum possibility and the actual levels of carbon dioxide reduction are likely to be lower.

Table 5. Biotech crop environmental benefits from lower insecticide and herbicide use 1996–2007: developing versus developed countries

	Change in field EIQ impact (in terms of million field EIQ/ha units): developed countries	Change in field EIQ impact (in terms of million field EIQ/ha units): less developed countries
GM HT soybeans	–3,559	–2,724
GM IR maize	–516	–12
GM HT maize	–1,910	–23
GM IR cotton	–1,053	–6,080
GM HT cotton	–726	–22
GM HT canola	–444	Not applicable
Total	**–8,208**	**–8,862**

Concluding comments

Biotechnology has, to date, delivered several specific agronomic traits that have overcome a number of production constraints for many farmers, decreased pesticide spraying and signficantly boosted farm incomes. In addition, this has contributed to reducing the release of greenhouse gas emissions from agriculture. The technology has also made important contributions to increasing the yields of many farmers, reducing production risks, improving productivity and raising global production of key crops. This combination of economic and environmental benefit delivery is, therefore, already making a valuable contribution to improving the sustainability of global agriculture, with these benefits and improvements being greatest in less developed countries.

Table 6. Context of carbon sequestration impact 2007: car equivalent

Crop/trait/country	Permanent carbon dioxide savings arising from reduced fuel use (million kg of carbon dioxide)	Average family car equivalents removed from the road for a year from the permanent fuel savings ('000s)	Potential additional soil carbon sequestration savings (million kg of carbon dioxide	Average family car equivalents removed from the road for a year from the potential additional soil carbon sequestration ('000s)
US: GM HT soybeans	247	110	3,999	1,777
Argentina: GM HT soybeans	609	271	6,136	2,727
Other countries: GM HT soybeans	91	40	1,341	596
Canada: GM HT canola	131	58	1,627	723
Global GM IR cotton	37	16	0	0
Total	**1,115**	**495**	**13,103**	**5,823**

Notes: Assumption: an average family car produces 150 grams of carbon dioxide of km. A car does an average of 15,000km/year and therefore produces 2,250kg of carbon dioxide/year

Graham Brookes is an agricultural economist and consultant who has, over the last twelve years, undertaken a number of research projects relating to the impact of agricultural biotechnology and written widely on the subject. This work includes annual updates of the global economic and environmental impact of GM crops since 1996, papers on co-existence of GM and non GM crops, the possible impact of GM crops in the a number of EU countries (eg, UK, Poland, Slovakia and Hungary), the actual impact of insect resistant maize in Spain and herbicide tolerant soybeans in Romania, GM crop market dynamics and GM rice crop developments to 2012, the impact of GMO labelling in Europe, the economic impact of GMO zero tolerance legislation and the cost to the UK economy of failure to embrace agricultural biotechnology.

Peter Barfoot is a specialist in biotechnology, having previously worked for the Agricultural Genetics Company (UK) and now runs the successful Bioportfolio.com website. He formed PG Economics with Graham in 1999 specifically to undertake research consultancy projects focusing on the impact of new technology in agriculture. He has co-authored several papers on the impact of biotechnology in agriculture (see above) with Graham Brookes.

SCI
where science meets business

Future Prospects for Chemical Insecticides: A Symposium for Michael Elliott

Thursday 21 January 2009
Rothamsted Research, UK

The importance of chemistry in delivering food security is vital, especially in aspects such as crop protection from herbivorous pests and intervention against insect vectors of human pathogens such as malaria.

The symposium will bring together scientists in the fields of chemical lead discovery, lead development, applications, environmental health, resistance management and modes of action, areas that must work synergistically to meet challenges related to food security, which can no longer be taken for granted.

Biotech crops have now been grown commercially on a substantial global scale since 1996. This article examines the production effects of the technology and impacts on cereal and oilseed markets through the use of agricultural commodity models. It analyses the impacts on global production, consumption, trade, and prices in the soybean, canola, and corn sectors. The analysis suggests that world prices of corn, soybeans, and canola would probably be, respectively, 5.8%, 9.6%, and 3.8% higher, on average, than 2007 baseline levels if this technology was no longer available to farmers. Prices of key derivatives of soybeans (meal and oil) would also be between 5% and 9% higher, with rapeseed meal and oil prices being about 4% higher than baseline levels. World prices of related cereals and oilseeds would also be expected to be higher by 3% to 4%.

Key words: biotech crops, prices, yield, soybeans, corn, canola, partial-equilibrium model, price effects.

The effect of no longer using the current widely used biotech traits in the corn, soybean, and canola sectors would probably impact negatively on both the global supply and utilization of these crops, their derivatives and related markets for grain and oilseeds. The modeling suggests that average global yields would fall for corn, soybeans, and canola and despite some likely 'compensatory' additional plantings of these three crops, there would be a net fall in global production of the three crops of 14 million tonnes. Global trade and consumption of these crops/derivatives would also be expected to fall. The production and consumption of other grains such as wheat, barley, and sorghum and oilseeds—notably sunflower—would also be affected. Overall, net production of grains and oilseeds (and derivatives) would fall by 17.7 million tonnes, and global consumption would fall by 15.4 million tonnes. The cost of consumption would also increase by $20 billion (3.6%) relative to the total cost of consumption of the (higher) biotech-inclusive level of world consumption. The impacts identified in this analysis are, however, probably conservative, reflecting the limitations of the methodology used. In particular, the limited research conducted to date into the impact of the cost-reducing effect of biotechnology (notably in herbicide-tolerant [HT] soybeans) on prices suggests that the price effects identified in this article represent only part of the total price impact of the technology.

Introduction

Biotechnology crop traits have been grown on a widespread commercial global basis since 1996, and in 2008, the global cultivation area of biotech crops reached 125 million hectares, a 74-fold increase from the 1996 level. The number of countries adopting biotech crop cultivation has also increased from six in 1996 to 25 in 2008, with the United States leading the way in the utilization of biotechnology in crop production. The rapid growth of biotech crop hectares between 1996 and 2008 has made this the most rapidly adopted crop technology in agriculture over this period (James, 2008).

Currently, the biotech crop hectares are primarily utilized for soybeans, corn, cotton, and canola. The technology used thus far has been agronomic, cost-saving technology delivering herbicide tolerance in all four of these crops and insect resistance in the crops of corn and cotton. This technology has provided farmers with productivity improvements through a combination of yield improvement and cost reductions. As such, the technology is likely to have had an impact on the prices of soybeans, corn, cotton, and canola (and their derivatives) both in the countries where farmers have used biotech traits and in the global market.

Assessing the impact of the biotechnology applications on the prices of soybeans, corn, cotton, and canola (and their derivatives) is challenging since current and past prices reflect a multitude of factors—of which the introduction and adoption of new, cost-saving technologies is one. This means that disaggregating the effect of different variables on prices is far from easy. Previous

studies have contributed to the literature by evaluating the impacts of biotechnology application for field crops on national/regional economies and farmers' welfare (e.g., Anderson, Valenzuela, & Jackson, 2008; Martin & Hyde, 2001; Sobolevsky, Moschini, & Lapan, 2005). However, most of these studies primarily focused on a single crop, such as soybeans, corn, or cotton. Thus, the impact analysis of biotechnology adoption did not capture the responsiveness of the production of other crops. Furthermore, since the application of biotechnology usually occurs in various field crops, the joint impacts of biotechnology adoption on local and global agricultural markets need to be further explored.

Realizing the surging significance of biotechnology application in the US and global crop markets, this article summarizes the productivity impacts of biotech crops[1] (on production) and presents the findings of analysis that has sought to quantify the impact of the use of biotech traits on usage and the prices of corn, soybeans, and canola and their main derivatives.[2]

Methodology

The approach used to estimate the impacts of biotech crops on usage, trade, and prices of the three crops and their derivatives has been to draw on part of a broad modelling system of the world agricultural economy comprised of US and international multi-market, partial-equilibrium models of production, use, and trade in key agricultural commodities.[3] The models cover major temperate crops, sugar, ethanol and biodiesel, dairy, and livestock and meat products for all major producing and consuming countries and calibrated on most recently available data. Extensive market linkages exist in these models, reflecting derived demand for feed in livestock and dairy sectors, competition for land in production, and consumer substitution possibilities for close substitutes such as vegetable oils and meat types. The models capture the biological, technical, and economic relationships among key variables within a particular commodity and across commodities. They are based on historical data analysis, current academic research, and a reliance on accepted economic, agronomic, and biological relationships in agricultural production and markets. A link is made through prices and net trade equations between the US and international models. The models are used to establish 10-year commodity projections for a baseline and for policy analysis and are used extensively for the market outlook and policy analysis.

In general, for each commodity sector, the economic relationship that supply equals demand is maintained by determining a market-clearing price for the commodity. In countries where domestic prices are not solved endogenously, these prices are modelled as a function of the world price using a price transmission equation. Since the models for each sector can be linked, changes in one commodity sector will impact other sectors. For this particular study, the US Crops, International Grains, International Oilseed, International Sugar, and International Bio-fuels models were used.

In terms of the structure of the models, the following identity is satisfied for each country/region and the world.

$$\text{Beginning Stock} + \text{Production} + \text{Imports} = \text{Ending Stock} + \text{Consumption} + \text{Exports} \quad (1)$$

Production is divided into yield and area equations, while consumption is divided into feed and non-feed demand. The models include behavioral equations for area harvested, yield, crop production on the supply side, and per-capita consumption and ending stocks on the demand side. Equilibrium prices, quantities, and net trade are determined by equating excess supply and excess demand across countries and regions.

More specifically, in terms of acreage, harvested area is expressed as a function of own and competing crop prices in real terms as well as lagged harvested area and prices. Prices enter area functions either as part of real gross returns per unit of land (price multiplied by yield) or merely as prices, depending on the particular commodity model. The US model, because of extensive data availability, is divided into nine regions. The planted area for each crop within each region depends on expected net returns—which include real, variable production expenses per unit of land—for the crop and competing crops.

To satisfy the identity in Equation 1, two different methods are used. In most of the countries, domestic price is modelled as a function of the world price with a price transmission equation, and the identity is satisfied with one of the variables set as the residual. In other cases, prices are solved to satisfy the identity.

1. *Drawing primarily on work by one of the authors, Brookes and Barfoot (2008). A more detailed paper is also available on http://www.pgeconomics.co.uk/pdf/globalimpactstudyjune2008pgeconomics.pdf.*
2. *The impact of biotech traits in the cotton sector is not included in the analysis.*
3. *More details about the modelling structure are presented in Appendix A.*

Agricultural and trade policies in each country are included in the models to the extent that they affect the supply and demand decisions of the economic agents. The models assume that the existing agricultural and trade policy variables will remain unchanged in the outlook period. Macroeconomic variables, such as GDP, population, and exchange rates, are exogenous variables that drive the projections of the model. All models are calibrated on 2007/08 marketing year data for crops; 10-year annual projections for supply and utilization of commodities and prices for the US and the world are generated for the period between 2008 and 2017. Elasticity values for supply and demand responses are based on econometric analysis and on consensus estimates. Elasticity parameters estimates and policy variables are available at Iowa State University's Food and Agricultural Policy Research Institute (FAPRI) website.[4]

Data for commodity supply and utilization are obtained from the F.O. Lichts online database, the Food and Agriculture Organization (FAO) of the United Nations (FAOSTAT Online, 2006), the Production, Supply, and Distribution View (PS&D) of the US Department of Agriculture (USDA), the European Commission Directorate General for Energy and Transport, the ANFAVEA (2005), and UNICA (2006). Supply and utilization data include production, consumption, net trade, and stocks. The macroeconomic data are gathered from the International Monetary Fund and Global Insight.

The empirical analysis relies on these agricultural commodity models of the main regions of the world (e.g., North and South America, the EU-27, etc.) to estimate the impact on national, regional, and world markets and prices for cereals and oilseeds. These models have been developed to allow for forward-looking projections (over a 10-year period) to be made relating to production, use, trade, and prices of key commodities. The models are not directly able to estimate the impact of the technology on past prices (of corn, soybeans, and canola and their key derivatives). One advantage of these models is that it is possible to establish a baseline and then remove the impact of biotechnology on yields. This allows the isolation of the impact on prices and usage due to biotech crops and not due to other factors such as macroeconomic and weather variables. However, the models *do not* allow for estimating the impact on crop prices arising from changes to the cost base of crop production (a major impact of HT technology). Some (limited) economic analysis has been previously undertaken to estimate the impact of biotechnology-induced cost-of-production changes, notably on the global prices of soybeans. Moschini, Lapan, and Sobolevsky (2000) estimated that by 2000 the influence of biotech soybean technology on world prices of soybeans had been between -0.5% and -1%, and that as adoption levels increased this could be expected to increase up to -6% (if all global production was biotech). Qaim and Traxler (2002, 2005) estimated the impact of GM HT soybean technology adoption on global soybean prices to have been -1.9% by 2001. Based on this analysis, they estimated that by 2005 it was likely that the world price of soybeans may have been lower by between 2% and 6% than it might otherwise have been in the absence of biotechnology. This benefit will have been dissipated through the post-farm gate supply chain, with some of the gains having been passed onto consumers in the form of lower real prices. We, therefore, acknowledge the failure to include the potential impact of biotechnology on costs of production and prices as a limitation of the research, which potentially underestimates the impact of the technology on prices. In addition, the analysis uses 2007 as the baseline against which the analysis is run. This assumes that the level of biotech trait adoption in 2007 represents the 'counterfactual situation.' In doing so, it fails to take into account likely trends in biotech trait adoption post 2007 and hence, this additional weakness of the analysis probably contributes further to understating the price effect of biotechnology. Despite these methodological weaknesses, the approach used in this article provides a useful tool for assessing the impact of biotech traits on the prices of corn, canola, soybeans, and derivatives of these crops on global markets.

Yield and production change assumptions for the impact of biotech crops were used as bases for analysis in the models by projecting forward a 'what if' scenario in which the currently used biotech traits were no longer available. The yield and production change assumptions used were those identified in the published work of Brookes and Barfoot (2008).[5] For example, insect-resistant (IR) corn technology in the United States has delivered an average 5% improvement in corn yields. The Brookes and Barfoot analysis is itself based on a literature review of impacts of biotechnology traits globally

5. *Also available at http://www.pgeconomics.co.uk. The specific yield impacts used derive from Appendix 2 of the AgBioForum article (2008).*

Table 1. Corn: Yield and production impact of IR traits, 1996-2006.

	Cumulative total corn area (ha)[a]	Cumulative trait area (ha)	% of crop to trait[b]	Average trait impact on yield %[c]	Average yield impact (tonnes/ha)	Additional production from trait (tonnes)
US corn-borer resistant	351,842,503	81,016,473	23%	+5.0%	+0.45	36,078,447
US corn-rootworm resistant	As above	6,596,520	1.9%	+5.0%	+0.45	3,130,130
Canada corn-borer resistant	13,269,070	4,239,214	31.9%	+5.0%	+0.38	1,628,075
Canada corn-rootworm resistant	As above	35,317	0.3%	+5.0%	+0.38	14,537
Argentina corn-borer resistant	23,951,406	10,024,000	41.9%	+7.6%	+0.49	4,862,787
Philippines corn-borer resistant	10,082,808	247,698	2.5%	+24.1%	+0.52	127,920
South Africa corn-borer resistant	21,909,720	2,392,000	10.9%	+14.5%	+0.43	1,034,735
Uruguay corn-borer resistant	184,000	100,000	54.3%	+6.1%	+0.31	30,559
Spain corn-borer resistant	4,013,343	303,656	7.6%	+7.6%	+0.72	218,132
Cumulative totals	**425,252,850**	**104,954,778**	**24.7**	**+5.7%**	**+0.45**	**47,125,322**
2006	**41,751,216**	**20,640,503**	**49%**	**+6.7%**	**+0.47**	**9,734,898**

[a] *For consistency purposes, the total areas presented refer only to the years in which the IR traits were used by farmers—from 1996 in the US and Canada, from 1998 in Spain and Argentina, from 2000 in South Africa, from 2003 in the Philippines, and from 2004 in Uruguay. Corn rootworm-resistant corn has also been available to US farmers from 2003 and to Canadian farmers from 2004.*

[b] *From year of first commercial planting to 2006.*

[c] *Average of impact over years of use, as used by Brookes and Barfoot (2008).*

since 1996, and details of the specific country and trait-specific studies used can be found in the references section of this article. To analyze the impact of this yield improvement, first a baseline is established (starting in 2008, and for the next 10 years covered by the model projections) with the trend growth rate of yield. Then a scenario is run where the yields were effectively lower than the baseline level (starting in 2008 and ending in 2017). The baseline represents the current status quo (technology used) and the scenario implies that the technology is no longer available. The difference between the baseline and scenario represents the impact of the technology (or more literally the impact of no longer using the technology).

The models effectively assume the decreases in average crop (e.g., corn) yield in the countries using GM technology as a 'shock' change to the various regional parts of the models. This then calculates revised yield values, changes in production and consumption, changes in stocks, changes in imports and exports, and changes in areas allocated to other crops. 'Knock-on' effects[6] on the price of each crop (corn, soybeans, and canola) plus effects on other crop (e.g., wheat, barley, sunflower) were also derived, both at a regional and a world level. Knock-on effects on derivatives of corn, soybeans, and canola are also derived.

Production and Yield Assumptions

The production and yield change assumptions used in this analysis derive from the work of Brookes and Barfoot (2008), which itself draws on numerous crop and country-level impact studies. The next section (*Production and Yield Impacts of Biotech Crops*) provides a summary of this data, and the assumptions used for the analysis are presented in the following section (*Conversion of Production and Yield Impacts into Useable Assumptions*).

6. *Indirect effects on the prices of derivatives as a result of changes in the price of the base commodities (e.g., a change in the price of soybeans affecting the price of soymeal). Also, the effect on prices arising from changes in production levels.*

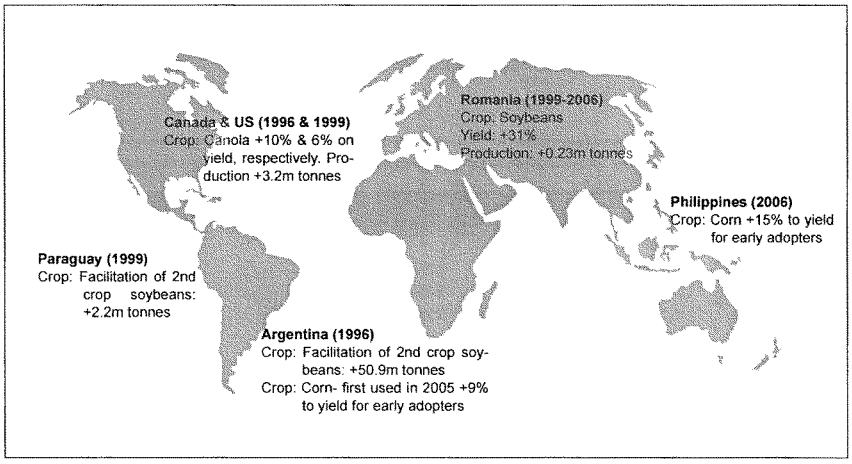

Figure 1. Herbicide-tolerant crops: Yield and production impact of biotechnology 1996-2006 by country.

Production and Yield Impacts of Biotech Traits

IR Corn Impacts. Two biotech IR traits have been commercially used to target the common corn-boring pests—European corn borer or ECB (*Ostrinia nubilalis*) and Mediterranean stem borer or MSB (*Sesamia nonagroides*)—and corn rootworm pests (*Diabrotica*). These are major pests of corn crops in many parts of the world and significantly reduce yield and crop quality, unless crop-protection practices are employed.

The two biotech IR corn traits have delivered positive yield impacts in all user countries when compared to average yields derived from crops using conventional technology (mostly application of insecticides and seed treatments) for control of corn-boring and rootworm pests.

The yield impact varies from an average of about +5% in North America to +24% in the Philippines (Table 1). In terms of additional production, on an area basis, this is in a range of +0.31 tonnes/ha to +0.72 tonnes/ha.

Average yield and production impact across the total area planted to biotech IR corn traits over the 11-year period has been +5.7% (+0.45 tonnes/ha). This has added 47 million tonnes to total corn production in the countries using the technology.

In 2006, the technology delivered an average of 0.47 tonnes/ha in extra production, which was equal to an extra 9.7 million tonnes of corn production (Table 1).

HT Soybeans. Weeds have traditionally been a significant problem for soybean farmers, causing important yield losses (from weed competition for light, nutrients, and water). Most weeds in soybean crops have been reasonably well controlled, based on application of a mix of herbicides.

Although the primary impact of biotech HT technology has been to provide more cost effective (less expensive) and easier weed control versus improving yields from *better weed control* (relative to weed control obtained from conventional technology), improved weed control has, nevertheless occurred, delivering higher yields. Specifically, HT soybeans in Romania improved the average yield by over 30% (Figure 1).

Biotech HT soybeans have also facilitated the adoption of no-tillage production systems, thus shortening the production cycle. This advantage enables many farmers in South America to plant a crop of soybeans immediately after a wheat crop in the same growing season. This second crop, additional to traditional soybean production, has added 53.1 million tonnes to soybean production in Argentina and Paraguay between 1996 and 2006. In 2006, the second-crop soybean production in these countries was 11.6 million tonnes (Table 2).

Table 2. Second crop soybean production facilitated by biotech HT technology in South America 1996-2006 (million tonnes).

Country	Year first commercial use of HT soybean technology	Second-crop soybean production from date of first commercial use to 2006
Argentina	1996	50.9
Paraguay	1999	2.2
Total		53.1

Table 3. Yield impact assumptions: To lower average yields for countries/crops assuming no biotech used from 2008 onwards.

Crop/country	Average yield/production effect on biotech area 2006	% of crop to trait (2006)	Yield impact of technology related to average yield on total crop if no longer used
Corn			
US	+5%	49%	-2.45%
Canada	+5%	50%	-2.45%
Argentina	+7.6%	73%	- 5.55%
Philippines	+24.1%	4%	-0.97%
South Africa	+14.5%	35%	-5.1%
EU-27	+6.1% (Spain)	15% of Spain, 3.3 % of EU-27 area	-0.2% on EU-27 average yield
Soybeans			
EU-27	+31% (Romania)	26% of EU-27 area	-8.1%
Paraguay	+7.5% second crop	7.5%	-7.5%
Argentina	+20% second crop	20%	-20%
Canola			
US	6%	98%	-5.9%
Canada	+3.7%	84%	-3.1%

HT Canola. Weeds represent a significant problem for canola growers because they contribute to reduced yield and impair quality by contamination (e.g., with wild mustard seeds). Conventional canola weed control is based on a mix of herbicides, and it has provided reasonable levels of control, although some resistant weeds have developed (e.g., to the herbicide trifluralin). Canola is also sensitive to herbicide carryover from (herbicide) treatments in preceding crops, which can affect yield.

The main impact of biotech HT canola technology—used widely by canola farmers in Canada and the United States—has been to provide more cost-effective (less expensive) and easier weed control, coupled with higher yields. The higher yields have arisen mainly from more effective levels of weed control than were previously possible using conventional technology. Some farmers have also obtained yield gains from biotech-derived improvements in the yield potential of some HT canola seed.

The average yield impacts have been about +6% (+0.1 tonnes/ha) in the United States and about +10% (+0.15 tonnes/ha) in Canada (Figure 1). Over the 1996-2006 period, the additional North American canola production arising from the use of biotech HT technology was 3.2 million tonnes.

HT Corn. Weeds have also been a significant problem for corn farmers, causing important yield losses. Most weeds in these crops have been reasonably controlled based on application of a mix of herbicides.

The HT technology used in corn has mainly provided more cost-effective (less expensive) and easier weed control rather than improving yields from better weed control (relative to weed control levels obtained from conventional technology).

Improved weed control from use of the HT technology has, nevertheless, delivered higher yields in some regions (Figure 1). For example, in Argentina, where HT corn was first used commercially in 2005, the average yield effect has been +9%, adding +0.36 tonnes/ha to production. Similarly in the Philippines, (first used commercially in 2006), early adopters are finding an average of +15% to yields (+0.72 tonnes/ha).

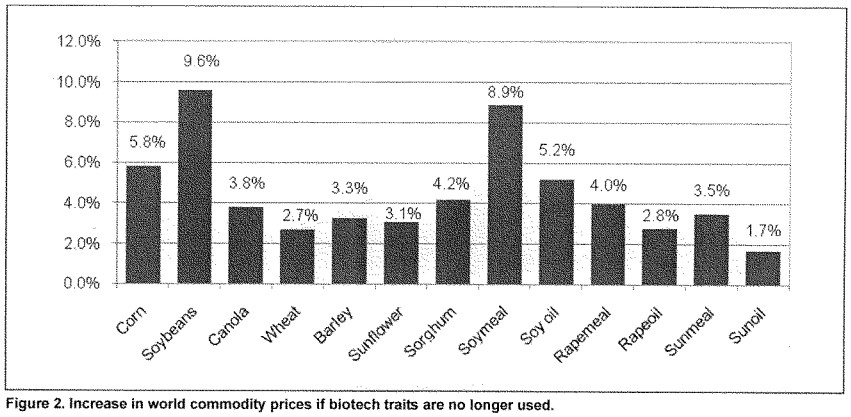

Figure 2. Increase in world commodity prices if biotech traits are no longer used.

Conversion of Production and Yield Impacts into Usable Assumptions

To provide suitable assumptions for input into the agricultural commodity models, the production and yield impacts summarized in the above section (Production and Yield Impacts of Biotech Traits) were converted into national-level yield equivalents. These are presented in Table 3. These yield change assumptions were then introduced into the models to identify impacts of withdrawing the (bio) technology from production systems and hence indirectly identify the impact of the biotech traits to date. The results are presented next.

Impact of Biotech Traits on Prices, Production, Consumption, and Trade in the Cereals and Oilseeds Sectors

World Level

Prices. The running of the agricultural commodity models under the 'no biotech traits' scenario suggests that the impact that these productivity-enhancing biotech traits in corn, soybeans, and canola have had on world prices of both these crops/derivatives and other cereals and oilseeds is significant. We consider the no-biotech scenario as a deviation from the 2007 baseline. In the scenario, the yield shocks are fully implemented from 2008 through 2017. We report the average of these annual changes for the years 2008-2010 as a summary indicator of the short term impacts. The scenario run shows that if these traits were no longer used in global agriculture, the loss of the yield and production-enhancing capabilities of the technology would result in world prices of corn, soybeans, and canola increasing by +5.8%, +9.6%, and +3.8%, respectively (Figure 2). There would also be knock-on effects on the prices of derivatives (e.g., a +9% increase in the world price of soymeal and a +5% increase in the price of soy oil) and other cereals and oilseeds (e.g., increases in prices of +2.7% to +4.2% of wheat, barley, and sorghum). In response to the decline in yields of corn, soybean, and canola, the production of these crops decline and their prices increase. This leads to area reallocation away from wheat, thus increasing its price—though less of an increase relative to corn, soybean, and canola prices. Given the limitations of the analysis (in not including an examination of the impact of the cost-reducing impact of the technology), these estimates of the impact on crop prices are probably understated. Additional information is presented in Appendices B and C to help readers follow how the summary values presented in this section were derived.

In monetary ($ terms), Figure 3 shows the impacts of these price increases relative to the average 2007/08 world price levels.[7]

7. *The impacts presented in Appendix B show the price increases relative to the baseline price levels (average of 2008 through 2010) and are therefore marginally different from the changes presented in Figure 3, which relate to actual 2007/08 average prices. Appendix C summarizes the 2007/08 data used as the base for this figure.*

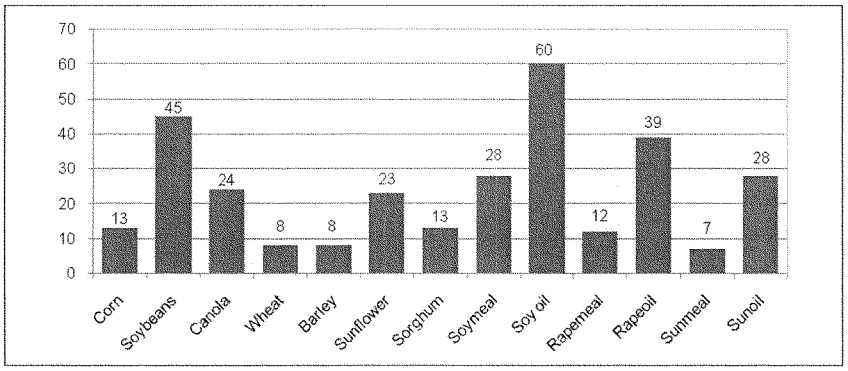

Figure 3. Increase in world commodity prices if biotech traits are no longer used ($/tonne).

Table 4. Global consumption of key commodities/derivatives 2007-08 and impact of price changes.

	Consumption (million tonnes)	Cost of consumption ($ billion)	Additional cost of consumption if biotech traits no longer available ($ billion)
Corn	776.80	169.3	9.82
Wheat	618.10	194.1	5.24
Barley	136.30	33.0	1.09
Sorghum	63.28	18.9	0.79
Soymeal	157.09	49.3	4.39
Soy oil	37.40	43.1	2.24
Canola meal	27.12	8.1	0.32
Canola oil	18.34	25.9	0.72
Sunflower meal	10.43	2.0	0.07
Sunflower oil	9.41	15.4	0.26
Total	**1,854.00**	**559.1**	**24.94**

Sources: Baseline data from USDA Market & Trade reports. Prices based on import/export levels using mainstream ports of trade (USDA). These consumption figures (see Appendix C) differ marginally from the consumption values used in the model baseline presented in Appendix B because they are based on more recent (updated) values to those originally input into the models.

Relating these price changes to global consumption, this is equivalent to adding $25 billion (+4.5%) to the total cost of consumption of these crops/derivatives in 2007/08 (Table 4). The sectors most affected would be the corn- and soybean/derivative-using sectors, although there would also be a significant knock-on effect in the wheat sector.

In terms of income, it is important to recognize that the productivity-enhancing technology has already had an impact on producer (farmer) incomes. The downward world price effects of the technology identified above represent a loss to farmer incomes but a gain to consumers. The negative price effects at the producer level have, though, been more than offset by the direct income gains associated with adoption of the technology for those farmers who have used biotech traits. The direct farm-income gain identified from adoption of biotech traits over the period 1996-2006 was $33.8 billion (Brookes & Barfoot, 2008); this income gain was calculated net (inclusive) of the price effects identified above by using current farm-level prices for each crop, country, and year. In contrast, those farmers who have chosen to not adopt the technology or been denied access to the technology (e.g., on political or regulatory grounds) have experienced the negative price effect but not gained from the yield gains and cost savings associated with using the technology.

Table 5. Potential change to global production base if biotech traits are no longer used.

	Area change (million ha)	Yield (tonnes/ha)	Production (million tonnes)
Corn	+0.48 (+0.3%)	-0.08 (-1.5%)	-9.48 (-1.2%)
Soybeans	+2.27 (+2.5%)	-0.11 (-4.3%)	-4.36 (-2%)
Canola	+0.11 (+0.4%)	-0.01 (-0.65%)	-0.14 (-0.3%)
Soymeal	n/a	n/a	-2.69 (-1.7%)
Soy oil	n/a	n/a	-0.67 (-1.8%)
Canola/ rape meal	n/a	n/a	-0.03 (-0.1%)
Canola/ rape oil	n/a	n/a	-0.04 (-0.2%)

Notes: n/a = not applicable. Baseline for these changes are 2007/08 values. These are marginally different to the model baseline values presented in Appendix B.

Production, Trade and Consumption Impacts. The effect of no longer using the current biotech traits in the corn, soybean, and canola sectors will have an impact on both the supply and utilization of these crops, their derivatives, and related markets for grain and oilseeds.

By taking away the positive yield and production impacts of the technology from the areas planted to these traits, the negative impacts would be felt most in the current-user (technology) countries (see *Production and Yield Assumptions* section). At the global level, the model analysis suggests that the negative impacts on the yields of the three crops are equal to an average reduction of 1.5%, 4.3%, and 0.65%, respectively, for corn, soybeans, and canola (Table 5).

The dynamic effect on subsequent plantings and the production base would result in a projected increase in the total area planted to these three crops of just under 3 million hectares, although this 'compensatory' additional planting would not offset the yield-reduction effects of no longer using biotech traits, resulting in a net fall in global production of the three crops of 14 million tonnes. In respect of the key oilseed derivatives of meal and oil, the reduction in the supply of the base seed (soybeans and rapeseed) would result in knock-on falls in global production of soymeal (1.7%), soy oil (1.8%), rapemeal (0.1%), and rape oil (0.2%). The total reduction in supply of these crops and key derivatives of meal and oil is projected to be 17.4 million tonnes.

The change in the supply availability of these three crops and the resulting upward effect on prices is forecast to lead to falls in global trade of these crops/derivatives. The modelling suggests that world trade in these crops/derivatives would fall by about 6.6 million tonnes, of which the main changes would be decreased trade volumes of 3.2 million tonnes, 1.65 million tonnes, and 1.24 million tonnes for corn, soymeal, and soybeans, respectively.

Table 6. Potential global changes to other grains and oilseeds if biotech traits are no longer used.

	Production (million tonnes)	Consumption (million tonnes)
Wheat	-0.61 (-0.1%)	0.09 (0.01%)
Barley	Nil	+0.10 (+0.07%)
Sorghum	+0.32 (+0.5%)	+0.36 (+0.57%)
Sunflower meal	Nil	+0.02 (+0.2%)
Sunflower oil	Nil	+0.02 (+0.2%)

The model also predicts annual decreases in global consumption of these commodities and derivatives of 14.25 million tonnes. The main decreases in consumption would be for corn (8.07 million tonnes: a 0.98% decrease), soymeal (2.67 million tonnes: 1.7% decrease), and soy oil (0.64 million tonnes: a 1.7% decrease). Change in global consumption of canola/rapeseed derivatives would be marginal.

The analysis also identifies impacts on related grain and oilseed sectors. In addition to the impact on prices (see *IR Corn Impacts* section), the production and consumption of grains such as wheat, barley, sorghum, and oilseeds, notably sunflower, would be affected (Table 6). The global production of wheat is projected to fall by 0.1%, while the production of sorghum would increase by 0.5%. The decline in wheat production is due to area reallocation away from wheat towards crops such as corn, soybean, and canola, which experienced price increases after a yield decline when biotechnology was no longer available. This is in part due to the impact of looking only at the yield impacts of biotech crops, but not at the lower production cost advantages brought about by biotech. In relation to global consumption, this is projected to fall for wheat but increase for barley, sorghum, sunflower meal, and oil.

Taking both the impacts on the three directly affected sectors of corn, soybeans, canola, and related grains and oilseeds, the net impacts of existing biotech traits (if no longer used in global agriculture) are an additional 2.64 million hectares of land being brought into grain and oilseed production. Despite this increase in total planted area, net production of these grains and oilseeds (excluding derivatives) would fall by 14.3 million tonnes. Inclusive of the main oilseed derivatives (including sunflower), net production is forecast to fall by 17.7 million tonnes. World trade in these commodi-

Table 7. Potential change to the US production base if biotech traits are no longer used (% change).

	Area	Average yield	Production	Net trade (net exports)
Corn	-0.8%	-2.5%	-3%	-10%
Soybeans	+3.6%	0%	+3.4%	+14%
Canola	+0.2%	-5.9%	-5.7%	-10%

Table 8. Potential change to the Argentine production base if biotech traits are no longer used (% change).

	Area	Average yield	Production	Net trade (net exports)
Corn	+1.6%	-4.6%	-3.1%	-3.9%
Soybeans	-18.5% (inclusive of loss of second-crop soy)	-0%	-18.8%	-81%
Soymeal	n/a	n/a	-7%	-7%
Soy oil	n/a	n/a	-7%	-8%

Note: n/a = not applicable. The model results presented in Appendix B differ from the changes presented in this table because the model inputs the loss of second-crop soybeans as a yield decrease. The effects presented in this table therefore adjust the negative yield effect used in the modelling to an area change which is projected to be a 1.5% increase in first-crop soybean plantings, relative to a 20% decrease in second-crop soybeans.

ties and derivatives would also fall (by 6.6 million tonnes) and global consumption of these grains and oilseed derivatives is forecast to fall by 15.4 million tonnes. Lastly, the model estimates that the cost of global consumption of these crops and derivatives would increase by $20 billion (3.6%) relative to the total cost of consumption of the (higher) biotech-inclusive level of world consumption. In unit terms, the average cost of consumption would increase by about 4.6% from an average of $301/tonne to $315/tonne.

Country Level

This section discusses the impact at the global level on specific countries and regions of the world of biotech traits no longer being available.

US. If existing biotech traits were no longer available to farmers globally (including US farmers), the impact in the affected US cropping sectors would be significant (Table 7). The model analysis points to production of US corn and canola falling by 3% (10.8 million tonnes) and 5.7% (50,000 tonnes), respectively, mainly due to reduced yields (loss of yield-enhancing nature of the biotech traits). Soybean production, however, would potentially increase by 2.4 million tonnes due to increased plantings of soybeans (the yield losses to corn improving the relative competitive position of soybeans at the farm level).

Trade effects would be similar to the production impacts, with decreases in the volumes of exported corn and canola of about 10%. Soybean exports, however, would potentially increase significantly due to the additional production. The model also forecasts knock-on effects in other sectors; plantings of wheat and sorghum would be expected to fall, resulting in decreased production of these crops (0.6% for wheat and 0.5% for sorghum). In contrast, plantings and production of barley are expected to increase by 1.1%. Lastly, domestic US consumption of corn, soybeans, and canola is expected to fall by 2%, 0.5%, and 2%, respectively (caused by the higher price; see *Prices* section).

Argentina. The effect of no longer using biotech traits globally in the Argentine corn and soybean sectors is summarized in Table 8. Production of corn is forecast to fall by 3.1% (about 0.7 million tonnes) due to reduced yields (loss of yield-enhancing nature of the biotech traits). Output of soybeans is predicted to fall more significantly because of the negative effect on second-crop soybeans, which accounted for 20%-plus of the total Argentine soybean crop in 2006 (GM HT technology having contributed to shortening the production cycle for soybeans allowing many farmers to plant a crop of soybeans after wheat in the same season). As such, no longer having access to this technology would potentially threaten plantings of second-crop soy, resulting in a significant fall in total soybean production (equal to almost 9 million tonnes).

The declines in production of soybeans and corn would have an important negative impact on the wider Argentine economy. Domestic consumption of both corn and soybeans is forecast to fall by about 1% and 7%, respectively (due to reduced availability and higher prices). More importantly, the reduced levels of production would result in decreased volumes available for export, especially in the soybean and derivative sectors. Given that soybean exports have contributed and will continue to contribute tax revenues to the Argentine

Table 9. Potential change to the Canadian production base if biotech traits are no longer used (% change).

	Area	Average yield	Production	Net trade (net exports)
Corn	+0.4%	-2.5%	-2.1%	+5.6%
Soybeans	+2.2%	0%	+2.2%	+8.8%
Canola	+0.2%	-3.1%	-2.9%	-1.5%
Soymeal	n/a	n/a	-1.8%	-3.3%
Soy oil	n/a	n/a	-1.8%	-3.3%
Canola/ rape meal	n/a	n/a	-5.3%	-6.8%
Canola/ rape oil	n/a	n/a	-5.3%	-6.8%
Wheat	-0.14%	0%	-0.14%	0.13%

Note: n/a = not applicable

Exchequer, this would result in important cuts in government tax revenues. Lastly, the modelling results suggest that production of other cereals, notably wheat and barley, would potentially increase by over 1% due to increased plantings of these crops.

Canada. The estimated impact of no longer making available the existing biotech traits in the global corn, soybean, and canola markets on the relevant Canadian cropping sectors is summarized in Table 9. Production of corn and canola is forecast to fall by more than 2% (0.3 million tonnes for corn and 0.3 million tonnes of canola) due to reduced yields (loss of yield-enhancing nature of the biotech traits). Soybean production, however, would likely increase (by more than 2%) because of increased plantings (as in the United States, the yield losses to corn improving the relative competitive position of soybeans at the farm level). The model predicts that domestic consumption and use of all three commodities and derivatives would fall (by more than 4% for both soybeans and canola and by about 1% for corn) due to higher prices (see *World Level* section). Canada, a net importer of corn, increases its net imports because of the decline in production. Exports of soybeans, however, would potentially increase as decreased domestic consumption results in additional volumes becoming available for export. In contrast, exports of canola and derivatives would be expected to fall—exports being a major outlet for Canadian canola relative to domestic consumption; hence, any additional supplies available for export from reduced domestic consumption would be more than offset by the fall in production associated with the withdrawal of biotech traits. The changes in biotech crops also impact the other crop markets. With the increase in corn prices, wheat area in Canada declines as area shifts away from wheat to corn. This increases wheat prices and thus domestic use of wheat declines. Net exports of wheat in Canada increase since domestic use declines more than domestic supply because of the relatively larger decline in stocks of wheat.

South Africa and the Philippines—Corn Sector. Both these countries currently use biotech IR technology in their corn sectors. Consequently, if this technology was no longer available to these and all farmers globally, there would be important negative impacts for those farmers who currently use the technology. At the national level in South Africa, average corn yields would be expected to fall by more than 5%, resulting in a net 5.5% reduction in total corn production.[8] In the Philippines, where adoption of biotech IR corn traits is more recent—and hence less widespread than in South Africa (5% of total crop compared to 63% of the total corn crop in South Africa)—the national-level impacts are an average decrease in corn yield of 1% and production falling by about 0.5%.[9]

The modelling results suggest that domestic consumption of corn is also expected to fall by more than 1.5% in both countries (due to higher prices of corn). In terms of net trade, imports in the Philippines would increase by about 0.1 million tonnes (50%), while in South Africa, exports (of corn) would fall by nearly 30% (about 0.45 million tonnes).

The European Union. There were two biotech traits in use commercially in EU-27 countries of relevance during the 1998-2006 period: IR corn in several member states and HT soybeans in Romania. The modelling analysis identifies negative impacts of no longer using these technologies (both in the EU and globally).[10] Average EU-27 corn yields and production would be expected to fall marginally (by 0.2%),[11] while both con-

8. *Area planted is projected to fall by 0.5%.*
9. *Area planted is projected to increase by 0.7%.*
10. *The removal of access to this technology has, in fact, occurred in relation to herbicide tolerant soybeans in Romania, which joined the EU in 2007, and hence, had to adopt EU regulations relating to biotechnology—the planting of biotech herbicide tolerant soybeans is currently not permitted in the EU-27.*
11. *Readers should note that biotech IR corn was planted on about 0.1 million hectares in the EU-27 in 2007, equal to 1.3% of total EU-27 corn planting.*

sumption and net trade (imports) of corn would fall by 0.3% and 1.2%, respectively (negative effect of higher world prices for corn). Average soybean yields across the EU would also be expected to fall by -3.2%, and production would be lower by -1.3% due to the negative effect on yields and production of soybeans in the important EU soybean-producing country of Romania. This reduced supply of domestic soybeans is forecast to result in reductions in the EU production of soymeal and soy oil (by 1.1%). Usage of soymeal and soy oil is also forecast to fall by 2.6% and 1.4%, respectively (due to higher world prices).

Conclusions

This study quantified, through the use of agricultural commodity models, the impact of biotech traits on production, usage, trade, and prices in the corn, soybean, and canola sectors. The previous analysis (Brookes & Barfoot, 2008) estimated that biotech crops, through the two main traits of insect resistance and herbicide tolerance have, during the 1996-2006 period, added 53.3 million tonnes and 47.1 million tonnes, respectively, to global production of soybeans and corn. The technology has also contributed an extra 3.2 million tonnes of canola.

The estimated impact of these additional volumes of production on markets and prices in the cereals and oilseeds sectors has been significant. Our modelling analysis of the potential impact of no longer using these traits in world agriculture shows that the world prices of these commodities, their key derivatives, and related cereal and oilseed crops would be significantly affected. World prices of corn, soybeans, and canola would probably be respectively 5.8%, 9.6%, and 3.8% higher than the baseline 2007 levels (when the technology was available for the analysis purposes). Prices of key derivatives of soybeans (meal and oil) would also be between 5% (oil) and 9% (meal) higher than the baseline levels, with rapeseed meal and oil prices being about 4% higher than baseline levels. World prices of related cereals and oilseeds would also be expected to rise by 3-4%.

The effect of no longer using the current biotech traits in the corn, soybean, and canola sectors would also impact both the supply and utilization of these crops, their derivatives, and related markets for grain and oilseeds. Average global yields are estimated to fall by 1.5%, 4.3%, and 0.65% for corn, soybeans, and canola, respectively. While there is likely to be some 'compensatory' additional plantings (of just under 3 million hectares) of these three crops, this would not offset the yield-reduction effects of no longer using biotech traits, thus resulting in a net fall in global production of the three crops of 14 million tonnes. The modelling also suggests that a fall in the supply availability of these three crops and the resulting upward effect on prices would lead to a projected decrease in global trade of these crops/derivatives of 6.6 million tonnes, a 1.4% decrease in corn usage and a 1.7% decrease in usage of soymeal and soy oil (changes in global consumption of canola/rapeseed derivatives would be marginal).

The production and consumption of grains such as wheat, barley, and sorghum and oilseeds, notably sunflower, would also be affected (e.g., the global production and consumption of wheat would fall by 0.1% and 0.01%, respectively).

Overall, the net impacts of existing biotech traits (if no longer used) in global agriculture are that an additional 2.64 million hectares of land would probably be brought into grain and oilseed production. Despite this, net production of grains and oilseeds (including derivatives) would potentially fall by 17.7 million tonnes[12] and global consumption would potentially fall by 15.4 million tonnes. The cost of consumption would also increase by $20 billion (3.6%) relative to the total cost of consumption of the (higher) biotech-inclusive level of world consumption. In unit terms, the net cost of consumption would increase by about 4.6%.

The impacts identified in this analysis are probably conservative, reflecting the limitations of the methodology used to estimate the productivity-enhancing effects of biotech traits so far used in global agriculture. In particular, the limited research conducted to date into the impact of the cost-reducing effect of biotechnology (notably in HT soybeans) on prices and the assumption of using 2007 levels of biotech adoption as the 'counterfactual' position suggests that the price effects identified in this article represent only part of the total price impact of the technology. Subsequent research might usefully extend this analysis to incorporate consideration of the cost-reducing effect of the technology (especially HT technology), a more dynamic counterfactual position, and to examination of the cotton sector.

Appendix A: Agricultural Modelling System—Methodological Details

General Description of the Modelling System

This study uses part of a broad modelling system of world agricultural economy comprised of US and international multi-market, partial-equilibrium models. The models are econometric and simulation models covering all major temperate crops, sugar, ethanol and bio-diesel, dairy, and livestock and meat products for all major producing and consuming countries and calibrated on most recently available data. A Rest-of-the-World aggregate is included to close the models. Table A1 presents a detailed list of commodity and country coverage. Extensive market linkages exist in these models, reflecting derived demand for feed in livestock and dairy sectors, competition for land in production, and consumer substitution possibilities for close substitutes such as vegetable oils and meat types.

The models capture the biological, technical, and economic relationships among key variables within a particular commodity and across commodities. They are based on historical data analysis, current academic research, and a reliance on accepted economic, agronomic, and biological relationships in agricultural production and markets. A link is made through prices and net trade equations between the US and international models. The models are used to establish commodity projections for a baseline and for policy analysis, and are used extensively for the market outlook and policy analysis. This set of agricultural models have been used in a number of studies including Elobeid et al. (2007), Fabiosa et al. (2005, 2007), and Tokgoz et al. (2008).

In general, for each commodity sector, the economic relationship that supply equals demand is maintained by determining a market-clearing price for the commodity. In countries where domestic prices are not solved endogenously, these prices are modelled as a function of the world price using a price transmission equation. Since econometric models for each sector can be linked, changes in one commodity sector will impact other sectors. A detailed description of the models is available on Iowa State University's FAPRI website.[13] Figure A1 provides a diagram of the overall modelling system. For this particular study, the US Crops, International Grains, International Oilseed, International Sugar, and International Bio-fuels models were used.

More specifically in terms of the structure of the models, the following identity is satisfied for each country/region and the world:

Beginning Stock + Production + Imports = Ending Stock + Consumption + Exports

13. *http://www.fapri.iastate.edu/models/*

Table A1. Model inputs and output.

Commodities	Major countries/regions	Exogenous inputs	Historical data (inputs)	Output by commodity and country
Grains	**North America**	Population	Production	World prices
Corn	United States,	GDP	Consumption	Domestic prices
Wheat	Canada, Mexico	GDP deflator	Exports	Production
Sorghum		Exchange rate	Imports	Consumption

	Iran, Saudi Arabia, etc.			
	Rest of the World			

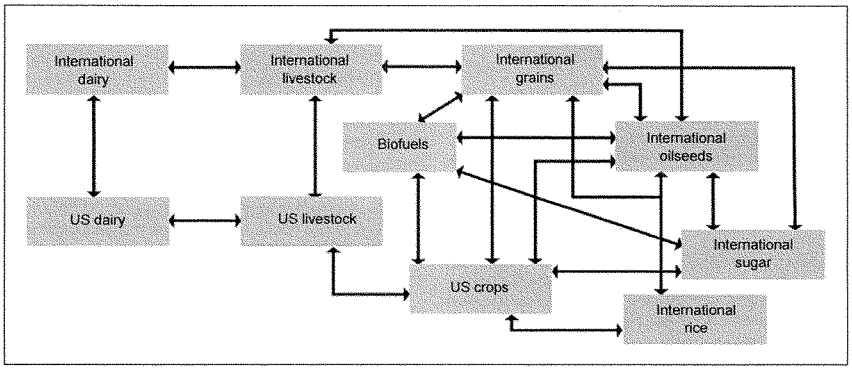

Figure A1. Model interactions: Trade, prices and physical flows.

Production is divided into yield and area equations, while consumption is divided into feed and non-feed demand. The models include behavioral equations for area harvested, yield, crop production on the supply side, and per-capita consumption and ending stocks on the demand side. Equilibrium prices, quantities, and net trade are determined by equating excess supply and excess demand across countries and regions. To satisfy the identity in Equation 1, two different methods are used. In most of the countries, domestic price is modelled as a function of the world price with a price transmission equation, and the identity is satisfied with one of the variables set as the residual. In other cases, prices are solved to satisfy the identity.

Agricultural and trade policies in each country are included in the models to the extent that they affect the

supply and demand decisions of the economic agents. Examples of these include taxes on exports and imports, tariffs, tariff rate quotas, export subsidies, intervention prices, and set-aside rates. The models assume that the existing agricultural and trade policy variables will remain unchanged in the outlook period. Macroeconomic variables, such as GDP, population, and exchange rates, are exogenous variables that drive the projections of the model. The models also include an adjustment for marketing-year differences by including a residual that is equal to world exports minus world imports, which ensures that world demand equals world supply.

All models are calibrated on 2007/08 marketing year data for crops and 2007 calendar year data for livestock and biofuels, and 10-year projections for supply and utilization of commodities and prices are generated for the period between 2008 and 2017. The models also adjust for marketing-year differences by including a residual that is equal to world exports minus world imports, which ensures that world demand equals world supply. Elasticity values for supply and demand responses are based on econometric analysis and on consensus estimates. Elasticity parameters estimates and policy variables are available in Iowa State University's FAPRI's Elasticity Database.[14]

Data for commodity supply and utilization are obtained from the F.O. Lichts online database, the Food and Agriculture Organization (FAO) of the United Nations (FAOSTAT Online, 2006), the Production, Supply and Distribution View (PS&D) of the US Department of Agriculture (USDA), the European Commission Directorate General for Energy and Transport, the ANFAVEA (2005), and UNICA (2006). Supply and utilization data include production, consumption, net trade, and stocks. The macroeconomic data are gathered from the International Monetary Fund and Global Insight.

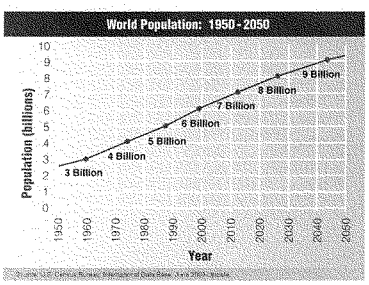
Facilitating Conservation Farming Practices and Enhancing Environmental Sustainability with Agricultural Biotechnology

EXECUTIVE SUMMARY

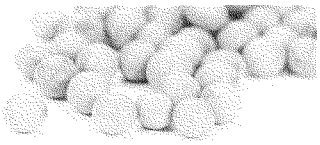


Today's farmers are under unprecedented pressure. The earth's population is nearly 7 billion, and is expected to reach 9 billion by 2050. Farmers must meet that growing demand – with a shrinking resource base – while protecting soil, air and water quality.

Nobel laureate Norman Borlaug, the father of the Green Revolution, summed up the challenge when he wrote that farmers and ranchers will be called upon to produce more food in the next 50 years than their ancestors did in the past 10,000 years – and do it in an environmentally sustainable manner.

Biotechnology-derived crops and the sustainable farming systems they facilitate are key tools in the race to grow more food, feed, fiber and fuel while protecting the environment.

Worldwide benefit of agricultural biotech, 1996-2007: $44 billion.



Race Against Time

To meet the projected soybean demand of 2030, growers would have to add 168 million acres of soybeans to existing production if global yields remained the same as today, or double those yields to 59.5 bushels per acre to harvest enough soybeans on today's acreage.

Biotech crops show promise to double or triple the current rate of yield increase in corn, and match or exceed the average 0.5-bushel-per-acre annual increase in soybean yields.

Not surprisingly, millions of farmers have adopted biotech crops readily. In the U.S., 91.5 percent of the soybeans, 85 percent of the corn and 88 percent of the cotton in the 2009 crop was planted to biotech varieties.

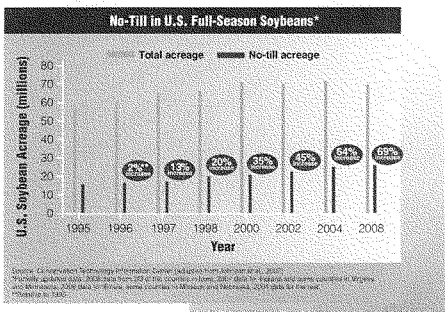
A New Generation

The first wave of biotechnology-derived crops focused primarily on input traits, which improved production efficiencies. In fact, the worldwide economic benefit of agricultural biotechnology between 1996 and 2007 was calculated at $44 billion.

The next generation of biotech crops will feature additional input traits such as tolerance to more herbicides and insects, as well as more efficient use of water and nitrogen. It will also introduce valuable output traits, including:

- Improved health profiles of oils and grains,
- Modification or elimination of major allergens, and
- More efficient conversion to biofuels.

Biotech means fewer applications. In 2007, U.S. farmers cut:
- ***47.4 million pounds of herbicide***
- ***8.67 million pounds of insecticide***



on acreage with biotech crops.

Protecting the Environment

Environmental benefits from biotech input traits add up quickly in pounds of herbicides and insecticides eliminated from the production system. For example:

- Herbicide-tolerant soybeans and cotton reduced U.S. herbicide usage in 2007 by 47.4 million pounds of active ingredient, and
- Insect-resistant cotton and corn varieties decreased insecticide applications that year by 8.67 million pounds of active ingredient.

There are significant long-term benefits, too. The adoption of biotech crops – especially soybeans – closely tracks the expansion of conservation tillage and no-till production. Between the introduction of Roundup Ready® soybeans in 1996 and the 2008 cropping season, the U.S. acreage of no-tilled full-season soybeans grew by nearly 70 percent.

Conservation tillage and no-till improve soil quality, conserve water and provide wildlife habitat. They also significantly reduce soil erosion, nutrient enrichment of streams and herbicide runoff. In fact, a number of studies show reductions in soil loss of more than 90 percent and reduced movement of total phosphorus by more than 70 percent on no-till fields.

High-residue farming practices also build up soil organic matter by capturing and storing atmospheric carbon. In fact, reducing tillage can quadruple carbon sequestration in cropland soils, and no-till can increase annual carbon storage five-fold. Reducing or eliminating tillage also lowers fuel consumption, cutting greenhouse gas emissions further. In all, conservation tillage and no-till can significantly improve the carbon footprint of farm operations.

Markets for water quality and carbon credits are emerging that could make environmental services such as combating water pollution and sequestering carbon – which conservation farming practices can often accomplish more cost-effectively than many alternatives – into income opportunities for farmers.

Best Option

No other options have been identified with the potential to improve yields and safeguard the environment as well as biotech crops farmed with sustainable practices.

Every ton of soil saved on the field, every pound of pesticide that doesn't have to be applied, every dollar that helps a farmer stay economically viable and every bushel of yield produced is a milestone in the effort to provide for a steadily increasing global population.

PUBLISHED BY THE CONSERVATION TECHNOLOGY INFORMATION CENTER © 2010

The Conservation Technology Information Center (CTIC) is a national, nonprofit 501(c)(3) organization. CTIC champions, promotes and provides information about comprehensive conservation and sustainable agricultural systems that are beneficial for soil, water, air and wildlife resources and are productive and profitable for agriculture.

This publication was made possible through funding provided by the United Soybean Board (USB) Sustainability Initiative. USB is made up of 68 farmer-directors who oversee the investments of the soybean checkoff on behalf of all U.S. soybean farmers. Checkoff funds are invested in the areas of market utilization, human utilization, industrial utilization, industry relations, market access and supply. As stipulated in the Customer Protection, Research and Consumer Information Act, USDA's Agricultural Marketing Service has oversight responsibilities for USB and the soybean checkoff. The opinions expressed are those of the authors based on a comprehensive review of the published literature.

Top 10 Benefits of Conservation Tillage

1 Reduces labor, saves time
As little as one trip for planting compared to two or more tillage operations means fewer hours on a tractor and fewer labor hours to pay ... or more acres to farm. For instance, on 500 acres the time savings can be as much as 225 hours per year. That's almost four 60-hour weeks.

2 Saves fuel
Save an average 3.5 gallons an acre or 1,750 gallons on a 500-acre farm.

3 Reduces machinery wear
Fewer trips save an estimated $5 per acre on machinery wear and maintenance costs—a $2,500 savings on a 500-acre farm.

4 Improves soil tilth
A continuous no-till system increases soil particle aggregation (small soil clumps) making it easier for plants to establish roots. Improved soil tilth also can minimize compaction. Of course, compaction is also reduced by reducing trips across the field.

5 Increases organic matter
The latest research shows the more soil is tilled, the more carbon is released to the air and the less carbon is available to build organic matter for future crops. In fact, carbon accounts for about half of organic matter.

6 Traps soil moisture to improve water availability
Keeping crop residue on the surface traps water in the soil by providing shade. The shade reduces water evaporation. In addition, residue acts as tiny dams slowing runoff and increasing the opportunity for water to soak into the soil. Another way infiltration increases is by the channels (macropores) created by earthworms and old plant roots. In fact, continuous no-till can result in as much as two additional inches of water available to plants in late summer.

7 Reduces soil erosion
Crop residues on the soil surface reduce erosion by water and wind. Depending on the amount of residues present, soil erosion can be reduced by up to 90% compared to an unprotected, intensively tilled field.

8 Improves water quality
Crop residue helps hold soil along with associated nutrients (particularly phosphorous) and pesticides on the field to reduce runoff into surface water. In fact, residue can cut herbicide runoff rates in half. Additionally, microbes that live in carbon-rich soils quickly degrade pesticides and utilize nutrients to protect groundwater quality.

9 Increases wildlife
Crop residues provide shelter and food for wildlife, such as game birds and small animals.

10 Improves air quality
Crop residue left on the surface improves air quality because it: Reduces wind erosion, thus it reduces the amount of dust in the air; Reduces fossil fuel emissions from tractors by making fewer trips across the field; and Reduces the release of carbon dioxide into the atmosphere by tying up more carbon in organic matter.

Update on Increasing Crop Productivity

Increasing Crop Productivity to Meet Global Needs for Feed, Food, and Fuel

Michael D. Edgerton*

Monsanto Company, St. Louis, Missouri 63167

Global demand and consumption of agricultural crops for food, feed, and fuel is increasing at a rapid pace. This demand for plant materials has been expanding for many years. However, recent increases in meat consumption in emerging economies together with accelerating use of grain for biofuel production in developed countries have placed new pressures on global grain supplies. To satisfy the growing, worldwide demand for grain, two broad options are available: (1) The area under production can be increased or (2) productivity can be improved on existing farmland. These two options are not mutually exclusive and both will be employed to produce the additional 200 million tonnes/year of corn (*Zea mays*) and wheat (*Triticum aestivum*) estimated to be needed by 2017. Both options will alter the environmental footprint of farming. Of the two options, increasing productivity on existing agricultural land is preferable as it avoids greenhouse gas emissions and the large-scale disruption of existing ecosystems associated with bringing new land into production. In the United States, breeders, agronomists, and farmers have a documented history of increasing yield. U.S. average corn yields have increased from approximately 1.6 tonnes/ha in the first third of the 20th century to today's approximately 9.5 tonnes/ha. This dramatic yield improvement is due to the development and widespread use of new farming technologies such as hybrid corn, synthetic fertilizers, and farm machinery. The introduction of biotechnology traits and development of new breeding methodology using DNA-based markers are further improving yields. Outside the United States, similar farming practices have been adopted in some agricultural nations, but in many major grain-producing countries, yields still lag well behind world averages. By continuing to develop new farming technologies and deploying of them on a global basis, demand for feed, fuel, and food can be met without the commitment of large land areas to new production.

Global demand for corn and wheat is growing at a rapid pace. As disposable incomes have risen in developing countries, meat consumption has increased. Among urban Chinese, meat consumption rose from 25 kg person^{-1} year^{-1} to 32 kg person^{-1} year^{-1} between 1996 and 2006 (von Braun, 2007). It is anticipated that meat consumption will continue to grow in developing countries because global consumption levels remain far below the approximately 100 kg person^{-1} year^{-1} meat consumption rate of the United States and many western European countries. Globally, meat consumption is expected to grow by 55 million tonnes to 310 million tonnes/year over the next decade (OECD-FAO, 2008). During this same period, biofuel production from corn and, to a lesser extent, wheat is expected to grow by 28 billion liters to 67 billion liters/year (Fig. 1). Meeting the expected demand for meat will require feed grain usage to increase by about 50 million tonnes to about 640 million tonnes/year. Concomitantly, grain consumption for biofuel production is likely to increase by about 60 million tonnes to about 145 million tonnes/year. When food use for corn and wheat is added to the calculation, total demand for corn and wheat over the next decade is expected to increase by about 15% or about 200 million tonnes/year to a total of approximately 1.5 billion tonnes/year (Table I; FAPRI, 2008).

The Food and Policy Research Institute (FAPRI) estimates that an additional 6 million ha of corn and 4 million ha of wheat plus a roughly 12% increase in global corn and wheat yields will be used to produce this additional 200 million tonnes of grain. Both increases in planted area and increases in yield are likely to be needed to meet global demand for grain. However, improving yield on existing agricultural land will have a lower environmental impact than bringing new land into production. Cultivation of new acreage requires land clearing and subsequent tillage that results in significant greenhouse gas emissions (Fargione et al., 2008) also has negative impacts upon biodiversity and water quality (Foley et al., 2005).

Increasing the productivity of existing agricultural land will also have environmental consequences (Tilman et al., 2002), but the negative consequences are generally less onerous and in some cases can be positive, depending upon how the land was previously used. Increased use of nitrogen fertilizers, a concern with both methods of increasing production, can increase nitrous oxide emissions, reduce water quality, and increase the size of hypoxic zones (Donner and Kucharik, 2008). However, incremental yield increases can be achieved on existing agricultural land through conservation tillage or transgenic insect control. Conservation tillage can decrease erosion, conserve soil

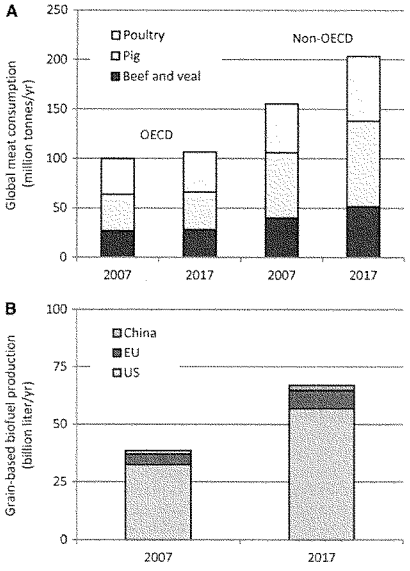

Figure 1. Estimates of global meat consumption and grain-based biofuel production. A, Global meat consumption estimates from OECD-FAO (2008). Meat consumption outside of the OECD is expected to increase by 48 million tonnes/year in the next decade. B, Global grain-based biofuel production estimates from FAPRI (2008). Grain-based biofuel production is expected to increase by 28 billion liters/year in the next decade.

moisture, and increase soil organic matter (Lal, 2004), and transgenic insect control can reduce broad spectrum insecticide use (Qaim and Zilberman, 2003; Cattaneo et al., 2006).

Global corn yields average 4.9 tonnes/ha and have been increasing steadily for many years (Fig. 2). This is encouraging, but yields in major grain-producing countries are nearly double the global average, suggesting that there is room for significant improvements in global yields. Average corn yield in the United States is 9.4 tonnes/ha and Canadian farmers attain average yields of 8.2 tonnes/ha with this crop of tropical origin. In contrast, corn yields in the 10 largest lower-yielding corn-producing countries are just 2.8 tonnes/ha (Table II; FAO, 2008), well below the global average. Much of the disparity in yields can be ascribed to agronomic practices, such as the use of open-pollinated corn varieties instead of hybrids, low input rates, or poor soil management. Brazil (29%), India (56%), and Romania (57%) all plant significant amounts of open-pollinated varieties. Weather is also a significant factor in some countries, but the use of less robust production systems can magnify the effects of unfavorable weather in countries such as South Africa and Romania. Increasing the use of modern farming practices in these countries, together with the infrastructure, marketing, and risk management tools needed to support them, could lead to significant increases in crop production that limit the need to bring incremental land into production.

Higher crop prices, prompted in part by rising demand, have increased costs for urban consumers, especially those in poorer countries. However, higher crop prices will also provide farmers with the economic incentive to invest in farming methods and technologies that improve crop yields (von Braun, 2007; Gallagher, 2008). Raising corn yields in the 10 largest, below average, corn-producing countries to just the world average will result in the production of an additional 100 million tonnes of corn or about 80% of the projected growth in demand by 2017. Implicit in this scenario is the idea that rising yields will markedly diminish the global need for new crop acreage.

Rates of gain for yield have changed as new agricultural technologies have been developed and adopted (Griliches, 1960; Troyer, 2006). Average annual corn grain yields in the United States were relatively steady at approximately 1.5 tonnes/ha prior to the 1930s. Yields began to increase when hybrid corn was first introduced and the rate of gain accelerated further in the 1950s as single cross hybrids were introduced

Table I. *Global corn and wheat production and consumption estimates from FAPRI's 2008 U.S. and World Agricultural Outlook*

All values are in million tonnes/year.

Crop	Crop Year	Production	Feed	Fuel	Food/Other
Corn	07/08	767	492	84	191
	17/18	896	528	143	225
	Increase	129	36	58	35
Wheat	07/08	603	98	1	503
	17/18	688	113	3	572
	Increase	85	14	2	68
Combined	07/08	1,370	590	85	694
	17/18	1,584	641	146	797
	Increase	214	50	60	103

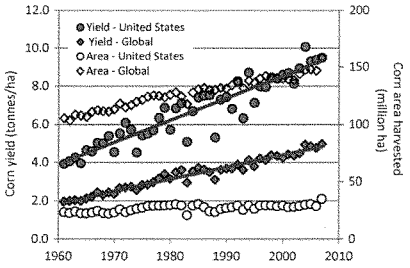

Figure 2. Annual corn yield averages and area planted in the United States and the world. Yield rate of gain in the United States from 1961 to 2007 was 0.11 tonnes ha^{-1} $year^{-1}$. Global yield rate of gain was about half of this at 0.06 tonnes ha^{-1} $year^{-1}$. Global corn area harvested has been increasing at the rate of 0.93 million ha/year. In the United States, corn area harvested increased by approximately 5 million ha in 2007 and 2008, although the long-term trend is much lower at 0.15 million ha/year (FAO, 2008). Lines indicate yield trend line.

(Troyer, 2006; Fig. 3A). Similarly, U.S. sorghum (*Sorghum bicolor*) yields increased sharply in the 1950s as hybrid sorghums were adopted (Miller and Kebede, 1984). Since that time, yield has improved steadily because of fertilizer management, the development of more efficient farm machinery, and the breeding of hybrids with improved stress tolerance that in turn enabled higher plant populations (Tollenaar and Lee, 2002) and earlier planting dates (Kucharik, 2008). Genetic gain experiments, in which hybrids that were widely grown at different points in time, often referred to as era hybrids, are compared side by side in the same trials, have been employed to estimate that about 50% of the yield gained between the introduction of hybrid corn, and today is derived from breeding and the remainder from improved agronomic practices (Duvick, 2005). Similar results have been reported from studies in France, Canada, and Brazil (Russell, 1991; Duvick, 2005). As new farming technologies are adopted by farmers, the gap between test plot results, such as those reported by Duvick, and on-farm yield averages decreases. Between 1935 and 1990 this gap shrank from about 3.0 tonnes/ha to about 1.8 tonnes/ha. However, as rates of gain derived from breeding have increased in recent years (Fig. 3B), this gap appears to have widened again. This observation supports the hypothesis that the immediate future will witness a shift in average rates of gain as newer hybrids are adopted more widely in the United States and elsewhere.

Marker-assisted breeding and biotechnology traits are relatively new technologies for the improvement of productivity. Incorporation of these technologies into crop improvement programs is likely to increase rates of gain beyond those seen in the last few decades. Results from a Monsanto Company study of a large number of commercial corn and soybean (*Glycine max*) populations indicated that use of markers can improve the rate of gain for yield and associated traits such as grain moisture and stalk lodging (Fig. 4; Eathington et al., 2007). Likewise, the suite of biotechnology traits currently used in commercial production in the United States increases average yields by protecting corn from the stress of competing pests and weeds (Fig. 5). Data

Table II. *Average corn yields from high- and low-yielding countries*

Values are 5-year averages from 2003 to 2007 (FAO, 2008). Yield, harvested area, and production were averaged independently and do not necessarily sum across this table.

Country	Area	Yield	Production
	million ha	*tonnes/ha*	*million tonnes*
High-yielding countries	64.4	7.5	482
United States	30.5	9.4	287
China	26.2	5.2	136
Argentina	2.5	6.8	17
France	1.6	8.4	14
Hungary	1.2	6.4	8
Canada	1.2	8.2	9
Italy	1.1	8.8	10
Low-yielding countries	48.0	2.8	132
Brazil	12.7	3.4	44
India	7.6	2.0	15
Mexico	7.4	2.9	21
Nigeria	3.8	1.6	6
Indonesia	3.4	3.4	12
Tanzania	2.9	1.1	3
South Africa	2.9	3.1	9
Romania	2.7	3.4	9
Philippines	2.5	2.2	6
Ukraine	1.9	3.7	7

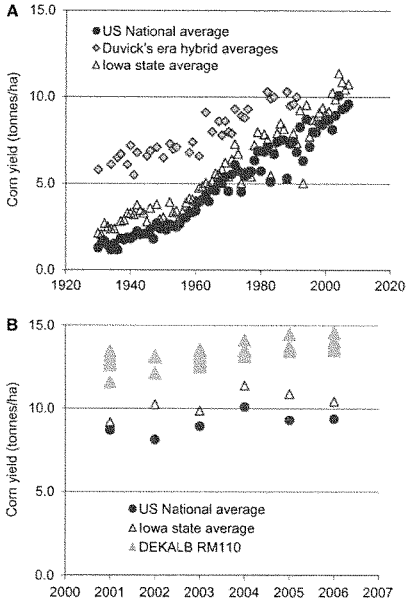

Figure 3. U.S. corn yield averages compared to yields obtained with widely used hybrids in test plots. A, National and Iowa corn yield averages (USDA ERS, 2008); Duvick's era hybrid average yields are from Duvick (1997). Iowa state averages are included as the era hybrid experiments were conducted in Iowa. The yield differential between test plots grown in Iowa and the Iowa state averages can be seen to decrease over time from approximately 3 tonnes/ha in 1936 to 1942 to approximately 1.8 tonnes/ha in 1988 to 1991. B, Genetic gain study of DEKALB commercial hybrids released from 2001 through 2006 in the 110-day relative maturity group (RM110), a region of the corn belt stretching across central Iowa. New RM110 commercial hybrids introduced from 2001 through 2006 were tested at 20 locations/year from 2005 through 2007 to produce the reported yield averages. All seed was from the same nursery and none of the hybrids contained biotechnology traits (Trevor Hohls, personal communication). Annual yield improvement was estimated at 0.24 tonnes ha^{-1} $year^{-1}$ for this group of hybrids and average yields were 3 tonnes/ha greater than Iowa and 4.2 tonnes/ha greater than the U.S. national average for this set of hybrids.

documenting the resulting reduction in risk to growers has been rigorously reviewed and acknowledged via the Federal Crop Insurance Corporation's Biotech Yield Endorsement, a risk management instrument that offers an insurance premium rate reduction for farmers using a suite of biotechnology traits (USDA FCIC, 2008). In 2008, farmers in the United States have planted 11 million ha of triple-stacked corn containing biotechnology traits that provide resistance to corn borers, corn rootworm, and the herbicide glyphosphate (Monsanto, 2008). While the yield benefits of these biotechnology traits vary from year to year, this level of planting will increase corn supply in the United States by approximately 5% if yield results seen in 2005 to 2007 are manifested in the 2008 growing season. The contribution of biotechnology traits to world corn supply will increase as they are used more widely.

The next generation of commercialized, biotechnology traits is likely to have a larger impact on crop yields. Improved drought tolerance will be one of the next major, transgenic technologies brought to the marketplace (Fig. 6; Nelson et al., 2007; Castiglioni et al., 2008). Drought tolerance has the potential to (1) increase yields in drier areas, (2) increase average yields in rain-fed systems by reducing the effects of sporadic drought, and (3) decrease water requirements in irrigated systems. Similarly, biotechnology traits that improve yield (Lundry et al., 2008) or oil concentration in soybean (Lardizabal et al., 2008) should improve global supplies of vegetable oil and protein meal. The first of these biotechnology traits, a higher-yielding, glyphosphate-tolerant soybean will be offered commercially in 2009 and commercialization of improved drought tolerance traits is expected around 2012. The transgenes described above are at relatively advanced stages of commercial development. A larger collection of transgenes derived from large-scale screening programs such as those described by Riechmann et al. (2000), Van Camp (2005), and Creelman et al. (2008) are at earlier stages of development. Biotechnology traits that improve grain yield and nitrogen use efficiency in replicated multiyear field trials are expected to reach farmers' fields in the second half of the next decade (Padgette, 2008).

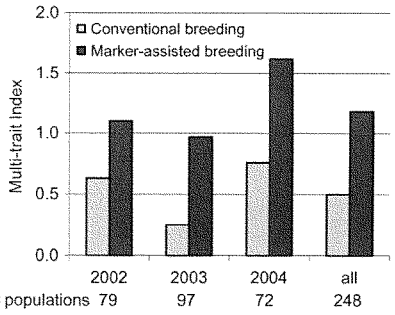

Figure 4. Breeding rates of gain for a multitrait index for 248 corn populations initiated across 3 years. The multitrait index is weighted toward yield, but also incorporates other agronomic traits such as grain moisture and stalk strength (Eathington et al., 2007).

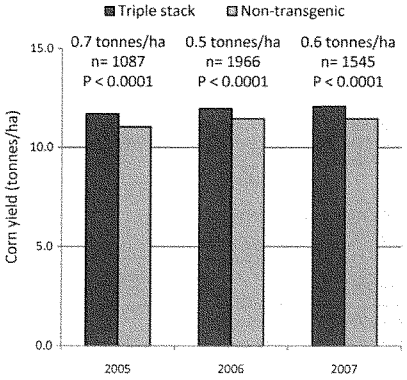

Figure 5. Yield advantage of triple-stack corn. Corn hybrids expressing either three biotechnology traits (YieldGard Plus with Roundup Ready Corn2 or YieldGard VT Triple) or without any biotechnology traits were tested in yield trials at the indicated number of locations across the United States in 2005, 2006, and 2007. Average yield values are shown in the bars and the yield difference between triple-stack and nontransgenic corn is indicated in the text above the bars. These are average values from yield trials run across corn-growing regions in the United States. Values can be significantly higher in regions with more insect pressure. Nontransgenic corn was treated with insecticide to control corn rootworm.

This group of genetically identified biotechnology traits are referred to as yield-enhancing traits, but the increase in yield may be due to an increase in yield potential and/or an improvement in tolerance to one or more stresses. Collectively, the next generation of biotechnology traits should contribute significantly to productivity on existing cropland, thereby increasing grain supplies and reduce the need to bring new land into production.

While breeders, agronomists, and farmers are working to increase yields, a number of factors that may reduce yields must be considered. Over the next two decades, climate change effects in the central United States are predicted to increase night air temperatures, the number and severity of adverse weather events, and increase the incidence of insect pests and disease. The result could be a drag on crop yields (Hatfield et al., 2008). Rapid adaptation of crops to changing climatic conditions may help mitigate these effects. Such rapid adaptation may occur for crops supported by strong breeding programs that continuously develop and introduce superior, locally adapted hybrids and varieties. New, higher-yielding hybrids produced from Monsanto's North American corn breeding program currently have a product half-life of approximately 4 years and are completely turned over about every 7 years, raising hopes that, for corn and possibly soybean, new varieties adapted to local conditions will be produced as a part of the ongoing breeding program. Unfortunately, this is not the case for crops such as wheat and rice (*Oryza sativa*) that lack the support of large, private breeding programs. Accordingly, increased public support for crop improvement efforts are sorely needed if new wheat and rice varieties are to be adapted to changing local climatic conditions. This is particularly true for regions of the world predicted to undergo more dramatic near term changes in climate than the central United States.

Nitrogen is another factor that may limit crop yields. Nitrogen may become less available as the cost of fertilizer rises and the continued growth of eutrophic dead zones and nitrous oxide emissions leads to changes in the way fertilizer is used (Donner and Kucharik, 2008). Nitrogen use efficiency, defined as the amount of crop produced per unit of input, has steadily improved in the United States since the 1980s (Frink et al., 1999). More precise nitrogen applications and genetic improvements in crops are likely to sustain improvements in nitrogen use efficiency although there is a limit to how far nitrogen application can be reduced. A 10 tonnes/ha corn crop contains around 100 kg nitrogen/ha as protein and at least this amount of nitrogen must be added back to the field to maintain fertility. Lastly, a sharp downturn in the global economy could restrict demand for both meat and fuel in ways that reduce the economic incentive to increase crop yields (IMF, 2008).

The combination of marker-assisted breeding, biotechnology traits, and continued advances in agro-

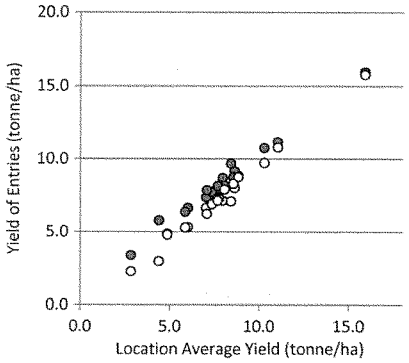

Figure 6. Yield increase in corn plants expressing cspB, a cold shock protein from *Bacillus subtilis*. Hybrids from a single transgenic event were tested in yield trials over 3 years at managed stress locations. Yield of the transgenic hybrid (green circles) and nontransgenic isogenic hybrids (white circles) at individual locations are plotted against the yield of all entries tested at that location (Castiglioni et al., 2008).

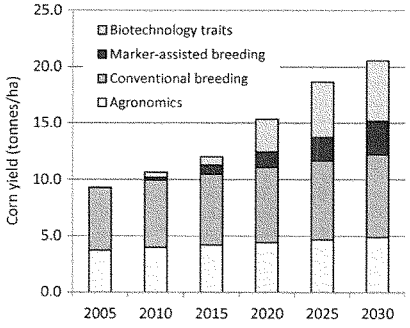

Figure 7. Anticipated impact of improvements in agronomics, breeding, and biotechnology on average corn yields in the United States. Rate of yield improvement due to breeding is extrapolated from observations such as those shown in Figure 3B, using data extending across maturity groups from Monsanto's North American corn breeding program. Agronomic (planting density, fertilizer use efficiency, improvements in soil management) contributions to the rate of yield improvement are considered to proceed at current historical rates based on estimates in Duvick (2005). Rate of yield improvement for biotechnology traits is a combination of the effects of current yield-protecting biotechnology traits, the introduction of biotechnology traits for drought tolerance, and additional yield-enhancing biotechnology traits. Biotechnology contributions to yield from herbicide tolerance, corn borer, and corn rootworm protection are estimated from the data presented in Figure 5. Biotechnology contributions to yield from drought tolerance are estimated from data presented in Figure 6 and an assumption that drought conditions strong enough to reduce yield will be seen on approximately 10% of the planted acres. Biotechnology contributions from yield-enhancing transgenes assume the introduction of three new biotechnology traits with effects similar to those described by Padgette (2008) over the course of the next decade. In each case biotechnology trait adoption curves such as those observed for current commercially available biotechnology traits are assumed (Monsanto, 2008).

nomic practices has the potential to double corn yields in the United States over the next two decades (Fig. 7). Doubling U.S. average yields would raise average yields to approximately 20 tonnes/ha, values now seen rarely in nonirrigated corn. The theoretical light-limited maximum for corn yields in the United States has been estimated at approximately 25 tonnes/ha (Specht et al., 1999; Tollenaar and Lee, 2002), close to the 24.2 tonnes/ha recorded on a 2-ha plot by David Hula of Charles City, Virginia in the 2007 National Corn Growers Association Corn Yield Contest. This fact suggests that corn yields can be doubled without large increases in yield potential, although significant improvements in broad stress tolerance, water use efficiency, and broad dissemination of excellent agronomic practices will be required to approach the Hula yield on broad acreage. Improving yields in corn and other crops on a global basis will allow farmers to meet global demand for feed, fuel, and food while minimizing the need to bring large amounts of new land into crop production. Even if crop producers supported by the agricultural sector fall short of doubling yields, continued public and private investment in agricultural technology will lead to significant increases in productivity that will help supply the world's needs for food, meat, and energy in a sustainable fashion.

ACKNOWLEDGMENTS

Many colleagues at Monsanto have contributed to this review. John Anderson, Marsha Stanton, Beth Calabotta, Dusty Post, Trevor Hohls, and Paolo Castiglioni have all provided data, helpful suggestions on content, or editing. In addition, a much larger group of people have contributed to the research and development that has made the inventions described in this review possible.

TABLE OF CONTENTS

INTRODUCTION: 1
- Recreating the prairie soil cycle 1
- Conservation tillage benefits the environment 1
- Biotechnology and the growth of no-till 1
- What is conservation tillage? 2
- Tillage was once necessary to control weeds, prepare soil 3

ENVIRONMENTAL BENEFITS OF CONSERVATION TILLAGE 4
- Erosion is reduced by nearly 1 billion tons per year 4
- $3.5 billion in sedimentation costs saved in 2002 4
- Insects, earthworms and microbes thrive 6
- Habitat for birds and mammals improves 6
- Preventing sediment and nutrient loss improves aquatic habitat 7
- Runoff into streams is reduced 7
- Decreased flooding, increased soil moisture 9
- Reducing "greenhouse gases" while enriching the soil 9
- Improved air quality 11
- No-till saves 3.9 gallons of fuel per acre 11

TRENDS LINK BIOTECH, CONSERVATION TILLAGE 12
- Improvements in weed control 12
- No-till has grown steadily since 1994 14
- Clear association between sustainable tillage and biotech 15
- Farmers not using h-t seeds not likely to practice conservation tillage 16

SUMMARY STATEMENT 17

Recreating the Prairie Soil Cycle

Two hundred years ago, most of the lands that today make up America's row-crop farms were vast expanses of grasslands or forests. These areas supported an ecological cycle that changed radically after settlers first put plows to the soil.

In the prairies, the annual cycle of grasses created a deep layer of litter, which protected the soil from wind and water erosion and temperature extremes. Soil organisms and insects thrived in the layers of dead grasses that built up each season. As prairie plants decayed, carbon and other nutrients returned to the soil. Water, instead of running off fields, seeped back into the soil, replenishing groundwater and nearby streams.

Nearly two centuries of intensive tillage later, that cycle has been radically altered. Organic matter has been lost, and erosion has taken topsoil. Within the past decade, however, many farmers have begun to recreate the cycle that once characterized the prairie soils and forests before they were cleared for farming. Corn, cotton, soybeans, wheat and other crops have replaced the tall grasses of the 18th century, which exist only in small pockets today. Nevertheless, the life cycle of the native soils is slowly returning as farmers convert their land to soil-saving conservation tillage while continuing to produce abundant crops.

Instead of plowing and disking their fields before planting, many farmers are leaving the residue of the previous crop on the soil surface. This layer of decaying plant material provides protective litter and begins to create conditions that existed before people first began to till the soil.

Conservation Tillage Benefits the Environment

Conservation tillage, as defined by the Conservation Technology Information Center, (www.ctic.purdue.edu) means any minimal tillage system that leaves the soil surface at least 30 percent covered by crop residue. Farmers employ various conservation tillage systems, which leave various amounts of residue. No-till, in which the soil is left undisturbed by tillage and the residue is left on the soil surface, is the most effective soil-conserving system. Research shows that land left in continuous no-till can eventually create a soil, water and biological system that more closely resembles characteristics of native soils before the advent of agriculture. No-till systems also can provide cover for wildlife if the stubble from the previous crop is left standing. Other studies show that reducing tillage can produce many other environmental benefits, such as:

- Reduced soil erosion.
- Improved moisture content in soil.
- Healthier, more nutrient-enriched soil.
- More earthworms and beneficial soil microbes.
- Reduced consumption of fuel to operate equipment.
- The return of beneficial insects, birds and other wildlife in and around fields.
- Less sediment and chemical runoff entering streams.
- Reduced potential for flooding.
- Less dust and smoke to pollute the air.
- Less carbon dioxide released into the atmosphere.

Biotechnology and the Growth of No-Till

The movement toward leaving more crop residue on farm fields expanded rapidly in the early 1990s. The federal government largely drove this by requiring soil conservation efforts on highly erodible acres in order to participate in farm programs. The introduction of improved high-residue seeding equipment and improved weed control technology also aided adoption.

The conversion of acreage to conservation tillage began to level off somewhat by the mid-1990s. However, since the mid-1990s, farmers have been increasing the amount of residue left on the soil surface. While reduced tillage practices such as mulch-till and ridge-till have been fairly static, farmers have been moving toward no-till farming. This agricultural practice, which has the potential to most closely approximate the native soil cycle, has expanded steadily during the time period when herbicide-tolerant crops, developed through biotechnology, have been adopted by U.S. and Canadian farmers.

There is a strong association between the use of herbicide-tolerant biotech crops and recent improvements in tillage reduction. Four trends support this conclusion:

- Weed control is a major consideration when farmers are weighing whether to implement conservation tillage, and several surveys indicate that farmers have more confidence in weed control since the introduction of herbicide-tolerant biotech crops. In some surveys, farmers say herbicide-tolerant crops enabled them to increase the amount of residue they leave on their fields.

- No-till, the tillage system that most relies on good herbicide performance, has grown more than other reduced tillage systems since 1996, and nearly all the growth has occurred in crops where herbicide-tolerance technology is available – soybeans, cotton and canola. (Herbicide-tolerant corn has not been widely adopted due to pending regulatory approval in Europe, nor has no-till corn expanded as rapidly as other crops.)
- Farmers who purchase herbicide-tolerant seeds use them disproportionately on their conservation tillage acres.
- Farmers who do not purchase herbicide-tolerant seeds are not as likely to participate in conservation tillage.

The main reason farmers till their soil is to control weeds, which compete with their crops for space, nutrients and water and can interfere with harvesting equipment. Historically, farmers have plowed under emerged weeds before planting and tilled the soil in preparation for herbicides that prevent additional weeds from emerging. If herbicides failed due to weather conditions, farmers could use additional tillage as a rescue.

With herbicide-tolerant crops, farmers allow weeds to emerge with their crops. Then they apply herbicide over the top of their crop, removing the weeds without harming the crop, which has been modified through biotechnology to withstand the herbicide. This improvement in weed control gives increased confidence that weeds can be controlled economically without relying on tillage. It partially explains why no-till farming has been increasing significantly in crops where the technology is available.

Many analyses have shown that conservation tillage provides economic benefits by saving time and reducing fuel and equipment costs. Despite these benefits, many farmers were reluctant to commit to a new system in which they saw potential risk of yield reduction due to competition from weeds. The trends since 1996, when herbicide-tolerant crops were first introduced, provide a strong indication that improved weed control made possible with the new biotech crops has given growers the confidence to increase their use of conservation tillage, especially no-till.

WHAT IS CONSERVATION TILLAGE?

Crop residues left on the soil surface protect the soil from the energy of wind and raindrops. Research shows that reductions in erosion are proportional to the degree that the soil surface is covered by crop residue.[2]

The Conservation Technology Information Center (CTIC) has defined various tillage systems according to how much crop residue is left on the soil surface and types of tillage tools used.

Conservation tillage – Any tillage and planting system that covers more than 30 percent of the soil surface with crop residue, after planting, to reduce soil erosion by water. Where soil erosion by wind is the primary concern, any system that maintains at least 1,000 pounds per acre of flat, small grain residue equivalent on the surface throughout the critical wind erosion period. No-till, ridge-till, and mulch-till are types of conservation tillage.

No-till – The soil is left undisturbed from harvest to planting except for planting and nutrient injection. Planting or drilling is accomplished in a narrow seedbed or slots created by coulters, row cleaners, disk openers, in-row chisels or rotary tillers. Weed control is accomplished primarily by herbicides. Cultivation may be used for emergency weed control.

Ridge-till – The soil is left undisturbed from harvest to planting except for nutrient injection. Planting is completed in a seedbed prepared on ridges with sweeps, disk openers, coulters or row cleaners. Residue is left on the surface between the ridges. Weed control is accomplished with herbicides and/or mechanical cultivation. Ridges are rebuilt during cultivation.

The residue from the previous year's crop remains on the surface of this no-till soybean field, protecting the soil from water and wind erosion.

Mulch-till – The soil is disturbed prior to planting. Tillage tools such as chisels, field cultivators, disks, sweeps, and blades are used. Weed control is accomplished with herbicides and/or mechanical cultivation.

Conventional-tillage leaves less than 15 percent residue cover after planting, or less than 500 pounds per acre of small grain residue equivalent throughout the critical wind erosion period. It typically involves plowing or intensive tillage. Tillage types that leave 15 to 30 percent residue cover after planting or 500 to 1,000 pounds per acre of small grain residue sometimes are referred to as **reduced tillage**, but they do not qualify as **conservation tillage.**

As a significant percentage of agriculture is left untilled, more like the original prairies, the water and soil cycles also will begin to return to a more natural state. Continued adoption of no-till practices will bring additional environmental benefits, which include increasing the amount of topsoil that is saved each year, reducing runoff into streams and further cutting back on fuel use and emissions.

Improved weed control available through herbicide-tolerant crops will be an important factor in continued adoption of no-till.

Tillage was once necessary

Repeated tillage to prepare crop seedbeds and control weeds was an indispensable component of agriculture until the last half of the 20th century. However, excessive tillage causes soil erosion, thus reducing the sustainability of agriculture. For example, 100 years after Iowa was settled, nearly half the original topsoil had eroded.[1] Repeated tillage also can reduce soil quality and productivity by destroying soil structure, reducing organic matter content and harming beneficial invertebrates such as earthworms. Sediment eroded from intensively tilled fields fouls aquatic systems, and runoff of water contributes to flooding. Tillage destroys wildlife food sources and reduces surface crop residues that serve as wildlife cover.

Edward Faulkner was one of the earliest proponents of eliminating the use of the moldboard plow, the most widely used primary tillage tool until the late 20th century. In his 1943 book, "Plowman's Folly,"[2] he called the plow "the villain in the world's agricultural drama." He concluded that plowing crop residues deep into the soil, leaving the soil's surface bare, reduced the long-term productivity of the soil. Faulkner wrote: "Had we not originally gone contrary to the laws of nature by plowing the land, we would have avoided the problems … the erosion, the sour soils, the mounting floods, the lowering water table, the vanishing wildlife, the compact and impervious soil surfaces."

Although many of Faulkner's predictions of benefits from what was later to be called "conservation tillage" turned out to be true, poor weed control, experienced when tillage was reduced, prevented most farmers from adopting the systems until the introduction of herbicides. Development of effective herbicides in the 1960s allowed farmers to reduce their dependence on repeated tillage to control weeds. Some eliminated tillage altogether.

However, weed control challenges and uncertainties remain. Some problem weeds, such as perennials, remain difficult to control. A few weeds have developed resistance to some popular herbicides. Because most herbicides do not control all weed species present in fields, farmers often apply two, three or more herbicides in combination. Effective weed control with herbicides requires careful identification of weed species and precise application timing. Crop injury may occur if adverse weather conditions reduce crop tolerance, or herbicide residues in the soil injure rotational crops. Soil-applied herbicides may fail if sufficient rainfall does not occur to activate the chemical.

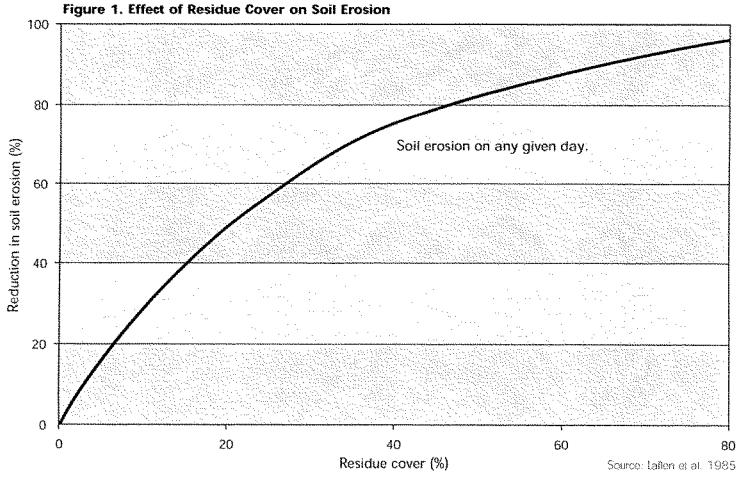
Biotechnology has given farmers additional weed control options by facilitating the development of crop varieties tolerant to herbicides, such as glyphosate and glufosinate. These herbicides, rather than preventing weed growth in the soil, are applied to emerged weeds and are effective against a broad spectrum of annual and perennial weeds. They are well-suited to conservation tillage systems because they do not require incorporation with tillage tools. In addition, they are applied at low rates, have low toxicity to animals and degrade rapidly. They cannot, however, be used with crops that have not been made tolerant through biotechnology, because they would have the same detrimental effect on the crop as they have on weeds.

As will be discussed later, farmers are using herbicide-tolerant crops disproportionately in reduced tillage systems, especially no-till. The majority of such crops are glyphosate-tolerant; therefore, subsequent discussion of herbicide-tolerant crops in this report will focus on glyphosate-tolerant varieties developed through biotechnology.

ENVIRONMENTAL BENEFITS OF CONSERVATION TILLAGE

As no-till acreage expands, farmers are able to recreate soil and water cycles more closely resembling characteristics of prairies and woodlands before settlers first put plows to the soil. The residue from the harvested crop is left on the soil surface. This layer of leaves and stems mimics the layer of litter that once covered native soils, protecting the soil from heat, preserving soil moisture and preventing erosion. Decaying root channels and burrows from earthworms serve as macropores, which aerate the soil and improve water infiltration. Other attendant benefits, including a return of soil organisms, birds and mammals, also are being realized.

Erosion is reduced by nearly 1 billion tons per year



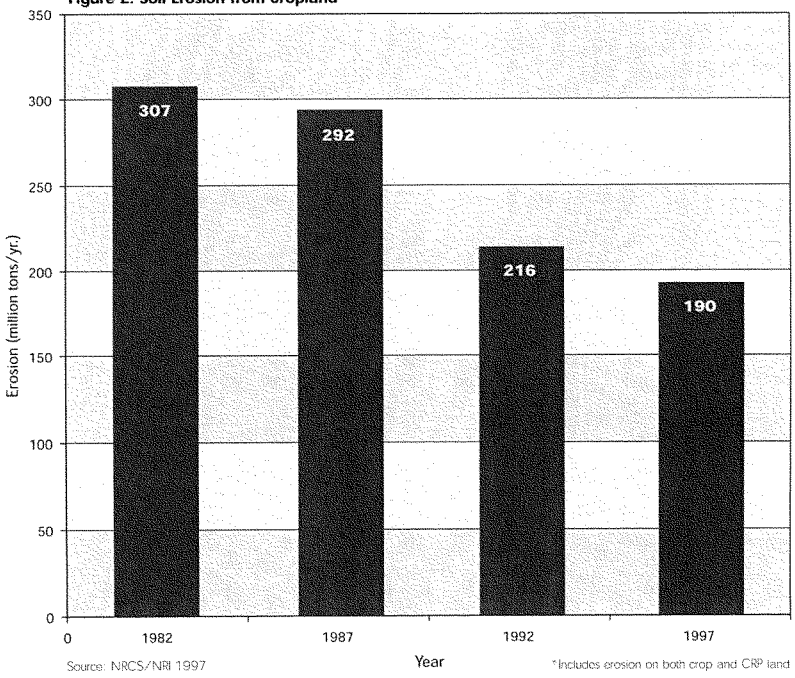
Conservation tillage is one of the most practical and economical ways to reduce soil erosion. Reducing or eliminating tillage operations leaves more crop residue on the soil surface, protecting the soil from the erosive impacts of wind and rain. Reductions in erosion are proportional to the amount of soil covered by crop residue (Figure 1).[3]

No-till systems, which leave nearly all plant surface residue in place, can reduce erosion by 90 percent or more.[4,5] The 1997 National Resources Inventory[6] showed that dramatic decreases in erosion have taken place in the United States since 1982. Much of this reduction can be credited to the adoption of conservation tillage by U.S. farmers. Sheet and rill (water) erosion on cultivated cropland fell from an average 4.4 tons per acre per year (9,856 kg/ha/year) in 1982 to 3.1 tons/acre/year (6,944 kg/ha/year) in 1997, a 30 percent decrease (Figure 2). The average wind erosion rate dropped 31 percent. Almost 1 billion tons per year of soil savings have occurred due to these changes in management. However, erosion is still occurring at a rate of 1.9 billion tons per year, and 108 million acres (29 percent of cropland) is still eroding at excessive rates.[7]

$3.5 billion in sedimentation costs saved in 2002

The 1998 National Water Quality Inventory reports that sedimentation is the most prevalent pollutant in streams that have been identified as environmentally impaired.[8] Unacceptable levels of sediment occur in 40 percent of impaired stream miles. Bacteria were the second most prevalent pollutant, present in 38 percent of impaired miles, followed by nutrients, occurring in 30 percent of impaired miles. Conservation tillage reduces the runoff of all these pollutants to surface water systems.

Figure 1. Effect of Residue Cover on Soil Erosion



Sediment decreases the storage capacity of reservoirs and interferes with the navigational and recreational uses of water. According to a U.S. Department of Agriculture study, the annual cost of damage to water quality from sediment originating on farmers' fields was $4 billion to $5 billion in the mid-1980s.[6]

Table 1 shows USDA estimates of the annual offsite damage from water and wind erosion. These damage values were calculated considering the cost of maintenance due to erosion, such as dredging rivers, cleaning road ditches and treating drinking water, as well as economic losses. Soil erosion rates fell 30 percent between 1982 and 1997, largely due to the adoption of conservation tillage by U.S. farmers and land enrolled in the Conservation Reserve Program (CRP).[6] The offsite erosion damages ($8.78 billion) shown in Table 1 were calculated in the 1980s. If offsite damages are proportional to erosion rates, an estimated $2.6 billion annual savings has resulted due

Table 1: Annual Offsite Damage from Soil Erosion in the United States

Damage Category	Annual Offsite Damage (Millions of $)
Water recreation	2,679
Water storage	1,090
Navigation	749
Flooding	978
Ditches	978
Commercial fishing	450
Municipal water treatment	964
Municipal and industrial use	1,196
Steam power cooling	24
TOTAL	$8,783

*Includes erosion on both crop and CRP land

to the erosion reduction achieved by farmers largely through conservation tillage. If adjusted for inflation this would represent a $3.5 billion annual savings in 2002.

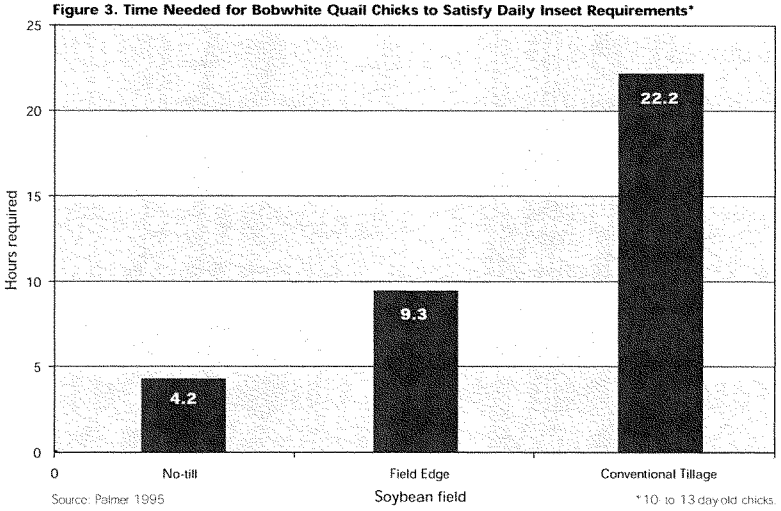
Sediment in water also has human health implications. Sediment and organic carbon carried on sediment cause problems for water utilities that use surface water as a drinking water source. Chlorine used to disinfect water reacts with organic carbon to produce trihalomethanes such as chloroform. Due to carcinogenicity, trihalomethanes are regulated under the Safe Drinking Water Act. Additional filtering is required to reduce sediment and organic carbon to prevent trihalomethane formation. Allowed levels of trihalomethanes are scheduled to decrease in the future, which will increase costs to water utilities.

Insects, earthworms and microbes thrive

Stinner and House[10] have reviewed studies of arthropods and invertebrates in no-till and other conservation tillage systems. They found that no-till crop fields generally have increased diversity of surface microarthropods. Many beneficial predatory arthropods, including ground beetles and spiders, are increased by no-till. For example, House and Parmalee[11] found 17.6 carabid beetles per square meter in no-till soybeans compared with 0.38 per square meter in plowed treatments. Carabid beetles are important predators of pests in many crops. Mites, which are important predators of other arthropods and nematodes, are increased in no-till.[12] Increased diversity of arthropods with no-till has been attributed to the increased structural diversity of litter.

Earthworm populations have consistently increased as tillage is reduced. House and Parmalee[11] compared a field with 17 years of no-till cropping with a conventionally tilled field and found from 3.5 to 6.3 times more earthworms in the no-till field. Earth-worms help incorporate organic residues into the soil, aerate the soil and improve water infiltration. Night crawlers (*Lumbricus terrestris* L.) are large, surface-feeding earthworms, which live in permanent, vertical burrows. Tillage harms earthworms by burying food sources and destroying burrows. As many as 81,000 burrows per acre (200,000/ha) have been reported in no-till fields.[13] Improvements in water infiltration, which often accompany conversion to no-till, have been at least partly attributed to these burrows.[14]

Tillage, which incorporates organic debris into the soil, is more suitable for microorganisms with higher turnover rates, such as bacteria and bactivorous fauna, including protozoa and nematodes.[15,16] Decomposition processes in no-tillage systems are controlled primarily by fungi, with fungivorous microarthropods, nematodes and earthworms dominant in subsequent steps in the food web.[17] Fungal dominated microbial communities of no-till systems store more organic material for longer periods, resulting in higher steady-state levels of organic matter. Fungal hyphae aid in the formation of soil aggregates or tiny soil particles bound into larger units. These aggregates aid in improving soil structure and increasing retention of soil carbon. Extracellular polysaccharides of fungi also are important in the formation of soil aggregates. Soil aggregates allow for the most desirable mix of air and water for good plant growth.



Total microbial populations are often higher in no-till soils than in tilled soils. Doran[18] found that counts of aerobic microorganisms, facultative anaerobes and denitrifiers in the surface of no-till soils were higher than in the surface of plowed soil. Phosphatase and dehydrogenase enzyme activities and contents of water and organic carbon and nitrogen in the surface of no-till soil also were significantly higher than those for conventional tillage. Such increases in microbial activity have been associated with increased rates of herbicide and insecticide degradation with no-till.[18,19] Rapid degradation of pesticides is one of the factors that reduce their potential to enter surface or ground-water supplies.

Habitat for birds and mammals improves

Research shows that no-till fields provide food and habitat for birds and mammals. Insects and other arthropods, which thrive in the protective residue in no-till fields, are important food sources for many birds. Palmer[20] studied bobwhite quail (*Colinus virginianus*) behavior in no-till and conventional fields in North Carolina. The research showed that quail chicks needed 22 hours to obtain their minimum daily requirement of insects in conventional soybean fields. In no-till soybean fields, only 4.2 hours were required to obtain the minimum daily requirement, about the same as the 4.3 hours required in natural fallow areas believed to be ideal quail habitat (Figure 3).

Cover provided by crop residue, plus waste grain and weed seed food sources left on the soil surface, along with less disturbance from field operations, are all beneficial to wildlife. Many studies have shown that no-till row crop fields have higher densities of birds and nests and are used by a greater variety of bird species during the breeding season than tilled fields.[21,22] Bird nesting success in conventionally tilled row-crop

Figure 3. Time Needed for Bobwhite Quail Chicks to Satisfy Daily Insect Requirements*

Source: Palmer 1995

*10- to 13-day-old chicks.

fields is usually below levels needed to sustain populations, often because field operations disrupt nests.[23] As fewer trips over the field with equipment are made with conservation tillage, nesting is favored, particularly for species that normally raise only one brood per year, such as the ringneck pheasant. Grassy nesting cover adjacent to no-till fields provides even more favorable habitat.

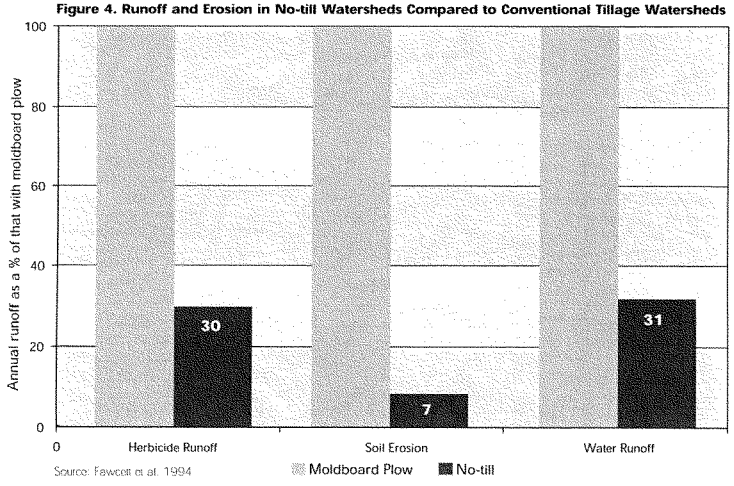
Small mammals also favor conservation tillage. In Illinois, no-till cornfields had more abundant and more diverse invertebrates, birds and small mammals than conventionally tilled corn.[22] Small-mammal populations, particularly deer mice, were more stable in no-till. Management changes can further improve wildlife habitat provided by no-till fields. Leaving stubble 10 to 14 inches tall when harvesting small grains provides improved habitat compared with shorter stubble heights. Additional research is needed to determine how to maximize the wildlife benefits of conservation tillage.

Preventing sediment and nutrient loss improves aquatic habitat

Sediment in rivers, streams and lakes covers gravel beds needed for habitat by fish and crustaceans. Sediment also clouds water, reducing sunlight penetration and reducing photosynthesis of submerged plants and algae, causing a cascading effect through food chains. Conservation tillage's ability to dramatically reduce erosion reduces delivery of sediment to aquatic systems, improving aquatic habitats.

Excessive loads of the nutrients phosphorus and nitrogen from agricultural land and other sources can lead to excessive growth of aquatic plants. When these plants decompose, oxygen concentrations in water can drop to levels too low to support some aquatic organisms, a condition called hypoxia. Hypoxia can occur in fresh water bodies or marine environments such as the Gulf of Mexico.[24] Because conservation tillage reduces nutrient losses, it is an important tool in reducing agriculture's impact on hypoxia.

Runoff into streams is reduced



As portions of agriculture are returned to an untilled state more like the original prairies and forests, the water cycle also will return to a more natural state.[25] With less water runoff and more infiltration, streams are fed more by subsurface flow than surface runoff. This allows better use of water and nutrients by crops and allows soil clay, organic matter and biological activity to filter the water before it becomes surface water.

Decreased runoff means that fewer pollutants enter streams. Several paired watershed studies showed that no-till fields produced no seasonal runoff while conventional tillage watersheds had significant water runoff, soil erosion and pesticide runoff.[26, 27, 28] An Ohio study compared total water runoff from a 1.2-acre (0.5 ha) watershed with 9 percent slope that had been farmed for 20 years in continuous no-till corn to a similar conventionally tilled watershed. Over four years, runoff was 99 percent less under the long-term no-till. This decrease in runoff was attributed to increases in infiltration due to development of soil macropores in the absence of tillage.[29] Cracks, root channels and earthworm holes allow water to bypass upper soil layers when rainfall exceeds the capacity of soil to absorb water through capillary flow, the movement through tiny spaces between soil particles.[14]

When runoff is reduced, the flow of pollutants such as sediment, fertilizers and pesticides also is reduced. Pesticides and fertilizers enter surface waters in liquid solution or attached to sediment that washes off farm fields. Studies have demonstrated how no-till reduces chemical runoff. Baker and Laflen[30] found that a 97 percent reduction in sediment loss for no-till (relative to the moldboard plow) resulted in a 75 to 90 percent reduction in total nitrogen loss for soybeans planted following corn and 50 to 73 percent reduction in nitrogen loss for corn following soybeans. Studies show reduction in phosphorus fertilizer runoff if the fertilizers are subsurface band-applied instead of surface-applied. Andraski *et al.*[31] compared runoff losses of phosphate from four tillage systems when fertilizer was subsurface banded in all systems. Three reduced tillage systems — no-till, mulch-till and strip-till — reduced total phosphate losses by 81, 70 and 59 percent respectively, compared with the moldboard plow. Soluble phosphorus losses also were reduced by no-till and mulch-till, which employs a chisel plow. When total phosphorus losses were compared in no-till and conventional tillage, a 97 percent reduction in soil erosion with no-till resulted in an 80 to 91 percent reduction in phosphorus loss[30] for soybeans following corn. For corn following soybeans, an 86 percent reduction in soil loss led to a 66 to 77 percent reduction in phosphorus lost.[30]

Runoff of pesticides, both soil-attached and dissolved, usually is reduced in conservation tillage. No-till sometimes has resulted in complete elimination of pesticide runoff.[26, 27, 28] A summary of published natural rainfall studies comparing no-till with moldboard plowing showed that, on the average (over 32 treatment-site-years of data), no-till resulted in 70 percent less herbicide runoff, 93 percent less erosion and 69 percent less water runoff than moldboard plowing (Figure 4).[32]

Figure 4. Runoff and Erosion in No-till Watersheds Compared to Conventional Tillage Watersheds

Source: Fawcett et al. 1994

Other conservation tillage systems also have reduced herbicide runoff. In a Kentucky natural rainfall study, both no-till and chisel plowing (mulch-tillage) reduced runoff of atrazine, simazine and cyanazine by more than 90 percent, compared with moldboard plowing.[33] Ridge-till has reduced herbicide runoff by an average 42 percent in natural rainfall studies.[32]

Because no-till often increases water infiltration, some feared that this tillage system might also increase leaching of chemicals through the soil profile to groundwater. Several studies have shown, however, that no-till either had little impact on nitrate leaching or decreased leaching slightly.[34, 35, 36] A few studies have shown increased leaching of certain pesticides to shallow depths in no-till compared with tilled soil,[37, 38] while others have documented less leaching of pesticides with no-till.[39, 40, 41, 42, 43, 44] As crops genetically modified to tolerate the herbicide glyphosate are increasingly planted in no-till systems, leaching potential should be lessened, because this compound binds tightly to the soil and is highly unlikely to move to groundwater. Reductions in leaching of other herbicides used in no-till may be due to greater microbial activity degrading the pesticide, greater organic matter adsorbing the pesticide or to water bypassing upper layers of soil containing the pesticide, due to flow down macropores. The mucous lining of earthworm burrows has also been shown to adsorb pesticides.[45] When the herbicide atrazine was poured down night crawler burrows, concentrations exiting at the bottom were reduced tenfold. Although conservation tillage has not always reduced pesticide leaching, because of favorable results in many studies, no-till is recommended as a practice to reduce pesticide leaching by some water quality specialists.[42, 44]

Decreased flooding, increased soil moisture

Reduced runoff due to conservation tillage also is associated with decreased flooding. Such a decrease was documented on the Pecatonica River in Wisconsin. A decrease in flood peaks and winter/spring flood volumes accompanied by an increase in base flow (due to infiltration) was documented. The changes were not correlated to climatic variations, reservoir construction or major land use changes but appeared "to have resulted from the adoption of various soil conservation practices, particularly those involving the treatment of gullies and the adoption of conservation tillage."[46]

Conservation tillage not only reduces water loss through runoff, it also reduces evaporation losses so that more soil moisture is preserved for crop production. In one study, cumulative water losses for the first five hours after tillage were 0.113 in. (0.29 cm) with conventional tillage vs. 0.052 in. (0.13 cm) for no-till.[47] In Kentucky, annual evaporation was reduced by 5.9 inches (15.0 cm) with no-till.[48] In areas where rainfall is limited, such as the Great Plains of the United States, grain production is made possible by fallowing land. No crop is planted for a year or part of a year so that soil moisture can be stored for use by the next planted crop. Weeds must be controlled during the fallow period to prevent them from drawing moisture out of the soil. Traditionally, weeds in fallow land were controlled by repeated tillage operations. However, tillage increases evaporation losses, causes wind and water erosion and disturbs wildlife habitat. Chemical fallow or ecofallow systems, which use herbicides to control weeds, have been developed for crops planted no-till following the fallow period.[49, 50] In Kansas, Norwood[51] found that water use efficiency was increased by 28 percent in no-till corn grown in a wheat-corn-fallow rotation, compared with conventional tillage. Corn yields were 31 percent higher with no-till. Widespread adoption of these conservation systems across the Great Plains has improved the economic welfare of farmers, as well as reduced erosion and improved wildlife habitat.

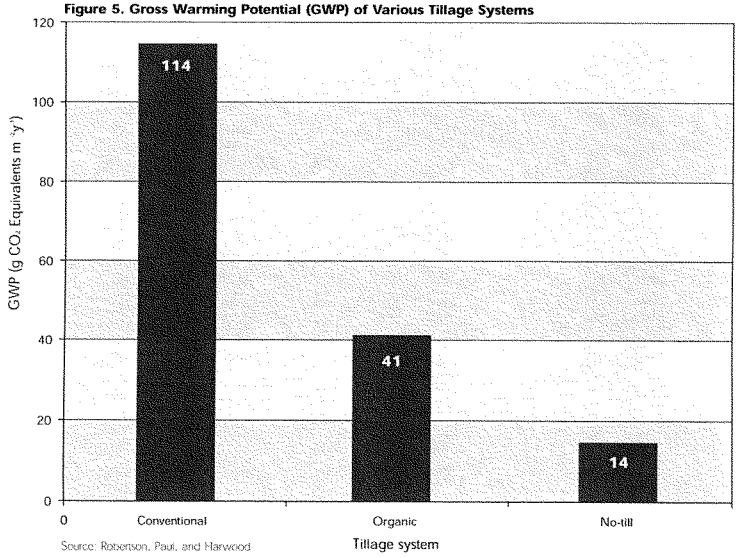
Irrigation efficiency also is improved by conservation tillage. More moisture from rainfall is stored, and more of applied irrigation water infiltrates to be used by crops. The residue on the soil surface also reduces crop evapotranspiration. Improved irrigation efficiency benefits farmers by increasing yields and decreasing pumping and irrigation water costs while protecting aquifers from depletion.

Reducing "greenhouse gases" while enriching the soil

Soil organic matter is considered to be the largest terrestrial carbon pool[52] and influences the atmospheric content of CO_2, CH_4 and other greenhouse gases.[53] Soil organic matter can serve as a source or a sink for atmospheric carbon.[54] Conservation tillage, especially no-till, increases the ability of soil to store or sequester carbon, simultaneously enriching the soil and protecting the atmosphere.

Tillage increases the availability of oxygen, thus speeding the microbial decomposition of soil organic matter. Decomposition releases large quantities of CO_2, a "greenhouse" gas linked to global climate change. A 10-year analysis of common cropping systems in the United States showed that no-till farming had far less global warming potential than conventional tillage or organic systems.[55] The researchers calculated the types and amounts of greenhouse gases that were emitted or stored by each cropping activity and calculated a

numerical value called the gross warming potential (GWP) for each. Conventionally plowed fields had the highest net GWP (114), compared with 41 for organic farming and 14 for no-till (Figure 5).



By converting land to no-till production, rather than depleting soil organic matter, organic matter can be increased, sequestering CO_2 from the atmosphere. Soil organic matter content has increased by 1,000 lb/acre/year (1120 kg/ha/year) in some no-till studies.[5,56] That is equivalent to 590 lb/acre (661 kg/ha) carbon stored per year, compared with the 15-20 lb/acre (17-22 kg/ha) carbon that was burned as fuel to produce the crop.

Kern and Johnson[57] projected changes in atmospheric carbon due to several scenarios involving adoption of conservation tillage in the United States until the year 2020. Converting from conventional tillage to no-till on 57 percent of crop acres would result in a gain in soil organic matter of 80 trillion to 129 trillion grams (Tg) (Tg = 1012g = 1 million metric tons = 1.102 million tons) and would remove a like amount of carbon from the atmosphere.

Lal *et al.*[55] have reviewed the importance of cropland as a source and sink for atmospheric carbon. The estimated 55,000 million metric tons (MMT) of historic soil-C loss from cultivated soils worldwide accounts for about 7 percent of the current atmospheric inventory. They conclude that cropland soils potentially can sequester a considerable part of this lost carbon with adoption of practices such as conservation tillage. Considering U.S. cropland, about 5,000 MMT of soil organic carbon has been lost from its pre-agricultural levels. The authors conclude: "One reasonably can assume that cropland potentially can sequester 4,000 to 6,000 MMT, with an average of 5,000 MMT in cropland soils – potentially more, with new technologies and proper management."

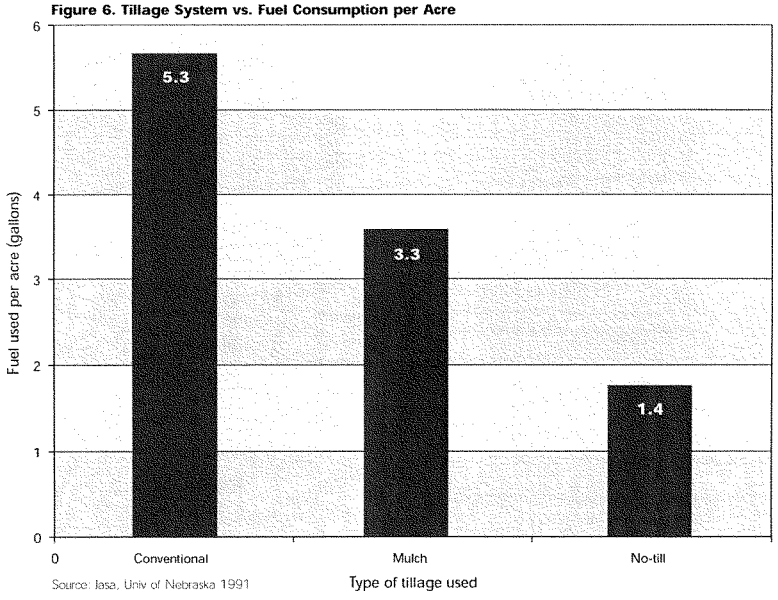
Reicosky *et al.*[58] measured CO_2 released from soil after tilling wheat stubble with various implements in the fall. Over a 19-day period, one pass of a moldboard plow caused five times as much CO_2 to be lost from the soil, compared with untilled plots. More organic matter was oxidized in 19 days than was produced all year in wheat straw and roots, helping explain why organic matter content has steadily declined in tilled

Figure 5. Gross Warming Potential (GWP) of Various Tillage Systems

Source: Robertson, Paul, and Harwood

soils until equilibrium is reached. Organic matter contents of agricultural soils in the United States have declined by as much as 50 percent or more due to this phenomenon. In effect, organic matter has been "mined" by agriculture. For example, the Morrow Plots at the University of Illinois were first established in 1876 and have been maintained in constant cropping systems to date.[59] Soil organic matter was first measured in 1903, when levels were about 40 tons per acre (44,800 kg/ha). By 1973, under continuous corn production, organic matter content had dropped to about 20 tons per acre (22,400 kg/ha). Conservation tillage systems, especially no-till systems, do not simply stop organic matter loss; they can cause soil organic matter content to increase. Reicosky *et al.* and Reeves found that organic matter has increased by as much as 1,800 pounds/acre/year (2000 kg/ha/year) in long-term no-till studies.[58, 60]

Improved air quality



Conservation tillage, by reducing wind erosion, also reduces the amount of dust that can enter the atmosphere. In some regions, dust from agricultural fields is a major air quality concern. Wind-eroded dust also carries other contaminants such as pesticides and nutrients into the atmosphere where they are later deposited by rainfall into aquatic systems.[61, 62]

Conservation tillage is also an alternative to the practice of burning residue left on fields. In some regions of the United States, crop residue is burned to facilitate planting of rotational crops. This practice not only causes air pollution with smoke but also releases CO_2 into the atmosphere and reduces soil quality by destroying organic matter. Adoption of conservation tillage systems has significantly reduced the practice of burning crop residues.

No-till saves 3.9 gallons of fuel per acre

As tillage operations in crop fields are reduced or eliminated with the adoption of conservation tillage, fuel consumption declines. Fuel usage for no-till may decrease from 3.5 gal/acre (32.7 L per ha) to 5.7 gal/acre (53.3 L per ha) depending on the number of tillage trips reduced, clay and moisture content of the soil, and type of tillage operations eliminated.[57] Moldboard plowing typically uses 5.3 gal/acre, chisel

Figure 6. Tillage System vs. Fuel Consumption per Acre

Source: Iasa, Univ of Nebraska 1991

plowing 3.3 gal/acre, and no-till 1.4 gal/acre.[63] For every gallon of diesel fuel saved, 3.72 lbs of CO_2 are not released.

In 2002, 15 million acres (6.1 million hectares) of corn and 26 million acres (10.5 million hectares) of soybeans were grown in no-till systems in the United States, amounting to 41 million no-till acres (16.6 million hectares). Using the 3.9 gallons per acre estimated savings from no-till,[62] a net savings of 160 million gallons (605 million liters) of fuel per year is being realized in the no-till production of just these two crops. The 55.3 million no-till acres (22.4 million hectares) planted from all crops in the U.S. in 2002 would account for a savings of 216 million gallons (817 liters) of fuel that year. Mulch-tillage saves two gallons per acre of fuel compared with conventional tillage, accounting for a fuel savings of 90 million gallons on the 45 million acres (18.2 million hectares) of mulch-till systems. The combined fuel reduction from no-till and mulch-till systems therefore accounted for a savings of 306 million gallons of fuel.

Significant reductions in tillage have occurred as herbicide-tolerant crop varieties have facilitated conversions to conservation tillage. A 2001 American Soybean Association survey[64] asked soybean growers if and how much tillage had been reduced between 1996 and 2001 (the period of time glyphosate-tolerant soybeans had been available). Soybean growers responded that they had reduced tillage by an average 1.8 passes per growing season. One tillage pass consumes about 0.7 gallons of diesel fuel per acre.[65] Thus, soybean growers have reduced fuel consumption by 1.26 gallons per acre since the introduction of glyphosate-tolerant soybeans. With more than 56 million acres of biotech soybeans planted in 2001, a savings of 70 million gallons of fuel occurred just from this crop. In 2002, 75 percent of all soybeans planted were biotech soybeans. (USDA/NASS)

TRENDS LINK BIOTECH, CONSERVATION TILLAGE

Many factors determine whether a farmer will practice conservation tillage. Cultural factors, climate, soil type, equipment availability, moisture content, tradition and other considerations all can be at play in making tillage decisions. Weed control is among the most important factors, at least in commonly grown row crops. The development of herbicide-tolerant crops has given farmers a new, versatile technology for controlling weeds. It has removed much of the uncertainty in weed control that prevented farmers from abandoning tillage.

Since the development of herbicide-tolerant soybeans and cotton, there have been marked increases in conversion to no-till, the system most dependent on herbicide performance. In other crops, where the herbicide-tolerant technology is not available, there have not been large increases in conservation tillage.

Farmers who use herbicide-tolerant seeds are more likely to engage in conservation tillage practices than in conventional tillage practices. Furthermore, farmers who use herbicide-tolerant seeds practice conservation tillage to a greater degree than farmers who do not use the new technology.

These facts and trends indicate that the advent of herbicide-tolerant crops, developed through biotechnology, has solidified the acreage converted to conservation tillage during the early 1990s and has contributed to the steady growth of no-till acreage since 1996, when the crops were introduced. Biotechnology may well have the potential to facilitate even more no-till.

An analysis of governmental, independent and industry data, as well as grower surveys, shows a strong association between herbicide-tolerant crops and growers' decisions to increase their level of crop residue. The following four findings emerge:

1. Improvements in weed control, including the adoption of biotech herbicide-tolerant crops, are important reasons for initial adoption and continuance of no-till.

Because the primary reason for tillage is weed control, many farmers, assured of weed control without disturbing the seedbed, will choose to reduce tillage. Herbicide-tolerant crops provide farmers with an important advancement in weed control capability.

Past surveys of farmers, assessing reasons for not adopting conservation tillage, consistently found that weed control was one of the greatest deterrents.[66] In 1991, Iowa farmers were surveyed on their attitudes about tillage. Weed control was most important to farmers considering tillage changes. Farmers who had tried no-till were asked to identify advantages or disadvantages to the system. Sixty-eight percent responded that weed control was a disadvantage. Only chemical costs (70 percent responding) ranked higher as a disadvantage.[67]

If farmers had greater confidence in no-till weed control systems, more farmers could be expected to convert to no-till. Conclusions from these surveys indicate that improvements in weed control, including the adoption of biotech herbicide-tolerant crops, are important reasons for initial adoption and continuance in no-till systems.

In 1999, corn and soybean producers in Iowa were surveyed to determine their tillage practices, yields and attitudes about tillage.[63] Among no-till farmers, 68 percent felt that herbicide effectiveness had increased in the last five years; 56 percent of farmers who had tried but quit no-till felt effectiveness had increased; and 34 percent of farmers who had never tried no-till felt herbicides were more effective. Thus, it is apparent that no-till adopters have more confidence in their weed control systems. Consistent weed control offered by herbicide-tolerant crop systems could increase the confidence of all farmers, resulting in the increased adoption of no-till by farmers who have never tried it and reducing the number of first time no-tillers who revert back to conventional tillage.

An American Soybean Association random survey of soybean growers planting 200 acres or more in the 19 major soybean-producing states documents the importance of glyphosate-tolerant soybeans in facilitating conversion from conventional tillage to no-till and reduced tillage. Soybean growers reported having reduced tillage by an average 1.8 passes from 1996 to 2001, during the period of time that glyphosate-tolerant soybeans were available. Average crop residue cover increased from 28 percent to 49 percent. During the same period, no-till soybean acres in the American Soybean Association survey more than doubled to 49 percent, and reduced tillage acres increased by more than one-fourth, to account for 83 percent of soybean acres. During this time, 53 percent of growers reported making fewer tillage passes, 73 percent left more crop residue on the soil surface, and 48 percent had increased their no-till acres.[64]

To what can these increases be attributed? Sixty-three percent of soybean growers who increased their crop residue between 1996 and 2001 cited glyphosate-tolerant technology as the key factor that made it possible for them to reduce tillage or increase residue.[64] That was an unaided response to the question: "In the past five years, what changes in technology such as equipment, chemicals or seed have made it possible for you to reduce tillage or increase crop residue in soybeans?"

When asked which of six factors had the greatest impact toward the adoption of reduced tillage or no-till during the past five years, growers indicated:

- The introduction of glyphosate-tolerant soybeans 54 percent.
- Availability of over-the-top or in-crop herbicides 12 percent.
- The cost of burndown herbicides 6 percent.
- The availability of burndown herbicides 3 percent.

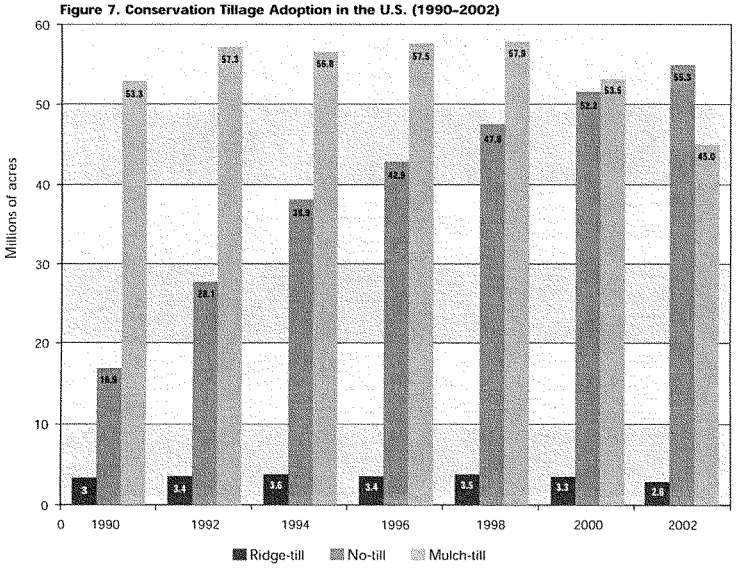
A total of 75 percent of surveyed farmers felt some aspect of weed control was the greatest factor in adopting reduced tillage or no-till. Availability of and improvements in no-till drills garnered responses of 9 and 15 percent respectively.[64]

In a Canadian survey, 26 percent of canola growers said they had increased their conservation tillage practices because of herbicide-tolerant technology.[69] Their average increase was 69 percent, which translates into 2.6 million acres or 1.05 million hectares in western Canada having been positively impacted by increased conservation tillage practices since the introduction of the technology.

Weed control is similarly important to cotton producers. A USDA survey showed that 76.3 percent of herbicide-tolerant cotton growers said they planted herbicide-tolerant varieties because of increased yields through better weed control, and 18.9 percent cited decreased herbicide input costs.[70]

Competition brought on by herbicide-tolerant technology has resulted in an overall lowering of weed control costs, thus addressing another concern about moving to no-till. Gianessi and Carpenter calculated that U.S. soybean growers spent $220 million less on weed control in 1998 compared with 1995, after the added costs of glyphosate-tolerant seed were factored in.[71] These benefits are supported by the rapid adoption of the technology since its introduction in 1996. Glyphosate-tolerant soybeans were planted on 75 percent of soybean acres in 2002, and glyphosate-tolerant cotton was planted on 58 percent of cotton acres.[72] In Canada, herbicide-tolerant varieties were planted on an estimated 55 percent of the 12 million acres (4.9 million hectares) of canola produced in 2000.[68]

Biotech crops have given farmers a new weed management tool, allowing the post-emergence use of highly effective broad-spectrum herbicides. Perennial weeds are often prevalent in conservation tillage, especially in no-till systems. Many perennials have been noted to



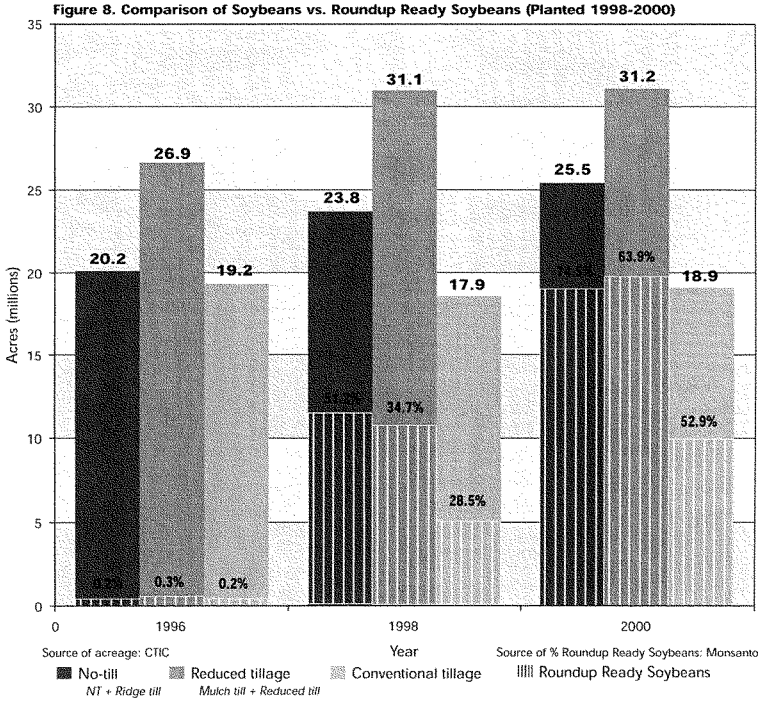
increase with conservation tillage.[7] The ability to apply glyphosate over tolerant crops, made possible by biotechnology, now allows control of tough perennials that escape most other herbicides. The risk of suffering poor weed control has been reduced significantly. Biotech crops are not required for the practice of conservation tillage or no-till, but the herbicide-tolerant crops developed through biotechnology have provided farmers with an additional weed management tool, solving some weed control problems faced by conservation tillage farmers.

2. No-till, the system that most depends on herbicide performance, has grown steadily since 1994. Nearly all of this growth occurred in crops where herbicide-tolerant technology is available.

CTIC tillage surveys are based on criteria it developed to define conservation tillage (at least 30 percent residue cover after planting). Mulch-till, ridge-till and no-till are the various forms of conservation tillage. Figure 7 shows national adoption trends for these systems from 1990 through 2002. Since 1996, conservation tillage adoption in the United States has remained fairly constant – about 36 percent of all annually planted cropland or between 103 million and 109 million acres. Thus, total conservation tillage acres appear to have temporarily reached a plateau. However, adoption of no-till, the most soil-conserving form of conservation tillage, continues to increase, rising from 40.9 million acres (14.7 percent of all cropland) in 1995 to 55.3 million acres (19.6 percent of all cropland) in 2002. This represents a growth of 35 percent in no-till since biotech crops were introduced in 1996, according to CTIC's National Crop Residue Management Survey.

The fact that no-till acreage increased while overall conservation tillage has remained steady indicates that growers who earlier made a commitment to some form of reduced tillage decided to leave even more residue on their fields. The 2001 American Soybean Association survey found that 73 percent of soybean growers were leaving more crop residue than five years earlier, and 48 percent of them had increased their no-till acreage from 1996 levels. As stated earlier, 75 percent of soybeans planted in 2002 were glyphosate-tolerant varieties.

Figure 7. Conservation Tillage Adoption in the U.S. (1990–2002)



Soybeans and cotton have the highest percentage of biotech crops and account for half of the total no-till acres planted in the U.S. in 2002, according to CTIC figures. It is also significant that the two crops for which glyphosate-tolerant (Roundup Ready®) varieties have been rapidly adopted continue to show increases in adoption of no-till. No-till soybean acres increased from 19.3 million acres (7.8 million hectares) in 1995 (before glyphosate-tolerant crops) to 26 million acres (10.5 million hectares) in 2002. No-till cotton acres increased from 0.5 million (0.2 million hectares) in 1996 (before glyphosate-tolerant crops) to 2 million acres (0.82 million hectares) in 2002. Glyphosate-tolerant soybean varieties have been available since 1996, and cotton varieties since 1997. Glyphosate-tolerant corn was first marketed in 1998. Herbicide-tolerant canola became available in Canada in 1996 and the United States in 1999. Only about 1.5 million acres of canola were planted in the United States in 2000.

3. There is a clear association between sustainable tillage practices and biotech crops.

Table 2 shows national percentages of tillage categories planted to glyphosate-tolerant soybeans, cotton and corn for 1998-2000. While farmers using all tillage systems have adopted the glyphosate-tolerant crops, conservation tillage farmers are much more likely to use the biotechnology crops. For example, in 1998, no-till soybeans were nearly twice as likely to be planted to glyphosate-tolerant varieties compared with conventional varieties, while no-till cotton was more than twice as likely to be planted to glyphosate-tolerant varieties. Adoption of glyphosate-tolerant crops by conservation tillage farmers continues to grow. In 2000, 52.9 percent of conventional tillage, 63.9 percent of reduced tillage, and 74.5 percent of no-till soybean acres were planted to glyphosate-tolerant varieties. Cotton acres planted to glyphosate-tolerant varieties for

Figure 8. Comparison of Soybeans vs. Roundup Ready Soybeans (Planted 1998-2000)

2000 were 46.8 percent of conventional tillage, 63.2 percent of reduced tillage and 86.2 percent of no-till. In 2000, 4.3 percent of conventional tillage, 4 percent of reduced tillage and 7 percent of no-till corn was planted to glyphosate-tolerant varieties.

No-till cotton is constrained by the predominance of furrow irrigation and boll-weevil eradication programs in some regions, such as California and Arizona, which restricts conversion to no-till. In other cotton-growing regions, producers who tried the relatively new no-till system for cotton used herbicide-tolerant varieties to facilitate the change. In Arkansas in 1998, only 6.7 percent of conventionally tilled cotton was planted to glyphosate-tolerant varieties, while 97.8 percent of no-till cotton acres were planted to the biotech varieties.[74]

In 2000, glyphosate-tolerant cotton was planted on 97, 96, 95 and 94 percent of no-till cotton in Georgia, Tennessee, Alabama and North Carolina, respectively.[75] The high adoption rate of glyphosate-tolerant cotton by no-till producers illustrates the utility of this technology in conservation tillage. In 2000, glyphosate-tolerant corn was planted on only 5 percent of corn acres in the United States, due in large part to a concern about export restrictions. About 7 percent of all no-till corn acres planted in 2000 were glyphosate-tolerant.

The American Soybean Association survey of grower practices confirms the greater usage of glyphosate-tolerant soybeans in no-till and reduced tillage systems. In the 19-state area represented by the survey, glyphosate-tolerant soybeans were planted on 36.8 million conservation tillage acres and only on 5.3 million conventionally tilled acres.[63] Clearly, with the glyphosate-tolerant seeds going disproportionately to the soybean acres in conservation tillage, farmers understand the value of the technology to reduced tillage systems.

4. Farmers who don't use herbicide-tolerant seeds are not as likely to engage in conservation tillage.

While it is clear that many farmers who use traditional weed control systems also participate in conservation tillage, there is significantly greater participation among those soybean and cotton farmers who use herbicide-tolerant varieties developed through biotechnology. Table 3 shows results of the American Soybean Association survey[63] comparing practices of glyphosate-tolerant soybean adopters to non-adopters. Glyphosate-tolerant soybean growers planted more no-till and reduced till acres than non-adopters. For the period 1996 to 2001, 52 percent of glyphosate-tolerant soybean adopters had increased no-till acres, compared with 21 percent of non-adopters. Fifty-eight percent of adopters reported reducing tillage passes, with 20 percent of non-adopters reducing tillage passes.

Likewise, in Canada, 50 percent of canola growers who used herbicide-tolerant varieties participated in conservation tillage practices, while only 35 percent of non-adopters practiced conservation tillage.[68]

Table 2: Adoption of glyphosate-tolerant (Roundup Ready) crop technology by tillage system for U.S. soybeans, corn and cotton 1998-2000

	Percent of Acres Planted to Glyphosate-Tolerant Crop		
Year	Conventional Tillage	Reduced Tillage	No-till
Soybeans			
1998	28.5	34.7	51.2
1999	47.0	55.9	70.7
2000	52.9	63.9	74.5
Cotton			
1998	21.3	37.7	57.2
1999	35.0	51.4	65.8
2000	46.8	63.2	86.2
Corn			
1998	1.2	1.1	1.8
1999	3.2	2.9	4.4
2000	4.3	4.0	7.0

SUMMARY STATEMENT

Herbicide-tolerant crops developed through biotechnology have provided farmers with an additional weed management tool. They have solved some weed control problems faced by conservation tillage farmers and simplified weed control. An analysis of surveys conducted since the introduction of herbicide-tolerant crops strongly supports the conclusion that these crops developed through plant biotechnology are facilitating the continued expansion of conservation tillage, especially no-till. As more acres are converted to conservation tillage, and especially no-till, significant environmental benefits will be derived.

Off-Farm Income, Technology Adoption, and Farm Economic Performance

Jorge Fernandez-Cornejo, with contributions from Ashok Mishra, Richard Nehring, Chad Hendricks, Malaya Southern, and Alexandra Gregory

Abstract

The economic well-being of most U.S. farm households depends on income from both onfarm and off-farm activities. Consequently, for many farm households, economic decisions (including technology adoption and other production decisions) are likely to be shaped by the allocation of managerial time among such activities. While time allocation decisions are usually not measured directly, we observe the outcomes of such decisions, such as onfarm and off-farm income. This report finds that a farm operator's off-farm employment and off-farm income vary inversely with the size of the farm. Operators of smaller farm operations improve their economic performance by compensating for the scale disadvantages of their farm business with more off-farm involvement. Off-farm work reduces farm-level technical efficiency, but increases household-level technical efficiency. And adoption of agricultural innovations that save managerial time is associated with higher off-farm income.

Keywords: Off-farm income, farm households, economic performance, managerial time, scale economies, scope economies, technical efficiency, technology adoption, farm size.

Acknowledgments

The authors thank James MacDonald, Keith Wiebe, Dayton Lambert, Carol Jones, and Utpal Vasavada, ERS, for the helpful comments provided on earlier drafts of the report. We also thank James Hrubovcak from the Office of the Chief Economist, Jane Schuchardt from the Cooperative State Research, Education and Extension Service, Bruce Gardner from the University of Maryland, and an anonymous reviewer. Finally, we are very grateful to Dale Simms for his valuable and prompt editorial assistance and Anne Pearl for cover design and document layout.

Summary

U.S. farmers must make a host of decisions relating to their farms' operation, including what to grow, when to grow it, in what quantities, and by what methods. Often overlooked in this calculation, but factoring heavily in the diversity of U.S. farms and farm households, is the fact that most operators split their time between farm and nonfarm activities. Large farms are typically able to economize on inputs and better coordinate stages of production. Smaller farms, though often unprofitable from a farm business perspective, have endured by being part of household enterprises that combine farm and off-farm activities. Their operators' onfarm decisions, from choice of technology to choice of specialty, are often influenced by off-farm commitments and income.

What Is the Issue?

Onfarm and off-farm activities compete for limited managerial time (mainly of the operator and spouse). How farm operator households allocate their time largely affects production decisions (such as technology adoption), economic performance, and the household's economic well-being.

The extent of off-farm work and its relationship with farm economic performance may have important policy implications. For example, government policies for agriculture (via conservation, research and development, extension, and commodity programs) may affect farm households differently, depending on the relative importance of onfarm versus off-farm income. And the effectiveness of policies promoting adoption of farm technologies might be improved by taking into account the different demands on managerial time and the relative ability of the farm household to accommodate those demands.

What Did the Study Find?

Operators of smaller farms typically participate more in off-farm employment, work more hours off the farm, and have higher off-farm income than operators of larger farms. In 2004, farm households with farm sales less than $10,000 had average off-farm earned income of $54,600, while households with farm sales of $500,000 – $1 million averaged only $30,100. More than 58 percent of operators with farm sales less than $10,000 reported off-farm hours worked in 2004, versus less than 20 percent for operators of farms with sales of $500,000-$1 million.

As previous studies have shown, **off-farm work is less likely on farms with labor-intensive enterprises** such as dairy. Moreover, dairy farmers who do work off the farm tend to require higher compensation to do so than farmers producing other commodities. Off-farm work has also been shown to be positively related to urban proximity and to the education and experience of the operator and spouse.

Including off-farm income-generating activities improves the overall economic performance of the farm household. Off-farm income clearly adds to total household income, but it can also improve efficiency and other

measures of performance of the farm household. Our estimates for corn and soybean farms show that households engaged in off-farm income-generating activities together with the production of traditional farm outputs have cost savings of 24 percent relative to carrying out those activities separately. The savings likely arise from the sharing of managerial expertise (and its many components, such as accounting and information processing skills, sales expertise, administrative and technical know-how, etc.) between onfarm and off-farm activities. For example, management skills acquired in farming might be applicable to (and shared with) a nonfarm business, and vice-versa.

From a farm business perspective, operators of smaller farms have a greater **incentive to expand**. However, from a household perspective (including off-farm income-generating activities), operators of small farms have a reduced tendency to increase their farm size.

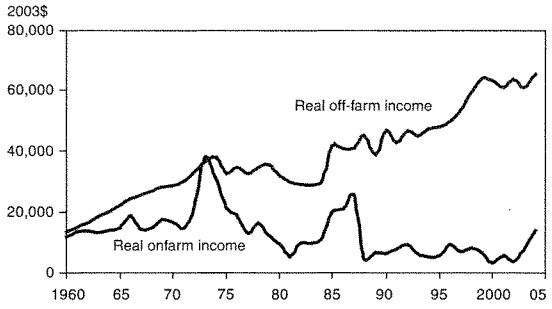
Large farms are generally more efficient than smaller farms in transforming farm inputs into outputs, given the technology at their disposal. But focusing on farm inputs and outputs alone is misleading because off-farm income-generating activities are increasingly important in determining economic performance of the farm household.

When off-farm activities are included, farm household-level efficiencies are higher than farm-level efficiencies across all farm sizes, and efficiency gains from integrating off-farm work into the output portfolio are relatively greatest for smaller farms. As a result, household-level efficiencies of smaller farms are comparable to farm-level efficiencies of larger farms. This suggests that households operating small farms have partially adapted to shortfalls in farm-level performance by increasing their off-farm income.

In addition to its links with the farm business, as traditionally examined, farmers' technology choices are closely related to off-farm income. Higher off-farm income is significantly related to the adoption of technologies that economize on management time (management saving such as herbicide-tolerant crops, conservation tillage). For example, a 16-percent increase in off-farm household income is associated with a 10-percent increase in the probability of adopting herbicide-tolerant (HT) soybeans. Household income from onfarm sources is not significantly associated with adoption of these technologies, but total household income (including income from off-farm sources) is. On the other hand, lower off-farm income is significantly related to adoption of managerially intensive technologies (such as precision farming). For example, an 8-percent decrease in off-farm income is associated with a 10-percent increase in the probability of adopting yield monitors, a key component of precision agriculture. These findings corroborate a tradeoff between household/operator time spent in onfarm and off-farm activities. Households operating small farms devote more time to off-farm opportunities and are more likely to adopt management-saving technologies.

How Was the Study Conducted?

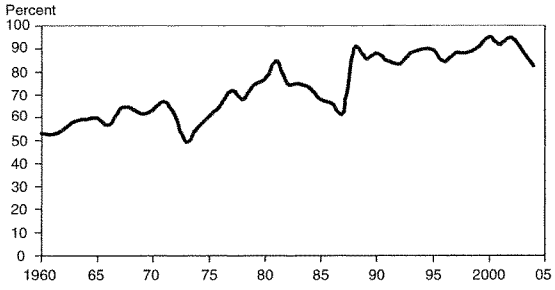
To examine the relationships between off-farm income, farm and household characteristics, and economic performance of U.S. farm households, we developed econometric models and estimated them using USDA's Agricultural Resource Management Survey (ARMS) data for several years (1996-2001). To examine the relationship between off-farm work and economic performance of farm households (including economies of scale and scope, and economic efficiency), we compared estimates obtained using traditional farm-level models to estimates obtained using household-level models (including off-farm income-generating activities along with traditional farm outputs such as crops and livestock). To examine the relationship between off-farm income and technology adoption, we developed a model that incorporates the adoption decision into the agricultural household framework. We examined the interaction of off-farm work and adoption of agricultural technologies of varying managerial intensity, including herbicide-tolerant crops, precision agriculture, conservation tillage, and Bt (*Bacillus thuringiensis)* corn, after controlling for other factors.



Introduction and Overview

Decisionmakers (mainly farm operators and their spouses) are a major determinant of farms' economic performance. The effort and ability to manage land, water, machinery, and other inputs— as well as adoption of technologies and production practices—can help secure farm business success and the economic well-being of a farm household. However, many farm operators (and other household members) use a large share of their time in off-farm income-generating activities. Consequently, for many farm households, economic decisions (including technology adoption and other production decisions) are likely to shape and be shaped by the allocation of managerial time to such activities. While time allocation decisions are usually not measured directly, we observe the outcomes of such decisions, such as onfarm and off-farm income.

Off-farm income (largely earned income from employment and off-farm business income) received by U.S. farm operators and their spouses has risen steadily over recent decades and now constitutes the largest component of farm household income (fig. 1a, b). The impact of off-farm income is felt particularly by households operating small farms, allowing many of them to survive and even flourish to an extent not thought possible 20 or 30 years ago (Gardner, 2005). In addition, the growth in off-farm income over the last 40 years reduced income inequality among farm households and helped U.S. farmers' average incomes overtake those of the nonfarm population (Gardner, 2002).



This report examines the empirical relationships between off-farm income, farm household characteristics, production decisions (particularly technology adoption), and various measures of economic performance for U.S. farm households. This research provides insights into farmers' choices in the context of farm/household integration and helps improve our under-

standing of the pace of technological innovation and its relation to the structure of agriculture.

The report also suggests the need to analyze the economics of the farm business and farm household in an integrated framework and describes two approaches for doing so. We summarize statistics of off-farm work and income in U.S. farm households and examine the relationship between off-farm income and farm size, location, and household characteristics.

Our main research focus is to examine how off-farm work influences the economic performance of the integrated farm business and household. To do this, we expand traditional concepts of economic performance, such as economies of scale and efficiency, to incorporate onfarm and off-farm income-generating activities of household members. In addition, we examine the relationship between off-farm income and the adoption of agricultural technologies of varying managerial intensity, namely herbicide-tolerant crops, precision agriculture, conservation tillage, and Bt (*Bacillus thuringiensis*) corn.

An Integrated Approach

While increasing household income, off-farm activities also compete for managerial time (mainly of farm operators and their spouses), which may affect the economic performance of the farm business. Consequently, economic decisions (including technology adoption and other production decisions) are likely to shape and be shaped by the underlying allocation of time within the farm operator household. So, rather than examining the farm business or farm household in isolation, an integrated approach captures the interplay of farm and nonfarm considerations and contributions.

Despite its importance, the role of off-farm income has been largely neglected in empirical analyses of farm economic performance and technology adoption.[1] Some exceptions include Gardner (2001), Boisvert (2002), Goodwin and Mishra (2004), Fernandez-Cornejo et al. (2005), Nehring et al. (2005), Paul and Nehring (2005), and Chavas et al. (2005).[2] One reason for this lack of studies may be the modeling and data challenges in moving from the traditional unit of analysis (the farm business) to the farm household.

While agricultural economists have made major contributions in understanding farm production functions, they may not have exploited as fully the concept of the household production function (Offutt, 2002). In this context, the allocation of time (and money) of household members to production, consumption, and other activities is particularly important. An integrated firm-household perspective was suggested back in 1952 by E.O. Heady, who observed that "the firm-household complex is important not only to defining the organization of resources and family activities which will maximize utility at a given point in time but also in helping to explain uncertainty precautions, capital accumulation, soil conservation, and other production-consumption decisions, which relate to time."[3]

Approaches To Integrate Off-Farm Work and Farm Production

Two approaches are used in this report to model the interaction of off-farm income-generating activities with traditional farm production activities. The unifying notion underlying the two approaches is that managerial time is a key resource in both onfarm and off-farm activities.

In one approach, we expand the agricultural household model to include the technology adoption decision together with the off-farm work decisions by the operator and spouse. The agricultural household model describes how a farm household allocates its time (and other resources) among producing commodities, earning off-farm income, leisure, and home production.[4] The model assumes that the farm household maximizes its utility subject to constraints on its time (including work and leisure), income, and production technology (production function). Household members derive utility from goods purchased for consumption, leisure, and factors exogenous to current household decisions, such as human capital, household characteristics, and weather. Using this model, we examine the interaction of off-farm work and the adoption of agricultural innovations (both management saving like herbicide-tolerant crops, and management using like precision agriculture or integrated pest management—IPM), then obtain empirical estimates of the relationship between adoption of these technologies and farm household income.

Though the agricultural household model has intuitive appeal in modeling farm household behavior, it requires much in the way of assumptions and data (Offutt, 2002). Parameter estimation for the models spawned by the household production function often requires hard-to-get data, including consumption expenditures, farm and off-farm labor supply, farm and nonfarm outputs and inputs, assets, and prices for all goods, inputs, and labor. Also needed is information on technologies and participation in

[1]Economic researchers have been examining farm economic performance focusing on the farm business for several decades (Heady; Griliches; Dawson and Hubbard; Hallam). Another line of research has focused on the farm household and the labor allocation decisions by the operator and their spouses (Huffman, 1980, 1991; Lass, Findeis, and Hallberg, 1989; Lass and Gempesaw, 1992; Kimhi, 1994, 2004).

[2]Boisvert (2002) stressed not only the growing links between farming activities and off-farm labor markets but also the links between farm household activities, conservation payments, and agricultural pollution.

[3]Loosely, utility is a measure of satisfaction. Economists assume that people act if doing so gives them utility.

[4]The household model initially received a great deal of attention in studies of developing countries' agriculture because of the relative importance of consumption activities in such households. Agricultural economists have also applied these models in developed countries to examine how household members make decisions about the allocation of labor both on and off the farm (Huffman, 1980, 1991; Sumner, 1982; Lopez, 1985; Singh et al., 1986; Lass et al., 1989; Lass and Gempesaw, 1992; Kimhi, 1994, 2004; Mishra and Goodwin, 1997; Goodwin and Holt, 2002). Other analysts have examined income and wealth distributions and links between income instability and consumption/investment (El-Osta and Morehart; Mishra and Morehart). Lopez is one of the few to have considered labor supply and farm production decisions simultaneously. In a very recent application, Chavas et al. used a farm household model to investigate the economic efficiency of farm households in Gambia (Chavas et al., 2005).

government programs, as well as demographic data. For these reasons, it is sometimes necessary to use alternative methods. In this approach, we expand the concept of scope economies to include as output all income-generating activities, on or off the farm, in addition to the traditional farm outputs such as corn, soybeans, and livestock (Nehring et al., 2005). In addition, we estimate scale economies and technical efficiency, and compare results at the farm and household levels.

Scale and Efficiency

Scale Economies

A farm is said to have economies of scale (or increasing returns to scale) if the average cost declines as output (scale of production) increases. If a farm is subject to economies of scale, it is cost effective for that farm to increase all outputs simultaneously while holding the mix of outputs constant (costs would rise less than proportionally). Thus, the existence of scale economies suggests that farms can achieve lower average costs by becoming larger. Economists have established (under reasonable conditions) the equivalence between the information provided by the costs and the production technology (Carlton and Perloff, 2000). Based on the production technology, economies of scale may be viewed from an output or input perspective.

From an output perspective, the term elasticity of scale is used to measure the percent increase in output generated by a 1-percent increase in all inputs (Varian, 1992). There are increasing returns to scale if the elasticity is greater than 1; that is, an increase in overall inputs generates a more than proportionate increase in output. For example, a scale elasticity of 1.15 means that a 1-percent increase in inputs leads to a 1.15-percent increase in output. Conversely, if the elasticity is lower than one there are decreasing returns to scale; that is, an increase in overall inputs generates a less than proportionate increase in output. For example, a scale elasticity of 0.8 means that a 1-percent increase in inputs leads to a 0.8-percent increase in output. Constant returns to scale means that a 1-percent increase in overall inputs generates a 1-percent increase in output; in this case the elasticity of scale is equal to 1.

From an input perspective, a similarly defined scale elasticity measures the percent increase in inputs required to support a 1-percent increase in all outputs. In this case, returns to scale are increasing when the input-oriented scale elasticity is less than one. For example, if the scale elasticity of a farm is 0.75, it means that a 0.75-percent increase in inputs will be needed to support an output increase of 1 percent. This suggests that there is an incentive for the farm to grow larger. If the elasticity is equal to one (constant returns to scale), there are no scale economies available. In this report, we use an input perspective (input distance function, appendix 1).

Technical Efficiency

Economic efficiency can be decomposed into technical efficiency and allocative efficiency. A farm is technically efficient if it uses the minimum possible levels of inputs to produce a given level of output, given the technology. An allocative efficient farm produces a given output using the best (minimum cost) input proportions given prevailing input prices. Unless specified otherwise, the efficiency results discussed in this report involve technical efficiency.

Technical efficiency is the ratio of current to maximum possible or "best practice" production and it is calculated in this study using an input distance function (see appendix 1). Technical efficiency is defined relative to an "efficient frontier" and all farms operating on the efficient frontier are classified as 100 percent efficient with an efficiency score equal to 1. Farms using more inputs to produce a given output level than those on the efficient frontier are inefficient and their efficiency score is less than 1. Technical efficiency is often associated with managerial ability and experience.

Off-Farm Work and Income in U.S. Farm Households

Off-farm income received by farm operators and their spouses has risen steadily over recent decades (fig. 1a) as job opportunities have grown and technological progress, such as mechanization, has lessened onfarm labor needs. The off-farm income share of total household income of U.S. farmers rose from about 50 percent in 1960 to more than 80 percent over the past 10 years (fig. 1b). Most of the off-farm income was earned. On average, a farm household earned about $48,800 from off-farm sources in 2004, received about $18,500 in unearned income (Social Security, interest, etc), and netted nearly $14,200 from farming activities (Covey et al., 2005).[5] Fifty-two percent of farm operators worked off farm in 2004 (up from 44 percent in 1979). The share of spouses working off farm grew from 28 percent of spouses in 1979 to 45 percent in 2004 (Mishra et al., 2002; 2004 ARMS data).

The trend is similar in terms of hours worked (table 1). Average hours worked off farm by farm operators has increased (from 830 hours per year in 1996 to 1,022 in 2004), while the hours devoted to farm work did not change markedly (1,525 hours in 1996 and 1,574 in 2004). Similarly, the number of hours worked off the farm by spouses increased from 690 in 1996 to 809 in 2004.

Farmers' Motivations To Work Off Farm

Once seen as a "temporary response to the Great Depression," off-farm employment is now regarded as a "regular feature of almost all farming societies" (Fuller, 1991; Bartlett, 1986; Bessant, 2000). More than half of U.S. farm operators now work off the farm.[6] Moreover, off-farm income appears to smooth out household income flows (Mishra and Goodwin, 1997; Mishra and Sandretto, 2002), and most farmers view off-farm employment as a permanent rather than a temporary or transitional (into or out of farming) pursuit (Ahearn and El-Osta, 1993).[7] Farm operators in a 1982 survey felt that full-time farming provided inadequate income (91 percent of the respondents), and that farm income was risky (70 percent) and offered no fringe benefits such as pensions and health insurance (55 percent). Capital and land constraints were considered less important disadvantages to full-time farming (42 and 30 percent) (Barlett, 1991). More

Table 1
Operator and spouse hours worked on and off farm,1996-2004

Item	1996	2000	2004
Operator hours worked:			
On farm	1,525	1,433	1,547
Off farm	830	1,011	1,022
Total	2,355	2,443	2,596
Spouse hours worked:			
On farm	366	337	877
Off farm	690	751	809
Total	1,056	1,089	1,686

Sources: 1996: Hoppe (2001, p. 29); 2000: Mishra et al. (2002, p. 50); 2004: ARMS data.

[5]Across all farms, operators earned 64 percent of all household off-farm earned income in 2001, spouses earned close to 33 percent, and other members earned 3 percent (O'Donoghue and Hoppe, 2005).

[6]There are, however, some issues regarding the definition of a farm. Since the USDA definition of a farm is not adjusted for inflation, the number of small operations that get defined as farms may increase over time, which may also increase the share of operators working off the farm.

[7]A minority of farmers (18.4 percent of the total in 1987) may be considered as a transitional group, i.e., full-time farmers who worked off farm because they faced heavy losses and high debts. Some of these farmers expected to return to full-time farming when their financial situation was resolved (Bartlett, 1991). Moreover, using agricultural census data spanning 1982 to 1997, ERS researchers identified 644 (out of over 5,000) small part-time farms that managed to grow into large commercial operations. These farms are called emergent adaptive farms (EAF). Off-farm work provided financial support during the early years of the typical EAF, but EAF operators spent more time on farm activities as their businesses expanded: 35 percent of EAF operators worked at least 200 days off the farm in 1987, but that share declined to 16 percent by 1997 (Newton, 2005).

recently, the 2004 ARMS asked operators and spouses to list the two main reasons for seeking off-farm work. The primary reason given by 35-50 percent of the operators and 44-63 percent of the spouses (depending on farm size and occupation of the farm operator) was "to increase income" of the farm household. Other reasons cited were to obtain fringe benefits (such as health insurance) and personal satisfaction (Covey et al., 2005).

So most operators and spouses report working off farm primarily to increase income for the farm household, but how was the additional income used? Contrary to conventional wisdom, most farm operators and spouses did not work off the farm to directly support their farm business. USDA surveys indicate reasons unrelated to the farm business, from buying groceries to funding a retirement account (Hoppe, 2001).

Farmers and spouses hold a variety of off-farm jobs, but especially in private businesses (54.1 percent of operators with off-farm jobs), self-employment (22.3 percent), and government (16.0 percent). Only 3.3 percent worked on another farm (Mishra et al., 2002). Spouses with off-farm work are most likely to be employed in the private sector (55.1 percent) and government (28.4 percent), with less than 1 percent working on another farm.

Opportunity Cost of Labor for Farm Operators

Opportunity cost is an important economic concept that measures the economic cost of an action or decision in terms of what is given up (opportunity forgone) to carry out that action. In the case of farm labor, for example, the opportunity cost of labor for the operator (or spouse) labor is often measured in terms of the wage that the operator (or spouse) can obtain working off farm. As the United Nations' Economic Commission for Europe notes: "In conventional accounting systems, 'unpaid' family labour does not usually appear as an explicit cost of production. Consequently, there is no explicit 'wage' paid to the labour that the farmer and his family [contribute to] production."

Farm household labor is a critical input in agricultural production. In the corn/soybean-producing States, farm household members provide more than 80 percent of all labor hours.[8] A significant proportion of those labor hours is not valued directly in the marketplace (e.g., through wages). Studies have estimated the opportunity costs of farm labor by using predicted off-farm wages (El-Osta and Ahearn, 1996).

Alternatively, a simplified approximation of the opportunity cost of labor for farm operators and their spouses can be obtained directly from ARMS data. The (nominal) opportunity costs for corn/soybean operators and spouses appear not to have increased over 1996-2000. The cost for the operator ($21.07 per hour for 2000) appears to run about 20 percent higher than that of the spouse, and both are higher than the actual wage rate for hired farm labor.[9]

It is also interesting to compare the opportunity cost of labor for corn/soybean farmers with those of dairy farmers. The cost for U.S. dairy farmers in 2000 was econometrically estimated at $27.58 per hour for oper-

[8]Corn/soybean-producing States are defined as those that account for most of the U.S corn and soybean production. States included are Illinois, Indiana, Iowa, Michigan, Minnesota, Missouri, Nebraska, Ohio, South Dakota, and Wisconsin.

[9]The opportunity cost of labor varies with the farm's region, size, and specialization, the operator's human capital (education and experience); and household characteristics (El–Osta and Ahearn). In addition, opportunity cost estimates may vary with the characteristics of the labor markets, the methodology used, and data sources.

ators (30 percent higher than for corn/soybean farmers) and $19.36 for spouses (18 percent higher) (Lovell and Mosheim, 2005). Given that labor requirements in dairy production are high and inflexible (El-Osta and Ahearn), dairy farmers likely require a higher "wage" to work off the farm than farmers working in other enterprises.

Table 2
Opportunity cost of labor for corn/soybean farm operators and spouses, and actual hired farm wage rate, 1996-2000

Year	Operator	Spouse	Hired
		Dollars per hour	
1996	22.88	17.87	7.42
1997	26.72	19.06	8.01
1998	22.14	18.77	8.30
1999	22.19	17.96	8.67
2000	21.07	17.47	8.99

Source: ERS estimates based on ARMS data for corn/soybean States analyzed (Nehring, Fernandez-Cornejo, and Banker, 2005).

Off-Farm Income and Farm/Household Characteristics

Like their nonfarm counterparts, many farm households are dual career. While operators and spouses across all sizes and typologies work off-farm or manage nonfarm businesses, the level of off-farm income varies with farm size, region, farm type, and the human capital of operators and spouses.

Off-Farm Income and Farm Size

Off-farm income varies inversely with farm size; operators of smaller farms have higher off-farm incomes, both earned and total.[10] Farm households with gross farm sales less than $10,000 had total off-farm income averaging nearly $74,000 in 2004 ($54,600 of which was earned), while households with farm sales between $250,000 and $499,999 had total off-farm income averaging about $45,000 ($33,200 earned) (table 3). While off-farm income constitutes the largest component of farm household income on average, its share decreases with farm size. For farms with gross sales higher than $250,000 (less than 8 percent of U.S. farms), off-farm income is no longer the largest component of household income (table 4).

Off-farm household income earned by the operators is more variable across farm sizes ($27,500 for operators of smaller farms versus less than $10,000 for operators of the largest farms) than that earned by spouses (between $12,000 and $14,000 across all sizes in 2004). Off-farm income earned by other household members averages around $1,000.

To a large extent, the inverse relationship between off-farm earned income and farm size is due to greater off-farm employment (and more hours worked off the farm) by operators of smaller farms. More than 55 percent of operators with farm sales less than $100,000 reported off-farm hours in 2004 versus 20 percent or less for operators of farms with sales above $250,000 (table 4). On the other hand, off-farm income earned by farm operators who work off-farm does not vary much with size, averaging $47,000 for operators of the smallest farms and $39,000 for operators of the largest farms.

[10]Smaller farms represent a very large share of farm population but a small share of the farm sales. For example, about 44 percent of the farms have sales less than $10,000 and more than 80 percent of the farms have sales below $100,000 (table 3). This distribution, however, is dependent on the definition of farm. In the United States, a farm is currently defined, for statistical purposes, "as any place from which $1,000 or more of agricultural products were sold or normally would have been sold during the year under consideration." (USDA, 2005).

Table 3
Off-farm household income by farm size, 2004

Farm sales	Share of farms	Income earned by the operator	Income earned by the spouse	Income earned by other members	Off-farm business income	Total earned income	Unearned income	Total off-farm income
	Percent				*Dollars*			
$9,999 or less	43.7	27,457	14,756	1,219	11,209	54,641	19,392	74,033
$10,000-$99,999	40.7	24,295	13,095	1,142	9,889	48,422	19,549	67,971

The inverse relationship between farm size and off-farm work still holds after controlling for other factors, as demonstrated econometrically by many researchers (Lass et al., 1989, 1991; Yee et al., 2004). In addition, Goodwin and Bruer (2003) and Fernandez-Cornejo et al. (2005) showed that the inverse relationship holds for both operator and spouse.

Time allocation between onfarm and off-farm activities by household members appears to be the underlying reason for the inverse relationship between farm size and off-farm work. This relationship appears to be valid regardless of the sequence in which time is allocated between farm and off-farm work. As Olfert (1984) notes, it may be the case that farmers choose farm size and type after knowing the time commitments required by an off-farm job, or farmers may choose the type and amount of off-farm work after taking into account the nature of the labor requirements on the farm.[11]

Off-Farm Income and Farm Location

Off-farm employment also varies geographically, with widely differing shares of off-farm income (to total income) even within States (fig. 2). In general, high ratios of off-farm earned income to total income are exhibited in the four regions—the Northeast, Appalachian, Southern Plains, and Northwest—where job opportunities tend to be highest or farm income lowest. In many cases, one family member may focus on the farm operation while the spouse and children work off the farm. In other situations, the farm operation may be a side job and a refuge from urban stress. The supply of off-farm labor has been shown to be positively related to urban proximity (Lass et al., 1991). Moreover, Gardner (2001) found that farmers' income growth is inversely related to the rural share of a State's population. Gardner observed that this finding supports Schultz's (1950) hypothesis that "a larger presence of nonfarm people in a State is good for

[11]The tradeoff between time spent in onfarm and off-farm activities also manifests itself in Conservation Reserve Program (CRP) participation. Boisvert and Chang (2006) found empirical evidence that a household's decision to participate in the CRP and to work off the farm are made jointly rather than independently. Participation in off-farm work with higher wages provides an incentive for operators to work less on the farm and to take land out of production and commit it to the CRP. As a result, participation in the CRP and off-farm work increase household income.

the growth of farmers' incomes, because it increases their off-farm earnings opportunities and increases the demand for the goods and services that farmers produce." This may be particularly true for agricultural States with large urban populations such as Texas, where off-farm opportunities increase near one of that State's four major cities—Dallas-Fort Worth, Houston, San Antonio, and Austin.

Off-Farm Income, Type of Enterprise, and Human Capital

Off-farm work is less likely on farms with labor-intensive enterprises such as dairy (Leistritz et al., 1985) and other livestock (Lass et al., 1991; Goodwin and Bruer, 2003). Moreover, dairy farmers who do work off the farm tend to require higher "wages" (the opportunity cost of labor is higher) to work off farm than farmers working in other enterprises.

The supply of off-farm labor has also been shown to be positively related to human capital such as education and experience of the operator and spouse (Lass et al., 1991). The number of children is positively associated with off-farm employment for farm men, but the association is negative for farm women. More children may imply more need for additional income but also additional child care at home.

Off-Farm Work, Scale and Scope Economies, and Efficiency

The importance of off-farm income to all U.S. farmers is widely acknowledged, and the relative dedication to off-farm work is related to farm size, location, specialty, and operator characteristics. However, is off-farm work actually helping farm households in general, and those operating small farms in particular, to improve their economic performance? Since scale and scope economies, as well as economic efficiency, are key concepts used by economists to examine economic performance, this section introduces those concepts as they relate to off-farm work.

A farm is said to have economies of scale (or increasing returns to scale) if the average cost of production declines as output (scale of production) increases (see box, p. 4). This decline in per-unit costs as output increases suggests that smaller farms can achieve cost advantages by becoming larger. The concept of economies of scale is an important one. For example, farms with lower average costs are better able to cope with higher input prices (Kumbhakar, 1993). On the other hand, increasing returns to scale in production may lead to consolidation of firms with potential effects on competition (Hallam, 1991).

With multiple outputs, the measurement of scale economies becomes more complicated. In addition to changes in costs that occur as output expands, there are also changes in costs due to the product mix (Hallam, 1991). If it is cheaper to produce several outputs in one operation than it is to produce them in separate operations, economies of scope are said to occur (see box, p. 14).

Off-Farm Work and Scale Economies

We estimated the scale economies for corn and soybean farms for 1996-2000, from an input perspective. Scale economies both at the farm level (the measure traditionally reported) and at the household level (including off-farm income-generating activities as an output) are considered. At the farm level, the elasticity of scale ranges from about 0.56 for smaller farms (gross sales less than $100,000), to about 0.8 for the larger farms (sales greater than $500,000) (table 5). This means that to support a 10-percent increase in outputs, smaller farms would require a 5.6-percent increase in all inputs, while larger farms would require an 8-percent increase in inputs. Thus, the greater scale economies available for smaller operations provide a major inducement to increase farm size (compared with the larger farms whose scale elasticities are closer to 1).

However, at the household level, with off-farm income-generating activities included, the scale economies available are lower (scale elasticity is closer to 1; that is, closer to constant returns to scale). Thus, the scale elasticity is higher for all sizes, ranging from 0.73 to 0.96 (table 5). So for smaller farms, a 10-percent increase in all outputs requires a 7.3-percent increase in inputs, while larger farms require a 9.6-percent increase in inputs.[12] More importantly, the difference between the scale elasticities at the household and farm levels is larger for the smaller farms (30 percent)

[12]The scale elasticity increases (moves closer to constant returns to scale) when off-farm income is included because of the theoretical relationship between scale and scope economies in multi-product firms: "the presence of scope economies 'magnifies' the extent of overall economies of scale beyond what would result from a simple weight sum of product specific economies of scale" (Baumol et al., 1982).

Table 5
Scale economies for corn/soybean farms, 1996-2000

Farm type[1]	Gross sales	Elasticity of scale: Farm level (Excluding off-farm income)	Elasticity of scale: Household level (Including off-farm income)
Farming occupation/ lower sales	< $100,000	0.56	0.73
Farming occupation/ medium sales	$100,000-$249,999	0.74	0.88
Large family farms	$250,000-$499,999	0.77	0.94
Vary large family farms	>$500,000	0.80	0.96
All farms		0.66	0.83

[1]Excluding limited-resource farms and retirement/residential farms. Limited-resource farms are small farms with gross sales less than $100,000, total farm assets less than $150,000, and total operator household income less than $20,000. Limited-resource farmers may report farming, a nonfarm occupation, or retirement as their major occupation. Retirement/residential farms are small farms whose operators report they are retired or engaged in a major occupation other than farming) (Hoppe et al., 1999)

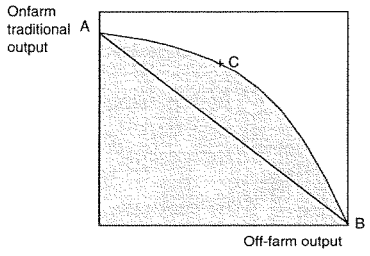
Source: Nehring et al., 2005.

than for the larger farms (around 20 percent). Thus, households operating smaller farms may compensate for the scale disadvantages of their farm business activities with the advantages of off-farm income-generating activities. This advantage may also support the notion that integrated farm and nonfarm labor markets are enabling many small farms to survive and flourish to an extent not thought possible three decades ago (Gardner, 2005).

Off-Farm Work and Economies of Scope

Scope economies measure the cost savings due to simultaneous production of outputs relative to the cost of separate production (see box, p. 14). The concept of economies of scope is useful in assessing the advantages of output diversification. Given the importance of off-farm income to U.S. farm households, scope economies may be expanded to include as output any income-generating activities on or off the farm (household-level scope economies) (see appendix 1).[13] Our estimates for corn and soybean farms show substantial household-level scope economies, 0.24 on average. This means that farm households engaged in off-farm income-generating activities together with the production of traditional farm outputs have cost savings of 24 percent relative to carrying out those activities separately.[14] The cost savings are likely to arise from the sharing of managerial expertise (of the operator and spouse) between onfarm and off-farm activities. Economic evaluations of the farm business alone, then, provide an incomplete view because they exclude off-farm activities, which are an important means of output diversification.

[13]Farms that produce the two output groups separately are those that either produce conventional outputs and no off-farm income or else generate off-farm income but no conventional outputs. While our sample includes farm households that produce conventional outputs with no off-farm activities, it technically does not include households with zero traditional outputs. However, the sample does include many farm households with very small revenues from traditional outputs because, for statistical purposes, in the U.S., a farm is currently defined "as any place from which $1,000 or more of agricultural products were sold or normally would have been sold during the year under consideration" (USDA, 2005). We consider five outputs (corn, soybeans, other crops, livestock, and operator/spouse off-farm labor) and five inputs (hired labor, operator labor, spouse labor, miscellaneous inputs, and pesticides). The method of calculating scope economies, as well as the underlying cost function, is shown in appendix 1.



[14]This result is valid on the average, not necessarily for all the corn/soybean farms studied. For example, it is not likely to be valid for the largest farms in the sample (whose operators are less likely to work off the farm, table 4). As shown in appendix 1, the underlying cost function is a function of the output quantities (and, thus, gross sales), and so are scope economies. The values reported here are calculated at the means of the sample.

Scope Economies

Scope economies measure the total cost savings due to simultaneous production of outputs relative to the costs of separate production (appendix 1). Given scope economies, it is less costly to produce several outputs in one operation than to produce each output in separate operations (or joint production in one operation generates more output than separate production in two different operations using the same resources). An often-cited example of scope economies is fast food outlets, where savings are obtained by sharing storage, cooking facilities, and customer service in the production of many food products. In general, scope economies may arise from the presence of public inputs or from sharing of imperfectly divisible quasi-fixed inputs in the production of different goods (Fernandez-Cornejo et al., 1992). In our context, farm households achieve scope economies by diversifying or pursuing off-farm activities in addition to the onfarm production of traditional commodities.

To illustrate the possible advantages of "producing" onfarm and off-farm outputs in a farm household, we may use the example of a production possibilities curve (often used in economics). When the production possibilities curve (ACB) is shaped as in the figure, it is advantageous to produce onfarm and off-farm outputs together. As the figure shows, total output produced by a farm household at point C (a combination of onfarm and off-farm outputs) is higher than output produced either at A or B (or a linear combination of both, line AB) while using the same amount of resources.

Diagram of a production possibilities curve

Scope economies for farm households are likely to arise from the sharing of managerial expertise (and its many components, such as accounting and information processing skills, sales expertise, administrative and technical know-how, etc.) between onfarm and off-farm activities.[15] The expertise of many farm operators and/or their spouses is used in off-farm jobs in private businesses and Government, and in self-employment (Mishra et al., 2002). A USDA survey shows that the largest share of off-farm work done by operators and their spouses is accounted by work in executive, administrative, and managerial positions, service occupations, administrative support, and sales (Covey et al., 2004).

[15]As is well known, diminishing marginal labor productivity is a determinant in the allocation of labor between onfarm and off-farm activities. In addition, labor requirements for crop production are often concentrated in very few months of the year. Thus, the marginal productivity of managerial labor for the rest of the year is often very low or negligible (Olfert, 1984).

Off-Farm Work and Efficiency

Technical efficiency measures how well a farm transforms inputs into outputs given the technology at its disposal (Kumbhakar and Lovell, 2000). Efficiency is of great importance to prevent the waste of resources. Technically inefficient farmers fail to produce the maximum attainable output with the amount of inputs used, and therefore can increase output with the existing level of inputs and available technology.

Two types of technical efficiency are examined here: traditional (farm-level) technical efficiency of the farm business in the production of commodities; and technical efficiency at the household level, which considers both on- and off-farm activities.[16]

Efficiency of the Farm Business

Kumbhakar et al. (1989) examined the effect of off-farm income on farm-level efficiency for dairy farmers. They reasoned that the larger the off-farm component of the operator's income, the less time the operator would spend managing the farm, eroding farm-level efficiency. Indeed, they found that farm-level efficiency of Utah dairy farmers in 1985 was negatively related to off-farm income and that the negative effect was strongest for the smallest farms, which had the largest off-farm incomes.[17] Fernandez-Cornejo (1992) calculated that the farm-level technical efficiency of vegetable farms in Florida was negatively related to off-farm work carried out by the operator. Similar results were obtained by Aigner et al. (2003) for the farm-level efficiency of U.S. corn farmers using 2001 data.

More recently, Goodwin and Mishra (2004) analyzed the relationship between farm-level efficiency and off-farm labor supply. With data collected from 7,699 farms in USDA's 2001 Agricultural Resource Management Survey (ARMS), they used gross cash income (appendix table 1) over total variable costs as an operational measure of farm-level economic efficiency. Greater participation in off-farm labor markets was shown to be significantly associated with lower farm-level efficiency. An additional 1,000 hours engaged in off-farm work would tend to lower the farm-level efficiency ratio by 0.17 with respect to the mean, which was $1.93 of cash farm income per dollar of variable cost. This effect, while not large, was statistically and economically significant. Such findings support the notion hypothesized by Smith (2002) that off-farm work may hinder "smart farming" and confirm a negative relationship between farming efficiency and the supply of labor to off-farm employment. As theory predicts, more efficient farmers are less likely to work off the farm, reflecting the higher opportunity cost for their labor. Furthermore, the statistical tests performed by Goodwin and Mishra suggest that off-farm labor supply and farm-level efficiency are jointly determined.[18]

Household-Level Efficiency

Rather than estimating the influence of off-farm work on the efficiency of the farm business, we estimated the household-level technical efficiency (including on- and off-farm activities), compared it with farm-level effi-

[16]We have adopted the terminology of "farm-level" and "household-level" efficiency following a recent publication by Chavas et al. (2005). Our earlier terminology (as used in Nehring et al., 2005) was less transparent.

[17]In a subsequent article, Kumbhakar (1993) showed that lower efficiency is the main reason that small farms are less profitable than medium and large farms: another reason being their higher returns to scale (lower scale economies).

[18]There is a two-way relationship between the two variables rather than a cause-and-effect relationship (in economic jargon, each variable is endogenous to the other).

ciency, and examined how those efficiencies vary with farm size. The technique used in this research isolates the best-practice farm within any size class, and measures technical efficiency by how close other farms are, on average, to the best-practice farms, which are assigned a technical efficiency equal to 1 and said to be on the "frontier." [19]

At the farm level, technical efficiencies of corn/soybean farms increase with size from 0.87 to 0.93 (table 6).[20] However, technical efficiencies at the household level (when off-farm income is included) are higher (around 0.95) and the measures of technical efficiency do not vary across size groups. Moreover, while the beneficial effect of off-farm income occurs at all sizes, it is stronger for smaller farms, whose household-level efficiency levels are comparable with the farm-level efficiencies of the larger farms. This suggests that small corn/soybean farmers have adapted to shortfalls in farm-level efficiency by increasing off-farm income.

Also, the higher household-level efficiencies are consistent with the positive scope economies found. Both findings reflect the more efficient use of resources at the household level, particularly the use of managerial labor (operator and spouse) shared between onfarm and off-farm activities.

Moreover, as Smith (2002) observes, as farm operators and other household members engage in off-farm activities, they have less time available for farm management. This may inhibit their adoption of management-intensive agricultural innovations and lead to less efficient farming.

Table 6
Technical efficiency of corn/soybean farms, 1996-2000

		Technical efficiency scores	
Farm type[1]	Gross sales ($)	Farm level (excluding off-farm income)	Household level (including off-farm income)
Farming occupation/ lower sales	< $100,000	0.87	0.95
Farming occupation/ medium sales	$100,000-$249,999	0.91	0.95
Large family farms	$250,000-$499,999	0.91	0.95
Very large family farms	> $500,000	0.93	0.95
All farms		0.91	0.95

[1]Excluding limited-resource and retirement/residential farms.

Source: Nehring et al., 2005

[19]The analysis uses several econometric techniques, including the estimation of an input distance function and stochastic frontier estimation (appendix 1; Nehring et al., 2005) to estimate technical efficiency at the farm (excluding off-farm income-generating activities) and at the household level (including off-farm income-generating activities). Data used were 1995-2003 survey data of corn/soybean farms from 10 States (Illinois, Indiana, Iowa, Michigan, Minnesota, Missouri, Nebraska, Ohio, South Dakota, and Wisconsin), that account for most U.S corn and soybean production.

[20]A farm unit with an efficiency score of 0.8 is said to be 80 percent as efficient as the farms on the 'frontier," i.e., the best performing farms in the data set.

Off-Farm Work and the Adoption of Agricultural Innovations

Technological change has been acknowledged as a critical component of productivity and economic growth (Solow, 1994; Griliches, 1995). The rapid adoption and diffusion of new technologies in U.S. agriculture has sustained growth in agricultural productivity and ensured an abundance of food and fiber (Huffman and Evenson, 1993). Technological innovations and their adoption have also changed the way farm households regard employment choices (Binswanger, 1974, 1978). Labor-saving technologies, in particular, have allowed farm household members to increase income by seeking off-farm employment (Mishra et al., 2002).[21]

While profitability (i.e., the extent of yield increases and/or reduction in input costs from an innovation relative to the costs of adoption and current management practices) plays a key role in technology adoption, most studies acknowledge that heterogeneity among farms and farm operators often explains why not all farmers adopt an innovation in the short or long run (Batte and Johnson, 1993; Feder and Umali, 1993; Khanna and Zilberman, 1997; Lowenberg-DeBoer and Swinton, 1997; Rogers, 1961, 1995) (see box, "Factors Influencing Technology Adoption").

Still, assessments of technology adoption using the traditional economic tools pioneered by Griliches (1957) have proven insufficient to explain differing adoption rates for many recent agricultural innovations. The standard measures of farm (accounting) profits, such as net returns (to management), give an incomplete picture of economic returns because they usually exclude the value of management time (Smith, 2002). For example, herbicide-tolerant soybeans were rapidly adopted despite showing no significant advantage in net returns over conventional soybeans. On the other hand, adoption of technologies such as integrated pest management (IPM) has been rather slow despite explicit economic and environmental advantages (Fernandez-Cornejo and McBride, 2002; Smith, 2002). This led to the hypothesis that adoption is driven by "unquantified" advantages, such as simplicity and flexibility, which translate into reduced managerial intensity, freeing time for other uses. An obvious use of managers' time is off-farm employment.

Off-Farm Work as a Factor in Early Studies of Technology Adoption

Early studies of technology adoption viewed off-farm income as influencing adoption of "conservation" practices by providing "supplemental income" to finance conservation expenditures (Blase, 1960). Ervin and Ervin (1982), on the other hand, argued that "off-farm income could reflect the need for supplemental income for family living expenses and essential farm production expenses other than conservation and less time to implement and maintain unfamiliar practices." Survey results on farmers' motivation to seek off-farm income and their view of such employment as permanent rather than temporary, suggest that motivation is closer the view of Ervin and Ervin.

[21]Off-farm employment was also facilitated by economic growth in the nonfarm economy, improved infrastructure (communications and transportation), as well as education level of farm household members (Banker and MacDonald, 2005).

Factors Influencing Technology Adoption

Rural sociologists recognized early that essential differences among farmers can explain why they do not adopt an innovation at the same time. In addition, the characteristics (perceived or real) of an innovation are widely known to influence the adoption decision (Rogers, 1995; Batz et al., 1999). Economists and sociologists have made extensive contributions to the literature on the adoption and diffusion of technological innovations in agriculture (e.g., Griliches, 1957, Feder et al., 1985; Rogers, 1962, 1995). Such research typically focuses on the long-term extent of adoption and the factors that influence the adoption decision.

Farm Structure/Size
A basic hypothesis regarding technology transfer is that the adoption of an innovation will tend to take place earlier on larger farms than on smaller farms. Just et al. (1980) show that, given the uncertainty and the fixed transaction and information costs associated with innovations, there may be a critical lower limit on farm size that prevents smaller farms from adopting. As these costs increase, the critical size also increases. It follows that innovations with large fixed transaction and/or information costs are less likely to be adopted by smaller farms. However, Feder et al. (1985) point out that lumpiness of technology can be offset by the emergence of a service sector (i.e., custom service or consultant). Disentangling farm size from other factors hypothesized to influence technology adoption has been problematic. Feder et al. (1985) caution that farm size may be a surrogate for other factors, such as wealth, risk preferences, and access to credit, scarce inputs, or information. Moreover, access to credit is related to farm size and land tenure because both factors determine the potential collateral available to obtain credit.

Human Capital
The ability to adapt new technologies for use on the farm clearly influences the adoption decision. Most adoption studies attempt to measure this trait through operator age, formal education, or years of farming experience (Fernandez-Cornejo et al., 1994). More years of education and/or experience is often hypothesized to increase the probability of adoption whereas increasing age reduces the probability. Factors inherent in the aging process or the lowered likelihood of payoff from a shortened planning horizon over which expected benefits can accrue would be deterrents to adoption (Barry et al., 1995; Batte and Johnson, 1993). Younger farmers tend to have more education and are often hypothesized to be more willing to innovate.

Risk and Risk Preferences
In agriculture, the notion that technological innovations are perceived to be more risky than traditional practices has received considerable support in the literature. Many researchers argue that the perception of increased risk inhibits adoption (Feder et al., 1985). Hiebert (1974) and Feder and O'Mara (1981) show that uncertainty declines with learning and experience. Innovators and other early adopters are believed to be more inclined to take risks than are the majority of farmers.

Tenure
While several empirical studies support the hypothesis that land ownership encourages adoption, the results are not unanimous and the subject has been widely debated (e.g., Feder et al., 1985). For example, Bultena and Hoiberg (1983) found no support for the hypothesis that land tenure has a significant influence on adoption of conservation tillage. The apparent inconsistencies in the empirical results are due to the nature of the innovation. Land ownership is likely to influence adoption if the innovation requires investments tied to the land. Presumably, tenants are less likely to adopt these types of innovations because the benefits of adoption will not necessarily accrue to them.

Credit Constraint, Location, and Other Factors
Any fixed investment requires the use of own or borrowed capital. Hence, the adoption of a non-divisible technology, which requires a large initial investment, may be hampered by lack of borrowing capacity (El-Osta and Morehart, 1999). Location factors—such as soil fertility, pest infestations, climate, and availability or access to information—can influence the profitability of different technologies across different farms. Heterogeneity of the resource base has been shown to influence technology adoption and profitability (Green et al., 1996; Thrikawala et al., 1999). Irrigation may also influence adoption. Irrigation generally increases yields and profitability and reduces production risk. However, irrigation may also increase risk; for example, it may encourage certain pest populations (Harper and Zilberman, 1989). Contractual arrangements for the production/marketing of the crop are also believed to influence the adoption of certain technologies. Contracts often specify the acreage to be grown or quantity and quality of product to be delivered and may also require the application of certain inputs and practices.

McNamara et al. (1991) used empirical evidence from peanut producers to conclude that integrated pest management (IPM) required substantial time for management and that off-farm employment may present a constraint to IPM participation. Fernandez-Cornejo et al. (1994), Fernandez-Cornejo (1996, 1998), and Fernandez-Cornejo and Jans (1996) found similar results for vegetable and fruit producers. Wozniack (1993) considered livestock feeding innovations and showed that off-farm wage income was inversely related to the likelihood of early adoption and acquiring information.[22] More recent survey results show that operators of high-sales, large, and very large farms—which depend on farm revenues more (and therefore less on off-farm employment) than smaller farms—tend to adopt more management-intensive technologies. For example, around 18 percent of the operators of larger farms adopted precision farming in 1998. In contrast, only 3 percent of the operators of smaller farms (who worked more off-farm hours) adopted precision farming (Hoppe, 2001).

[22]Measures used included off-farm income as a percentage of total household income (Ervin and Ervin, 1982) or days (or hours) per year that the operator worked off-farm (Fernandez-Cornejo, 1996, 1998; Fernandez-Cornejo and Jans, 1996).

Weaknesses of Early Studies

While insightful, early studies failed to model the interaction of technology adoption and off-farm employment decisions based on the underlying economic theory and consistent with farmers' optimization behavior. Rather, they simply included some measure of off-farm work as one explanatory variable in the adoption decision. Early studies also had some econometric problems, such as not accounting for simultaneity of the off-farm work and adoption decisions and the possibility of self-selection (see appendix 2).[23] Finally, earlier studies did not examine the relationship between technology adoption and household income from farm and off-farm sources.

[23]Self-selection occurs because farmers are not assigned randomly into groups (e.g., farmers that work off farm or not, adopt or not) but make the choices themselves. Therefore, group members may be systematically different, and these differences may manifest themselves in farm performance and could be confounded with differences due purely to working off farm (or adoption). This situation, called self-selection, may bias the statistical results unless it is corrected (appendix 2).

Modeling the Interaction Between Off-Farm Work and Adoption Decisions

To address these issues, we examine the interaction of off-farm income-earning activities and adoption of four agricultural technologies (see box, p. 22) of varying managerial intensity, including herbicide-tolerant crops (Fernandez-Cornejo and Hendricks, 2003; Fernandez-Cornejo et al., 2005), precision agriculture (Fernandez-Cornejo and Southern, 2004), conservation tillage (Fernandez-Cornejo and Gregory, 2004), and Bt (*Bacillus thuringiensis*) corn (Fernandez-Cornejo and Gregory, 2004). We also estimated empirically the relationship between the adoption of these innovations and farm household income from onfarm and off-farm sources.

For this purpose, we expanded the agricultural household model to include the technology adoption decision together with the off-farm work participation decisions by the operator and spouse (appendix 2).[24] We developed an econometric model to examine the interaction of off-farm work and adoption of agricultural technologies, as well as the impact of technology adoption on farm household income (from onfarm and off-farm sources) after controlling for such interaction (appendix 2). The model used data from nationwide surveys of corn and soybean farms in 2000-2001.

[24]The agricultural household model (Singh et al., 1986; Huffman, 1980, 1991; Lass et al., 1989; Lass and Gempesaw, 1992; Kimhi, 1994, 2004) combines in a single framework all important economic decisions of the farm household.

We hypothesize that adoption of managerial-saving technologies (such as herbicide-tolerant (HT) soybeans) frees up management time for use elsewhere (notably off-farm employment), leading to higher off-farm income. On the other hand, managerially intensive technologies (such as precision agriculture) would result in less time available for off-farm activities, leading to lower off-farm income.

It is also possible that farmers already working off farm may be more disposed to adopt managerial-saving technologies. This may lead to additional off-farm work and result in even higher off-farm income. Similarly, farmers who are working off farm may be reluctant to adopt managerially intensive technologies.[25]

In either case, we anticipated that adoption of managerial-saving technologies would be associated with higher off-farm income and adoption of managerially intensive technologies would be related to lower off-farm income. (In this report, we show only the empirical validity of the relationship, but not the direction of the causality.)

A two-stage econometric estimation method was used to estimate the empirical model (appendix 2). The first stage, the decision model, examines the factors influencing off-farm work participation and technology adoption decisions. The second stage is used to estimate the relationship between technology adoption and household income.

Technology Adoption and Off-Farm Income

We find that the relationship between the adoption of herbicide-tolerant (HT) soybeans and *off-farm* household income is positive and statistically significant (table 7). The elasticity of off-farm household income with respect to the probability of adoption of HT soybeans (calculated at the mean) is +1.59.[26] That is, after controlling for other factors, a 15.9-percent increase in off-farm household income is associated with a 10-percent increase in the probability of adopting HT soybeans. The adoption of HT soybeans is also positively and significantly associated with total household income (from off-farm and onfarm sources). A 9.7-percent increase in total household income is associated with a 10-percent increase in the probability of adopting of HT soybeans. On the other hand, adoption of herbicide-tolerant soybeans did not have a significant relationship with household income from farming (table 7).

Results for adoption of conservation tillage are similar to those obtained for HT soybeans, but of a lesser magnitude (table 7). Controlling for other factors, the association between the adoption of conservation tillage and off-farm household income is positive and statistically significant (elasticity +0.98). An increase in *off-farm* household income of 9.8 percent is associated with a 10-percent increase in the probability of adopting conservation tillage. The association of adoption of conservation tillage and total household income (including both off-farm and onfarm sources) is positive and statistically significant. The elasticity of total household income with respect to the probability of adopting conservation tillage is +0.46.

[25]As Olfert observes: "Given the nature of nonfarm jobs, where commitments to specific timeframes are frequently more precise than is the case in farming, it is possible that a nonfarm job receives first priority in the allocation of time with farm production undertaken as a second priority." However, Olfert adds: "It may also be the case that the decision regarding time allocation to farm and nonfarm work is made simultaneously or that the off-farm employment decision influences the type and size of farm that is optimal. Farm enterprises that are less demanding in their commitments may be chosen to permit nonfarm employment. Knowing the time commitments required by the nonfarm job, the farm size and type will be organized to accommodate that schedule. Similarly, given the nature of labour requirements on the farm, a choice will be made about the type and amount of nonfarm work."

[26]Results are expressed in terms of elasticity—the percent change in a particular variable (e.g., household income) relative to a small percent change in adoption of the technology from current levels, controlling for other factors. The elasticity results can be viewed in terms of the aggregate change in a particular variable (across an entire agricultural region or sector) relative to aggregate increases in adoption (as more and more producers adopt the technology). However, in terms of a typical farm —that has either adopted or not— the elasticity is usually interpreted as the (marginal) farm-level change associated with an increase in the probability of adoption, away from a given, or current, level of adoption. As shown in appendix 2, the regression model controls for farm location and typology, operator age, education, and experience, number of children, price of the crop, a measure of specialization on soybean/corn production, a measure of the extent of livestock operations, farm size, and proxies for local labor market conditions.

Table 7
Elasticities of farm household income with respect to the probability of adopting technologies of differing managerial intensity

Elasticity of	With respect to adoption of: Yield monitors	Bt corn[1]	Conservation tillage	Herbicide-tolerant (HT) soybeans
Onfarm household annual income	0[2]	0[2]	0[2]	0[2]
Off-farm household annual income	-0.84	0[2]	+0.98	+1.59
Total household annual income	0[2]	0[2]	+0.46	+0.97

[1]Bt = Bacillus thuringiensis)
[2]Statistically insignificant underlying coefficient. The underlying coefficients and their standard errors are shown in appendix 2.

On the other hand, the relationship between the adoption of yield monitors (an important component of precision agriculture) and off-farm household income is negative and statistically significant (elasticity = -0.84) when we control for other factors. That is, a decrease in off-farm household income by 8.4 percent is associated with a 10-percent increase in the probability of adopting yield monitors. Adoption of yield monitors did not have a statistically significant association with either farm household income or total household income. These results are quite different from those for HT soybeans and conservation tillage. This empirical evidence suggests that yield monitoring techniques are management-intensive compared with the other two technologies, which spare management time.

Finally, the relationship between the adoption of Bt corn with either off-farm or onfarm household income was not statistically significant, indicating that Bt corn may be managerially neutral.

These results are consistent with anecdotal evidence (see box "Selected Agricultural ...") that herbicide-tolerant soybeans save managerial time because of the simplicity and flexibility of weed control. Conservation tillage is also believed to save managerial labor, but to a lesser degree than HT soybeans. Our results for yield monitoring are also consistent with anecdotal evidence that precision farming techniques in general are managerially using. Before the commercial introduction of Bt corn in 1996, most farmers accepted yield losses rather than incur the expense and uncertainty of chemical control. For those farmers, the use of Bt corn was reported to result in yield gains rather than pesticide savings, and savings in managerial time were small.

Selected Agricultural Technologies and Their Managerial Intensity

Herbicide-tolerant (HT) soybeans contain traits that allow them to survive certain herbicides that previously would have destroyed the crop along with the targeted weeds. This allows farmers to use more effective postemergent herbicides, expanding weed management options (Gianessi and Carpenter, 1999). The most common herbicide-tolerant crops are resistant to glyphosate, a herbicide effective on many species of grasses, broadleaf weeds, and sedges. Adoption of HT soybeans has risen rapidly since commercial availability in 1996. HT soybean use rose quickly to about 17 percent of U.S. soybean acreage in 1997 and reached 87 percent in 2005 (Fernandez-Cornejo and McBride, 2002; USDA, NASS, 2003).

Herbicide-tolerant soybeans save managerial time because of the relative simplicity and flexibility of the weed control program. The herbicide-tolerant technology allows growers to apply one herbicide product over the soybean crop at any stage of growth, instead of using several herbicides, to control a wide range of weeds "without sustaining crop injury" (Gianessi and Carpenter, 1999). In addition, using HT soybeans is said to make harvest easier (Duffy, 2001).

Conservation tillage is defined as "any tillage or planting system that maintains at least 30 percent of the soil surface covered by residue after planting" (Conservation Technology Information Center, 2004). It includes no-till, ridge-till, and mulch-till techniques. The impact of conservation tillage in controlling soil erosion and soil degradation is well documented (Edwards, 1995; Sandretto, 1997). By leaving substantial amounts of residue evenly distributed over the soil surface, conservation tillage reduces soil erosion by wind/water, increases water infiltration and moisture retention, and reduces surface sediment and chemical runoff. Adoption of conservation tillage was estimated at 2 percent of planted acreage in 1968 and grew fastest during 1975-85, reaching nearly 28 percent in 1985 (Schertz, 1988). It reached about 37 percent of planted acreage in 2002 (Conservation Technology Information Center, 2004). Conservation tillage is used primarily to grow corn, soybeans, small grains, and cotton.

Conservation tillage is believed to save managerial labor (Sandretto, 1997; USDA, 1998). While it is accepted that adoption of conservation tillage leads to labor savings, its slower rate of adoption compared with HT crops may be because the managerial savings are less.

Bt crops carry the gene from the soil bacterium *Bacillus thuringiensis* (Bt) and are able to produce proteins that are toxic to certain insects. Bt corn, originally developed to control the European corn borer, was planted on 35 percent of corn acreage in 2005, up from 24 percent in 2002. The recent upswing may be due to the commercial introduction in 2003/04 of a new Bt corn variety that is resistant to the corn rootworm.

Before the commercial introduction of Bt corn in 1996, chemical pesticide use was often not profitable to control the European corn borer (ECB) and timely application was difficult (Fernandez-Cornejo and Caswell, 2006). Many farmers accepted yield losses rather than incur the expense and uncertainty of chemical control. For those farmers, the use of Bt corn resulted in yield gains rather than pesticide savings, and managerial time savings were minimal.

Precision agriculture (PA) is often characterized as a suite of technologies used to monitor and manage subfield spatial variability. It includes, for example, global positioning systems, grid soil sampling, yield monitors, and input applicators that can vary rates across a field (Daberkow et al., 2002). These technologies can be used independently or as a package of technologies that includes, for example, the use of grid soil sampling, a variable-rate input applicator, and a yield monitor. PA has been growing relatively slowly. Yield monitors, which provide farmers site-specific data to allow them to vary input application and production practices, are the most extensively adopted PA component. Yield monitors were used in about 33 percent of total corn acreage in 2001 and in about 25 percent of soybean acreage. Adoption of other components of PA is even slower. Adoption of variable-rate applicators reached just 10 percent of corn acreage for fertilizer and 3 percent for pesticides or seeds in 2001 (Daberkow et al., 2002).

Unlike herbicide-tolerant soybeans, which provide savings in management time (and therefore allow operators to obtain higher income from off-farm activities), yield monitors (and precision agriculture in general) are generally believed to be human capital-intensive (Griffin at al., 2004).

Conclusions

As onfarm and off-farm activities compete for scarce managerial time in U.S. farm operator households, economic decisions (including technology adoption and other production decisions) are likely to shape and be shaped by time allocation within the household. Time allocation decisions are usually not measured directly, but their outcomes, such as onfarm and off-farm income, are observable.

Our research finds that the farm-level efficiency of farm households decreases as off-farm activities increase. Smaller farms, which average the highest off-farm incomes, obtain the lowest farm-level efficiencies. These results support the hypothesis that farm operators who devote more time to off-farm activities have less time to manage the farm. However, examining efficiency from a wider perspective, we find that household-level efficiency (including off-farm income-generating activities) is higher across all farm sizes than farm-level efficiency alone. Moreover, the beneficial effect of off-farm income is higher for smaller farms. In fact, farm households operating small farms achieve efficiency levels comparable to those operating larger farms when off-farm income is included. These results, therefore, suggest that farm households operating small farms have adapted to shortfalls in farming performance by increasing off-farm income.

By including off-farm income-generating activities in the household output portfolio (in addition to the traditional farm products), many farm households, especially those operating smaller farms, are able to enhance diversification. The advantages of such diversification, measured by the household-level economies of scope, are substantial. These results suggest that off-farm employment may enhance onfarm diversification, especially for households operating small farms.

The economic inducement of smaller farms to increase their size (measured by the economic concept of scale economies) is reduced when we include off-farm income. Household-level scale economies (which include off-farm income-generating activities) are closer to constant returns to scale than are farm-level scale economies (which only consider the farm business). However, the beneficial effect of off-farm activities in improving scale economies is more pronounced for households operating smaller farms. These findings provide a different way of measuring the role of off-farm work in improving the economic condition of farm households, particularly those operating small farms.

The adoption of agricultural innovations is also linked to off-farm income through managerial time. For example, the adoption of managerial time-saving technologies is significantly related to higher off-farm household income for U.S. corn/soybean farmers, after controlling for other factors. On the other hand, managerially time-intensive technologies are associated with significantly lower off-farm income.

In a broader sense, these findings confirm the tradeoff between time spent on farm and off-farm activities or, in economic terms, the substitution of economies of scope (derived from engaging in multiple income-generating activities, on and off the farm) for economies of scale.

A number of implications follow. Each of these implications reinforces the importance of understanding farmers' decisions in the context of the farm household rather than the farm operation alone. First, our research provides empirical confirmation of Smith's suggestion that households operating small farms, which lack economies of scale, are more likely to devote time to off-farm opportunities, more likely to adopt management-saving technologies (like herbicide-tolerant crops), and less likely to adopt management-intensive technologies (such as integrated pest management).

The relationship between off-farm work and economic performance also suggests that a farm household's dependence on off-farm income has an effect on the distributional consequences of government policies. Government policies affecting agriculture—such as conservation, research and development, extension, and farm support—may affect farm households differently depending on the relative importance of onfarm and off-farm income-generating activities. Thus, the consequences of government policies depend on the diversity of U.S. farm households, particularly regarding their income sources. For example, a policy promoting the adoption of management-intensive agricultural techniques (such as IPM) may not be fully effective unless it takes into consideration the demands in managerial time imposed by IPM adoption.

This research also has implications for private agricultural research and development (R&D). While innovators often base their economic evaluations of returns to R&D on the expected profitability of potential innovations for farmers (i.e., the extent of yield increases and/or input cost reduction resulting from an innovation relative to the costs of adoption and current management practices), this report shows that there is an important additional element to be included in such evaluations: the value of management time.

Appendix 1—Economies of Scale and Scope and Technical Efficiency

This discussion uses two different but related methodologies and data sets and follows the analysis described in Nehring et al., 2005. First, using 1996-2000 survey data, we use an input distance function to estimate scale economies and technical efficiency, and compare these performance measures at the farm and household levels. Second, using 2000 survey data, we set up a multi-activity cost function to analyze labor allocation decisions within the farm operator household and estimate scope economies. We interpret off-farm income-generating activities as outputs, along with corn, soybeans, livestock, and other crops. For both estimations, we use detailed survey information of the farm operator household from USDA's Agricultural Resource Management Survey (ARMS).

Economies of Scale and Technical Efficiency

The analysis of production structure and performance requires representing the underlying multi-dimensional (input and output) production technology. This may be formalized by specifying a transformation function, $\boldsymbol{T(X,Y,R)=0}$, which summarizes the production frontier in terms of an input vector $\boldsymbol{X}$, an output vector $\boldsymbol{Y}$, and a vector of external production determinants $\boldsymbol{R}$. This information on the production technology can also be characterized via an input set, $L(\boldsymbol{Y,R})$, representing the set of all X vectors that can produce Y, given the exogenous factors $\boldsymbol{R}$.

An input distance function (denoted by superscript I) identifies the least input use possible for producing the given output vector, defined according to $L(\boldsymbol{Y,R})$:

$$(1) \quad D^{I}(\boldsymbol{X,Y,R}) = Max\{\rho : (x/\rho) \in L(\boldsymbol{Y,R})\}.$$

This multi-input, input-requirement function allows for deviations from the frontier. It is also conceptually similar to a cost function, if allocative efficiency is assumed, in the sense that it implies minimum input or resource use for production of a given output vector (and thus, implicitly, costs). However, it does so in a primal/technical optimization or efficiency context, with no economic optimization implied.

For the farm-level model, the $\boldsymbol{Y}$ vector contains Y_1 = crops (corn, soybeans, and other crops), Y_2 = livestock, and, for the household-level model, Y_1^* = crops and livestock, and Y_2^* = off-farm income-generating activities, as farm "outputs." With Y_2^* included, one might think of $\boldsymbol{Y}$ as a multi-activity rather than a multi-output vector. The components of X are defined as X_1 = land (LD), X_2 = hired labor (L), X_3 = operator labor (including hours worked off-farm)(K), X_4 = spouse labor (including hours worked off-farm) (E), X_5 = capital (F), and X_6 = materials (M).

The scale economies measure may be computed from the estimated model via derivatives or scale elasticities: $-\varepsilon_{DIY} = -\Sigma_m \partial \ln D^{I}(\boldsymbol{X,Y},t)/\partial \ln Y_m = \varepsilon_{XIY}$ for M outputs Y_m (similar to the treatment in Baumol et al. (1982) for a multiple-output cost model, and consistent with the output distance function

formula in Färe and Primont (1995). However, the inverse measure is more comparable to the cost literature, where the extent of increasing returns or scale economies is implied by the shortfall of the measure from 1. Again, this measure is based on evaluation of (scale) expansion from a given input composition base.

The distance function can be approximated by a translog functional as follows:

$$(2)\quad \ln D^{I}_{it}/X_{1,it} = \alpha_0 + \alpha_t\, t + \Sigma_m \alpha_m \ln X^{*}_{mit} + 0.5\, \Sigma_m \Sigma_n \beta_{mn} \ln X^{*}_{mit} \ln X^{*}_{nit} + \Sigma_k \alpha_k \ln Y_{kit} + 0.5\, \Sigma_k \Sigma_l \alpha_{kl} \ln Y_{kit} \ln Y_{lit} + \Sigma_k \Sigma_m \delta_{km} \ln Y_{kit} \ln X^{*}_{mit},$$

or

$$(3)\quad -\ln X_{1,it} = \alpha_0 + \alpha_t\, t + \Sigma_m \alpha_m \ln X^{*}_{mit} + 0.5\, \Sigma_m \Sigma_n \beta_{mn} \ln X^{*}_{mit} \ln X^{*}_{nit} + \Sigma_k \alpha_k \ln Y_{kit} + 0.5\, \Sigma_k \Sigma_l \alpha_{kl} \ln Y_{kit} \ln Y_{lit} + \Sigma_k \Sigma_m \delta_{km} \ln Y_{kit} \ln X^{*}_{mit} - \ln D^{I}_{it},$$

where i denotes farm and t time period. This functional relationship, which embodies a full set of interactions among the $\boldsymbol{X}$, $\boldsymbol{Y}$ and t arguments of the distance function, can more succinctly be written as: $-\ln X_{1,it} = TL(\boldsymbol{X}/X_1, \boldsymbol{Y}, t) = TL(\boldsymbol{X}^*, \boldsymbol{Y}, t)$.

The input distance function is well-suited to measure technical efficiency. For empirical estimation of technical efficiency, we append a symmetric error term, v, to equation (3) and change the notation "$-\ln D^{I}_{it}$," to "u." The resulting function (with the subscripts it suppressed for notational simplicity) is: $-\ln X_1 = TL(\boldsymbol{X}^*, \boldsymbol{Y}, t) + v - u$, where the term $(-u)$ may be interpreted as inefficiency (as technical efficiency measures the distance from the frontier). This method is known as a stochastic frontier production function, where output of a firm is a function of a set of inputs, inefficiency (- u) and a random error v (Aigner et al., 1977; Greene, 1995, 1997, 2000).

To estimate the function, we used Coelli's FRONTIER program (Coelli, 1996), based on the error components model of Battese and Coelli (1992). Since -u represents inefficiency, the technical efficiency scores are given by $\exp(-u) = D^{I}(\mathbf{X}^*, \mathbf{Y}, t)$. If a firm is not technically inefficient (the firm is on the frontier), u is equal to 0 and its technical efficiency score is 1.

In the absence of genuine panel data, repeated cross-sections of data across farm typologies are used to construct a pseudo-panel data set (see Deaton, 1985; Heshmati and Kumbhakar, 1992; Verbeek and Nijman, 1993). The pseudo-panels are created by grouping the individual observations into a number of homogeneous cohorts, demarcated on the basis of their common observable time-invariant characteristics, such as location and ERS farm typology. The subsequent economic analysis then uses the cohort means rather than the individual farm-level observations. ERS farm typology categories are summarized in Nehring et al. (2005). The resulting pseudo panel data set consists of 13 cohorts by State, for 1996-2000, measured as the weighted mean values of the variables to be analyzed. There are a total of 650 annual observations (130 per year), summarizing the activities of 1,934 farms in 1996, 3,890 in 1997, 2,311 in 1998, 3,201 in 1999, and 2,394 in 2000.

Economies of Scope

When a firm produces more than one output, there is a qualitative change in the production structure that makes the concept of economies of scale developed for a single output insufficient. For multiproduct firms, production economies may arise not only because the size of the firm is increased but also due to advantages derived from producing several outputs together rather than separately. Thus, more than one measure is necessary to capture the economies (or diseconomies) related to the scale of operation (volume of output) and the economies related to the scope of the operation (composition of output or product mix). The concepts of economies of scale and scope for multiproduct firms have been developed by Panzar and Willig (1977, 1981) and Baumol et al. (1982). They have been used in agriculture by Akridge and Hertel (1986) and Fernandez-Cornejo et al. (1992).

Economies of scope measure the cost savings due to simultaneous production relative to the cost of separate production. In general, scope economies occur when the cost of producing all products together is lower than producing them separately.

Formally, consider a partition of the output set N into two (disjoint) groups T and N-T. Let Y_T, Y_{N-T} be the output quantity (subvector) of each of the two groups and Y_N (or simply Y) the output vector, which consists of all the outputs. The respective cost functions $C(Y_T)$, $C(Y_{N-T})$ give the minimum cost of producing the two output groups separately, and $C(Y_N)$ denotes the minimum cost of producing them together (Nehring et al., 2005).

The degree of economies of scope *(SC)* relative to the (output) set T is defined as:

$$(1) \qquad SC = [C(Y_T)+C(Y_{N-T}) - C(Y_N)] / C(Y_N)$$

where SC will be positive if there are economies of scope and negative if there are diseconomies of scope. In our case, we consider the first subset of the partition to include the four conventional outputs (corn, soybeans, other crops, and livestock), $N=\{1,2,3,4\}$ and the second subset the non-conventional off-farm income-generating activities, $N\text{-}T=\{5\}$.

Farms that produce the two output groups separately are those that either produce conventional outputs with no off-farm activities or else those with off-farm work but no conventional outputs. While the sample includes farm households that produce conventional outputs and no off-farm activities, it technically does not include household with zero traditional outputs. However, the sample does include many farm households with very small revenues from traditional outputs because, for statistical purposes, a U.S. farm is currently defined as "any place from which $1,000 or more of agricultural products were sold or normally would have been sold during the year under consideration." (USDA, 2005).

The well-developed restricted cost function is used to estimate the scope economies. Consider n outputs, m variable inputs, and s fixed inputs and other exogenous factors such as location or weather proxies; $\mathbf{Y} = (Y1,...Yn)'$

denotes the vector of outputs, $\boldsymbol{X} = (X1,...Xm)'$ denotes the vector of variable inputs, $\boldsymbol{Z} = (Z_1,...Zs)'$ is the vector of non-negative quasi-fixed inputs and other (exogenous) factors, and $\boldsymbol{W} = (W1,...Wm)'$ denotes the price vector of variable inputs. The restricted profit function is defined by:

$$C(W,Y,Z) = Min\ [W'X : \in T]. \tag{3}$$

Under the usual assumptions on the technology (production possibilities set T), the restricted cost function is well defined and satisfies the usual regularity conditions.

Using a normalized quadratic variable cost function, which can be viewed as a second-order Taylor series approximation to the true cost function, we obtain:

$$C(W,Y,Z) = a_0 + (a'b'c')\begin{bmatrix} W \\ Y \\ Z \end{bmatrix} = 1/2(W'Y'Z')\begin{bmatrix} B & E & F \\ E & C & G \\ F & G & D \end{bmatrix}\begin{bmatrix} W \\ Y \\ Z \end{bmatrix} \tag{4}$$

where $\boldsymbol{W}$ is a vector of normalized variable input prices, a_0 is a scalar parameter, and $\boldsymbol{a}$, $\boldsymbol{b}$, and $\boldsymbol{c}$ are vectors of constants of the same dimension as $\boldsymbol{W}$, $\boldsymbol{Y}$, and $\boldsymbol{Z}$. The parameter matrices $\boldsymbol{B}$, $\boldsymbol{C}$, and $\boldsymbol{H}$ are symmetric and of the appropriate dimensions. Similarly, $\boldsymbol{E}$, $\boldsymbol{F}$, and $\boldsymbol{G}$ are matrices of unknown parameters.

Using Shephard's lemma, we obtain the demand functions for variable inputs which is estimated together with the cost function. We consider five outputs Y (corn, soybeans, other crops, livestock, and operator and spouse off-farm labor), five inputs X (hired labor, operator labor, spouse labor, miscellaneous inputs, and pesticides), and use the pesticides price as the *numeraire*. In addition the cost function is specified with two exogenous factors (Nehring et al., 2005).

The normalized quadratic variable cost function and the four cost-share equations are estimated in an iterated seemingly unrelated regression (ITSUR) framework using data for year 2000. The adjusted R^2's were 0.99 for the quadratic cost function, 0.26 for the hired labor input, 0.21 for the operator labor equation, 0.30 for the spouse labor equation, and 0.60 for the miscellaneous inputs equation. However, 48 percent of coefficients for the joint estimates are significant at the 10 percent level.

The own-price effects for the inputs exhibit the expected negative signs. The own-price effect for hired labor is significant at the 10-percent level, while the own-price effects for operator labor and spouse labor are not significant in this cross-section. The own price elasticity of demand for hired labor is highly elastic, with a value of -2.62. In contrast, the own- price elasticities of demand for operator and spouse labor are highly inelastic, with values of -0.105 and -0.283. These results, however, are not directly comparable with cost function studies in the literature that do not include off-farm income-generating activities as an output.

Appendix 2—Incorporating Technology Adoption in the Farm Household Model

The Theoretical Framework

This model combines in a single framework the technology adoption and off-farm work decisions by the operator and spouse and follows the analysis developed by Fernandez-Cornejo et al. (2005). The model expands the farm household model offered by Huffman (1991) with several additions to allow for technology adoption. According to the agricultural household model, farm households maximize utility U subject to income, production technology, and time constraints. Household members receive utility from goods purchased for consumption G, leisure (including home time) $L = (L_o, L_s)$ for the operator and the spouse, and from factors exogenous to current household decisions, such as human capital $H = (H_o, H_s)$, and other factors Ψ (including household characteristics and weather). Thus:

(1) $Max\ U = U(G, \mathbf{L}, \mathbf{H}, \Psi)$

Subject to the constraints:

(2) $P_g G = P_q Q - \mathbf{W}_x \mathbf{X}' + \mathbf{W}\mathbf{M}' + A$ (income constraint)

(3) $Q = Q[X(\Gamma), \mathbf{F}(\Gamma), \mathbf{H}, \Gamma, \mathbf{R}],\ \Gamma \geq 0$ (technology constraint)

(4) $\mathbf{T} = \mathbf{F}(\Gamma) + \mathbf{M} + \mathbf{L}, \mathbf{M} \geq 0$ (time constraint)

where P_g and G denote the price and quantity of goods purchased for consumption; P_q and Q represent the price and quantity of farm output; $\mathbf{W}_x$ and $\mathbf{X}$ are the price and quantity (row) vectors of farm inputs; $\mathbf{W} = (W_o, W_s)$ represents off-farm wages paid to the operator and spouse; $\mathbf{M} = (M_o, M_s)$ is the amount of time working off-farm by the operator and spouse; $\mathbf{F} = (F_o, F_s)$ is the amount of time working on the farm by the operator and spouse; A is other income, including income (from interest, dividends, annuities, private pensions, and rents) and government transfers (such as Social Security, retirement, disability, and unemployment); $\mathbf{R}$ is a vector of exogenous factors that shift the production function, and $\mathbf{T} = (T_o, T_s)$ denotes the (annual) time endowments for the operator and spouse. The production function is concave and has the usual regularity characteristics. Some technologies offer simplicity and flexibility that translate into reduced management time, freeing time for other uses. In these cases, the amount of time working on the farm by the operator and the spouse $\mathbf{F}$ (and possibly the use of other farm inputs $\mathbf{X}$) is a function of Γ, the adoption intensity (extent of adoption) of the technology. A technology-constrained measure of (cash) household income is obtained by substituting (3) into (2) (Huffman, 1991):

(5) $P_g G = P_q Q[X(\Gamma), \mathbf{F}(\Gamma), \mathbf{H}, \Gamma, \mathbf{R}] - \mathbf{W}_x \mathbf{X}(\Gamma)' + \mathbf{W}\mathbf{M}' + A$

The first order conditions for optimality (Kuhn-Tucker conditions) are obtained by maximizing the Lagrangian expression $\mathcal{L}$ over $(G, \mathbf{L})$ and minimizing it over the Lagrange multipliers (λ, μ), where $\mu = (\mu_0, \mu_s)$:

(6) $\mathcal{L} = U(G, \mathbf{L}, \mathbf{H}, \Psi) + \lambda \{ P_q Q[\mathbf{X}(\Gamma), \mathbf{F}(\Gamma), \mathbf{H}, \Gamma, \mathbf{R}] - \mathbf{W}x\,\mathbf{X}(\Gamma)' + \mathbf{W}\,\mathbf{M}' + A - P_g G \} + \boldsymbol{\mu} [\mathbf{T} - \mathbf{F}(\Gamma) - \mathbf{M} - \mathbf{L}]$

The off-farm participation and adoption decisions may be obtained from the following Kuhn-Tucker conditions:

(7) $\partial\mathcal{L}/\partial\mathbf{X} = \lambda (P_q\, \partial Q/\partial\mathbf{X} - \mathbf{W}_x) = \mathbf{0}$

(8) $\partial\mathcal{L}/\partial F = \lambda\, Pq\, \partial Q/\partial F - \boldsymbol{\mu} = \mathbf{0}$

(9) $\partial\mathcal{L}/\partial\Gamma = \lambda[P_q[(\partial Q/\partial X)(d\mathbf{X}/d\Gamma)' + (\partial Q/\partial\mathbf{F})(d\mathbf{F}/d\Gamma)' + \partial Q/d\Gamma] - \mathbf{W}_x (d\mathbf{X}/d\Gamma)'\} - \boldsymbol{\mu}\,(d\mathbf{F}/d\Gamma)' \leq 0,$

$\Gamma \geq 0, \quad \Gamma \cong \partial\mathcal{L}/\partial\Gamma = 0$

(10) $\partial\mathcal{L}/\partial\mathbf{M} = \lambda\, \mathbf{W} - \boldsymbol{\mu} \leq 0, \quad \mathbf{M} \geq 0, \quad \mathbf{M}(\lambda\, \mathbf{W} - \boldsymbol{\mu}) = 0$

(11a, b) $\partial\mathcal{L}/\partial G = U_G - P_g\, \lambda = 0, \; \partial\mathcal{L}/\partial\mathbf{L} = \mathbf{U}_L - \boldsymbol{\mu} = \mathbf{0}$

(12) $P_q\, Q[\mathbf{X}(\Gamma), \mathbf{F}(\Gamma), \mathbf{H}, \Gamma, R] - \mathbf{W}_x\, \mathbf{X}(\Gamma)' + \mathbf{W}\mathbf{M}' + A - P_g\, G = 0$

(13) $\mathbf{T} - \mathbf{F}(\Gamma) - \mathbf{M} - \mathbf{L} = \mathbf{0}$

where U_L, U_G are the partial derivatives of the function U. Without loss of generality, both the operator and spouse are assumed to have positive optimal hours of leisure and farm work, i.e., equation (8) and (11b) are equalities.

The off-farm participation decision conditions for the operator and the spouse may be obtained from the optimality conditions for off-farm work, equation (10), together with equations (8) and (11b):

(14) $\mathrm{W} \leq \boldsymbol{\mu}/\lambda = \mathrm{P_q}\, \partial Q/\partial F$

where $\boldsymbol{\mu}/\lambda$ is equal to the marginal rate of substitution between leisure and consumption goods (from equations 11a and 11b) and $P_q\ \partial Q/\partial F$ represents the value of the marginal product of farm labor for the operator and the spouse. Examining the components of (14), $W_i < \boldsymbol{\mu}_i/\lambda$ (strict inequality) indicates that the total time endowment for the operator ($i = o$) or spouse ($i = s$) is allocated between farm work and leisure; optimal hours of off-farm work are zero (corner solution), i.e., $M_i^* = 0$. On the other hand, if $W_i = \boldsymbol{\mu}_i/\lambda$, optimal hours of off-farm work may be positive ($M_i^* > 0$) and $W_i = \boldsymbol{\mu}_i/\lambda = P_q\ \partial Q/\partial F_i$ (interior solution) (Lass et al., 1989; Huffman, 1991; Kimhi, 1994; Huffman and El-Osta, 1997). In this case, the value of the marginal product of farm labor is equal to the off-farm wage rate.[27]

When an interior solution for $\boldsymbol{M}$ occurs, equations (7) and (8) can be solved together, independently of the rest of the Kuhn-Tucker conditions, to obtain the demand functions for onfarm labor, i.e., the optimal production and consumption decisions can be separated since the off-farm wage determines the value of the operator's and spouse's time ($\mathrm{W} = \boldsymbol{\mu}/\lambda$) (Huffman and Lange, 1989; Huffman, 1991).[28]

[27]The marginal value of time of the farm operator (or spouse) when all his/her time is allocated to farm work and leisure and none is allocated to off-farm work ($P_q\ \partial Q/\partial F_i\,|_{Mi=0}$) represents the shadow value of farm labor and is called the reservation wage for off-farm work for the operator (i = o) or spouse (i = s). In this context, the operator (or spouse) will work off-farm when his/her reservation wage is less than the anticipated off-farm wage rate and will not work off-farm otherwise. Assuming that both the operator and spouse face wages that are dependent on their marketable human capital characteristics ξi, local labor market conditions, and job characteristics Ω, but not on the amount of off-farm work (Huffman and Lange, 1989; Huffman, 1991; Tokle and Huffman, 1991), the off-farm market labor demand functions are $W_i = W_i(\xi i, \Omega), (i = o, s)$.

[28]Moreover, when an interior solution occurs, from (10), (11a), and (11b) we obtain $\mathbf{U}_L/U_G = \mathbf{W}/P_g$; that is, the marginal rate of substitution between consumption goods and leisure is equal to the ratio of the wage rate and the price of consumption goods.

The demand function for onfarm labor is then $\boldsymbol{F}^*=F(\boldsymbol{W}, \boldsymbol{W}_x, P_q, \boldsymbol{H}, \Gamma, R)$ and the demand for purchased farm inputs $\boldsymbol{X}^* = X(\boldsymbol{W}, \boldsymbol{W}_x, P_q, \boldsymbol{H}, \Gamma, \boldsymbol{R})$. These optimal input demand functions are substituted in the production function to obtain the supply of farm output $Q^* = S(\boldsymbol{W}, \boldsymbol{W}_x, P_q, \boldsymbol{H}, \Gamma, \boldsymbol{R})$ and the maximum net household income may be expressed as:

$$(15) \qquad NI^* = P_q\, S(\boldsymbol{W}, \boldsymbol{W}_x, P_q, \boldsymbol{H}, \Gamma, \boldsymbol{R}) - \boldsymbol{W}_x \boldsymbol{X}^{*\prime} + \boldsymbol{W}\boldsymbol{M}' + A$$

Solving jointly equations (10), (11), and (15) we obtain the demand for leisure $\boldsymbol{L}^* = L(\boldsymbol{W}, P_g, NI^*, \boldsymbol{H}, \Psi, \boldsymbol{T})$ and for consumption goods $G = G(\boldsymbol{W}, P_g, NI^*, \boldsymbol{H}, \Psi, \Gamma, \boldsymbol{T})$. The supply function for off-farm time is obtained by substitution of the optimal levels of leisure hours and farm work hours (Huffman, 1991):

$$(16) \qquad \boldsymbol{M}^* = \boldsymbol{T} - \boldsymbol{F}^* - \boldsymbol{L}^* \;= M(\boldsymbol{W}, \boldsymbol{W}_x, P_q, Pg, NI^*, \boldsymbol{H}, \Psi, \Gamma, \xi i, \Omega, \boldsymbol{R}, \boldsymbol{T})$$

Finally, a reduced-form expression of total household income is obtained by:

$$(17) \qquad NI^* = NI(\boldsymbol{W}_x, P_q, P_g, A, \boldsymbol{H}, \Psi, \Gamma, \boldsymbol{R}, \boldsymbol{T})$$

As Huffman (1991) notes, when optimal hours of off-farm work hours for the operator or the spouse are zero, the decision process is not recursive and production and consumption decisions must be made jointly. In this case, the arguments for the reduced-form expression of household income are the same as those in (17) but exclude the exogenous variables related to the job characteristics and labor marketability.

The technology adoption decision condition is obtained from the optimality conditions, equation (9) and equations (8) and (11b), noting that the expression in brackets in (9) is the total derivative $dQ/d\Gamma$. Thus, we obtain:

$$(18) \qquad Pq\, dQ/d\Gamma \; - \boldsymbol{W}_x\, (d\boldsymbol{X}/d\Gamma)' - (\boldsymbol{\mu}/\lambda)(d\boldsymbol{F}/d\Gamma)' \leq 0$$

But from (11a) and (11b) $\boldsymbol{\mu}/\lambda = P_g\, (U_L/U_G)$; then:

$$(19) \qquad P_q\, dQ/\Gamma \; - \boldsymbol{W}_x\, (d\boldsymbol{X}/d\Gamma)' - P_g\, (U_L/U_G)(d\boldsymbol{F}/d\Gamma)' \leq 0$$

The left-hand-side of this expression may be interpreted as the marginal benefit of adoption $P_q\, dQ/d\Gamma$ minus the marginal cost of adoption, which includes the marginal cost of the production inputs $\boldsymbol{W}_x\, (d\boldsymbol{X}/d\Gamma)'$ and the marginal cost of the farm work $P_g\, (\boldsymbol{U}_L/U_G)(d\boldsymbol{F}/d\Gamma)'$ (of the operator and the spouse) brought about by adoption (could be negative if adoption saves managerial time), valued at the marginal rate of substitution between leisure and consumption goods (which, when off-farm work hours are positive, equals the off-farm wage rate). It will not be optimal to adopt if the inequality is strict (corner solution), wherein the marginal benefit of adoption falls short of the marginal cost of adoption. An interior solution for the optimal extent of adoption will occur when the equality is strict or when the value of the marginal benefit of adoption is equal to the marginal cost of adoption.

Given the cross-sectional nature of the data, one can use the implicit function theorem to derive expressions for off-farm labor supply for farm operator and spouse and technology adoption (which affects off-farm labor

supply of farm operators and spouses) that are functions of wages, prices, human capital, nonlabor income, and other exogenous factors. These factors are replaced in reduced-form representations of labor supply and adoption by observable farm, operator, and household characteristics, including human capital. The "ambient variables" (family size, access to urban areas), which might affect the productive capacity of the farm operator and the spouse, are also included. The following section outlines the empirical model and estimation method used to conduct the analysis.

Empirical Model

A two-stage econometric model is specified. The first stage, the decision model, examines the off-farm work participation and the technology adoption decisions. The second stage is used to estimate the impact of adoption on household income.

A simplified "reduced form" approach is followed (Goodwin and Holt, 2002; Goodwin and Mishra, 2004) to specify the empirical model, rather than explicitly estimating a structural model of labor supply. In this approach, the reduced form of the decision model is obtained by specifying the endogenous variables ($\boldsymbol{M}$, $\boldsymbol{F}$, Q_g, $\boldsymbol{X}$) in terms of the exogenous variables, including $\boldsymbol{W}_x$, P_q, P_g, $\boldsymbol{H}$, Ψ, ξ_i, Ω, $\boldsymbol{R}$, $\boldsymbol{T}$. Equation (14), implied by the Kuhn-Tucker conditions, is central to the off-farm work decision of the operator and the spouse and equation (19) is central to the adoption decision. Thus, considering a first-order approximation (linear terms) and adding the stochastic terms, the empirical representation of the decision model, which includes the off-farm participation of the operator (20a) and spouse (20b), and the technology adoption decision (20c), is:

(20a) $$\boldsymbol{\beta}_o \boldsymbol{Z}_o' + \varepsilon_o \leq 0$$

(20b) $$\boldsymbol{\beta}_s \boldsymbol{Z}_s' + \varepsilon_s \leq 0$$

(20c) $$\boldsymbol{\beta}_a \boldsymbol{Z}_a' + \varepsilon_a \leq 0$$

where the (row) vectors Z_o, $\boldsymbol{Z}_s$, and $\boldsymbol{Z}_a$ include all the factors or attributes influencing linearly the off-farm participation (operator and spouse) and adoption decisions, and $\boldsymbol{\beta}_o$, $\boldsymbol{\beta}_s$, and $\boldsymbol{\beta}_a$ are vectors of parameters. Assuming that the stochastic disturbances are normally distributed, each of these equations may be estimated by probit. However, because the disturbances (ε_o, ε_s, ε_a) are likely to be correlated, univariate probit equations are not appropriate. Bivariate probit models have been used to model the off-farm employment decisions by the operator and spouse (Huffman and Lange, 1989; Lass et al., 1989; Tokle and Huffman, 1991). Since the decisions to work off farm and the technology adoption decision may be related, all three decisions are modeled together in a multivariate probit model (Greene, 1997). Formally, [ε_o, ε_s, ε_a] ~ trivariate normal (TVN) [0,0,0; 1,1,1; ρ_{12},ρ_{13},ρ_{23}], with variances ρ_{ij} ($i = j$) equal to 1 and correlations ρ_{ij} ($i \neq j$) where $i, j = 1$,2,3.

The joint estimation of three or more probit equations was computationally unfeasible until recently because of the difficulty in evaluating high-order multivariate normal integrals. Over the past decade, however, the estimation

has been made possible with Monte Carlo simulation techniques (Geweke et al., 1994; Greene, 1997).

The vector $\boldsymbol{Z}_i$ includes (i) farm factors, such as farm size and complexity of the operations; (ii) human capital (operator age/experience and education); (iii) household characteristics (such as the number of children); (iv) off-farm employment opportunities, which will depend on the farms' accessibility to urban areas and the change in the rate of unemployment in nearby urban areas; (v) farm typology; and (vi) government payments.[29] The factors or attributes influencing adoption, included in the vector $\boldsymbol{Z}_a$, are farm factors, human capital, farm typology, a proxy for risk (risk-averse farmers are less likely to adopt agricultural innovations), and crop/seed prices.

[29]Following Goodwin and Holt (2002), some prices are not included in our empirical models since prices are approximately constant across households when data consist of cross-sectional observations taken at a point in time. We did include some prices, like the price of soybeans, but its coefficient was statistically insignificant.

The second stage, the income impact model, provides estimates of the impact of adoption on household income after controlling for other factors. The empirical representation of this model—based on equation (17), the reduced-form expression of household income—is $NI^* = NI(\boldsymbol{W}_x, P_q, P_g, A, \boldsymbol{H}, \Psi, \Gamma, \boldsymbol{R}, \boldsymbol{T})$.

After linearizing this reduced form, separating out explicitly the adoption indicator variable, and appending a random disturbance å, assumed to be normally distributed, we have:

$$NI^* = \boldsymbol{\theta V}' + \alpha I + \varepsilon \tag{21}$$

where NI^* represents household income; $\boldsymbol{V}$ is a (row) vector of observable explanatory variables that may influence household income (other than technology adoption) such as prices, human capital, and "ambient variables" (family size, access to urban areas) that may affect the productive capacity of the farm operator and the spouse; I is an indicator variable for adoption ($I=1$ if adoption takes place and $I=0$ otherwise); and $\boldsymbol{\theta}$ and α are appropriately dimensioned parameters. The impact of adoption on household income is measured by the estimate of the parameter α. However, as noted by Stefanides and Tauer (1999), if α is to measure the impact of adoption on income of a representative farm, farmers should be randomly assigned among adopter and nonadopter categories. This is not the case, since farmers make the adoption choices themselves. Therefore, adopters and nonadopters may be systematically different and these differences may manifest themselves in farm performance and could be confounded with differences due purely to adoption. This situation, called self-selection, may bias the statistical results unless corrected (Fernandez-Cornejo et al. 2002).

To correct for self-selection bias, we follow Maddala (1983) and Greene (1995) and obtain consistent estimates of the parameters $\boldsymbol{\theta}$ and α by regarding self-selection and simultaneity (discussed earlier) as sources of endogenity. Because the dummy variable I cannot be treated as exogenous, instrumental variable techniques are used to purge the dependence of I. The predicted probability of adoption, obtained from the decision model, is used as an instrument for I in equation (21).

Unlike the traditional selectivity model, in which the effects are calculated (separately) using the subsamples of adopters and nonadopters, the impact model uses all the observations and is known as a "treatment effects model,"

used by Barnow et al. (1981). The treatment effects model consists of the regression $Y = \boldsymbol{\theta V}' + \alpha I + \varepsilon$ where the observed indicator variable I ($I = 1$ if $I^* > 0$ and $I = 0$ if $I^* \leq 0$), indicates the presence or absence of some treatment (adoption of herbicide-tolerant crops in this case) and the unobserved or latent variable I^* is given by $I^* = \boldsymbol{\delta} Z_a' + \nu$(Greene, 1995).

Total household income (NI^*), as represented in (17), has two components: household income from farming (*FARMHHI*) and off-farm household income (*TOTOFI*). Household income from farming includes farm business household income, operator's paid farm income, household members' paid farm income, etc. (see detailed definitions in appendix table 1). Off-farm household income includes off-farm business income, income from operating other farm businesses, off-farm wages and salaries, etc.

The components of vector $\boldsymbol{V}$ include farm location and typology, operator age, education and experience, number of children, price of soybeans, a measure of specialization on soybean production, a measure of the extent of livestock operations, farm size, and proxies for local labor market conditions.

The data are obtained from the nationwide Agricultural Resource Management Survey (ARMS) developed by USDA (USDA, ERS, 2003). The ARMS survey is designed to link data on the resources used in agricultural production to data on use of technologies, other management techniques, chemical use, yields, and farm financial/economic conditions for selected field crops. The ARMS is a multiframe, probability-based survey in which sample farms are randomly selected from groups of farms stratified by attributes such as economic size, type of production, and land use.

The 2000 data set (used for the HT soybean and Bt corn case study) includes 17 soybean (corn) producing States: Arkansas, Illinois, Indiana, Iowa, Kansas, Kentucky, Louisiana, Mississippi, Michigan, Minnesota, Missouri, Nebraska, North Carolina, Ohio, South Dakota, Tennessee, and Wisconsin. After selecting those farms that planted soybeans (corn) in 2000 and eliminating those observations with missing data, there were 2,258 observations available for the soybean analysis and 2513 observations for corn.

The 2001 corn data set (used for the yield monitor and conservation tillage case studies) includes observations of 17 corn-producing States. After eliminating observations with missing data, there were 1,763 observations available for analysis.

Because of the complexity of the survey design, a weighted least-squares technique is used to estimate the parameters using full-sample weights developed by the USDA's National Agricultural Statistics Service. Standard errors are estimated using a delete-a-group jackknife method (Kott, 1998; Kott and Stukel, 1997) where a group of observations is deleted in each replication. The sample is partitioned into r groups of observations (r = 15) and resampled, thus forming 15 replicates and deleting one group of observations in each replicate.

Appendix table 2 shows the parameter estimates α (equation 21) along with standard errors. These parameters may be interpreted as the derivatives of household income with respect to the probability of adoption and are used to obtain the elasticities shown in table 7.

Appendix table 1

Household (HH) income variable definitions

1. **Household income from farming (FARMHHI)** = Farm Business Income HH Share
   + Operator Paid on Farm
   + Household Members Paid on Farm
   + Net Income from Rented Land

Where:

Farm Business Income HH Share = Net Cash Farm Business Income
- Depreciation
- Gross Income from Rented Land
- Operator Paid Onfarm
- Income Due to Other Households

Net Cash Farm Income = Gross Cash Farm Income - Cash Operating Expenses

Gross Cash Farm Income = Crop and livestock income including CC loans + Other farm income (includes government payments, income from custom work and machine hire, income from livestock grazing, other farm-related income, income from farm land rented to others, fee income from crops removed under production contract, fee income from livestock removed under production contract).

Total Cash Operating Expenses (hired labor, contract labor, seed, fertilizer, chemicals, fuel, supplies, tractor and other equipment leasing, repairs, custom work, general business, real estate and property taxes, insurance, interest, purchased feed, purchased livestock).

2. **Off-Farm Household Income (TOTOFI)** = Off-farm business income
   + Income from operating other farm businesses
   + Off-farm wages and salaries
   + Interest and dividend income
   + Other off-farm income
   + Rental income

3. **Total Household Income (TOTHHI)** = Household Income from Farming (FARMHHI)
   + Off-Farm Household Income (TOTOFI)

Appendix table 2

Parameter estimates of probability of adoption term of the household income equation for technologies of varying managerial intensity

	Yield monitors			Bt corn			Conservation tillage			Herbicide-tolerant soybean		
	Estimate	std. err.	t-value	Estimate	std. err.	t-value	Estimate	std. err.	t-value	Estimate	std. err.	t-value
Onfarm household annual income	25.1	63.8	(0.39)	-13.9	10.9	(-1.29)	6.4	49.5	(0.13)	-30.4	29.8	(-1.02)
Off-farm household annual income	-124.9	35.3	(-3.54)	-36.7	36.2	(-1.07)	87.3	30.3	(2.88)	133.4	67.0	(1.99)
Total household annual income	-100.8	68.7	(-1.47)	-50.6	36.5	(-1.39)	93.9	51.3	(1.83)	104.1	59.0	(1.76)

Note. Standard errors calculated using the delete-a-group jackknife method.

THE NATIONAL ACADEMIES
Advisers to the Nation on Science, Engineering, and Medicine

The **National Academy of Sciences** is a private, nonprofit, self-perpetuating society of distinguished scholars engaged in scientific and engineering research, dedicated to the furtherance of science and technology and to their use for the general welfare. Upon the authority of the charter granted to it by the Congress in 1863, the Academy has a mandate that requires it to advise the federal government on scientific and technical matters. Dr. Ralph J. Cicerone is president of the National Academy of Sciences.

The **National Academy of Engineering** was established in 1964, under the charter of the National Academy of Sciences, as a parallel organization of outstanding engineers. It is autonomous in its administration and in the selection of its members, sharing with the National Academy of Sciences the responsibility for advising the federal government. The National Academy of Engineering also sponsors engineering programs aimed at meeting national needs, encourages education and research, and recognizes the superior achievements of engineers. Dr. Charles M. Vest is president of the National Academy of Engineering.

The **Institute of Medicine** was established in 1970 by the National Academy of Sciences to secure the services of eminent members of appropriate professions in the examination of policy matters pertaining to the health of the public. The Institute acts under the responsibility given to the National Academy of Sciences by its congressional charter to be an adviser to the federal government and, upon its own initiative, to identify issues of medical care, research, and education. Dr. Harvey V. Fineberg is president of the Institute of Medicine.

The **National Research Council** was organized by the National Academy of Sciences in 1916 to associate the broad community of science and technology with the Academy's purposes of furthering knowledge and advising the federal government. Functioning in accordance with general policies determined by the Academy, the Council has become the principal operating agency of both the National Academy of Sciences and the National Academy of Engineering in providing services to the government, the public, and the scientific and engineering communities. The Council is administered jointly by both Academies and the Institute of Medicine. Dr. Ralph J. Cicerone and Dr. Charles M. Vest are chair and vice chair, respectively, of the National Research Council.

Impact of Genetically Engineered Crops on Farm Sustainability in the United States
http://www.nap.edu/catalog/12804.html

Preface

Not since the introduction of hybrid corn seed have we witnessed such a sweeping technological change in U.S. agriculture. Hundreds of thousands of farmers have adopted the first generation of genetically engineered (GE) crops since their commercialization in 1996. Although not all GE varieties that have been commercialized have succeeded, those targeted at improved pest control now cover over 80 percent of the acres planted to soybean, cotton, and corn—that is, almost half of U.S. cropland. Forecasts suggest an expansion in GE-crop plantings in many other countries.

GE crops originate in advances in molecular and cellular biology that enable scientists to introduce desirable traits from other species into crop plants or to alter crop plants' genomes internally. Those powerful scientific techniques have dramatically expanded the boundaries that have constrained traditional plant-breeding. A new technology adopted so widely and rapidly has substantial economic, social, and environmental impacts on farms and their operators. Inevitably, both advantages and risks or losses emerge from such massive changes. The National Research Council has conducted multiple studies of specific aspects of GE crops, such as regulatory-system adequacy and food safety. However, the assigned tasks restricted the scope of their reports. As pressure mounts to expand the use of GE crops for energy, food security, environmental improvement, and other purposes, the scope and intensity of impacts will grow. Now is an opportune time to take a comprehensive look at the track record of GE crops and to identify the opportunities and challenges looming on the horizon. The National Research Council therefore supported the Committee on the Impact of Biotechnology on Farm-Level Economics and Sustainability to investigate this topic.

Despite the rapid spread of GE crops in U.S. agriculture, the technology continues to stir controversy around scientific issues and ideological viewpoints. The committee focused on the scientific questions associated with the farm-level impacts of the adoption of genetic-engineering technology and refrained from analyzing ideological positions, either pro or con. The committee adopted an "evidentiary" standard of using peer-reviewed literature on which to form our conclusions and recommendations. It is my hope that the report will give readers a firm grasp of the state of evidence or lack thereof on the scientific issues.

True to its charge, the committee adopted a sustainability framework that required an evaluation of environmental, economic, and social impacts of GE crops. Those three dimensions constitute the essential pillars of sustainability science. The summary and opening and closing chapters bring together the three perspectives for a fuller view of the technology's impact.

Given the controversies, readers will want to know the committee's composition and how it conducted its work in arriving at conclusions and recommendations. The biographies in Appendix C show a group of highly accomplished natural and social scientists who possess a broad array of research experience and perspectives on GE crops. That diversity of disciplines

Impact of Genetically Engineered Crops on Farm Sustainability in the United States
http://www.nap.edu/catalog/12804.html

and expertise proved beneficial in introducing checks and balances in evaluating information from many angles. The committee members divided into teams to work on the various sections of the report on the basis of the members' expertise. The drafts by each team were reviewed by the full committee to ensure that everyone had a chance to comment on and improve and approve each section. I was continually impressed with the members' dedication to a hard-nosed and impartial evaluation of the best science on GE crops. Equally important, they kept open minds in considering new evidence presented by their colleagues and external experts. The result was a model multidisciplinary research process in which each of us learned from the others and improved the report quality.

In closing, I want to express my deep appreciation to the committee members for their tireless work and good humor in completing such a challenging task while working full-time at their regular jobs. Their commitment and professionalism exemplify the best of public science. Each member made significant contributions to the final report. The committee also benefited from the testimony of several experts in the field and from the numerous comments of many conscientious external reviewers. Finally, the quality of the report would not have been attained without excellent support and substantive input by study director Kara Laney, the valuable assistance of Kamweti Mutu, the insightful counsel of Robin Schoen, and the editorial work of the National Research Council.

Acknowledgments

This report has been reviewed in draft form by persons chosen for their diverse perspectives and technical expertise in accordance with procedures approved by the National Research Council Report Review Committee. The purpose of the independent review is to provide candid and critical comments that will assist the institution in making its published report as sound as possible and to ensure that the report meets institutional standards of objectivity, evidence, and responsiveness to the study charge. The review comments and draft manuscript remain confidential to protect the integrity of the deliberative process. We wish to thank the following individuals for their review of the report:

David A. Andow, University of Minnesota, St. Paul
Charles M. Benbrook, The Organic Center, Enterprise, Oregon
Lawrence Busch, Michigan State University, East Lansing
Stephen O. Duke, Agricultural Research Service, U.S. Department of Agriculture, University, Mississippi
Robert T. Fraley, Monsanto Company, St. Louis, Missouri
Dermot J. Hayes, Iowa State University, Ames
Molly Jahn, Research, Education and Economics, U.S. Department of Agriculture, Washington, DC
Nicholas Kalaitzandonakes, University of Missouri, Columbia
Peter M. Kareiva, The Nature Conservancy, Seattle, Washington
Michelle A. Marvier, Santa Clara University, California
Paul D. Mitchell, University of Wisconsin, Madison
George E. Seidel, Colorado State University, Fort Collins
Greg Traxler, The Bill & Melinda Gates Foundation, Seattle, Washington

Although the reviewers listed above have provided many constructive comments and suggestions, they were not asked to endorse the conclusions or recommendations, nor did they see the final draft of the report before its release. The review of the report was overseen by Drs. Alan G. McHughen, University of California, Riverside, and May R. Berenbaum, University of Illinois. Appointed by the National Research Council, they were responsible for making certain that an independent examination of the report was carried out in accordance with institutional procedures and that all review comments were carefully considered. Responsibility for the final content of the report rests with the authoring committee and the institution.

Impact of Genetically Engineered Crops on Farm Sustainability in the United States
http://www.nap.edu/catalog/12804.html

Summary

With the advent of genetic-engineering technology in agriculture, the science of crop improvement has evolved into a new realm. Advances in molecular and cellular biology now allow scientists to introduce desirable traits from other species into crop plants. The ability to transfer genes between species is a leap beyond crop improvement through previous plant-breeding techniques, whereby desired traits could be transferred only between related types of plants. The most commonly introduced genetically engineered (GE) traits allow plants either to produce their own insecticide, so that the yield lost to insect feeding is reduced, or to resist herbicides, so that herbicides can be used to kill a broad spectrum of weeds without harming crops. Those traits have been incorporated into most varieties of soybean, corn, and cotton grown in the United States.

Since their introduction in 1996, the use of (GE crops in the United States has grown rapidly and accounted for over 80 percent of soybean, corn, and cotton acreage in the United States in 2009. Several National Research Council reports have addressed the effects of GE crops on the environment and on human health.[1] However, the effects of agricultural biotechnology at the farm level—that is, from the point of view of the farmer—have received much less attention. To fill that information gap, the National Research Council initiated a study, supported by its own funds, of how GE crops have affected U.S. farmers—their incomes, agronomic practices, production decisions, environmental resources, and personal well-being. This report of the study's findings expands the perspectives from which genetic-engineering technology has been examined previously. It provides the first comprehensive assessment of the effects of GE-crop adoption on farm sustainability in the United States (Box S-1).

Impact of Genetically Engineered Crops on Farm Sustainability in the United States
http://www.nap.edu/catalog/12804.html

BOX S-1
Statement of Task

An NRC committee will study the farm-level impacts of biotechnology, including the economics of adopting genetically engineered crops, changes in producer decision-making and agronomic practices, and farm sustainability.

The study will:

- review and analyze the published literature on the impact of GE crops on the productivity and economics of farms in the United States;
- examine evidence for changes in agronomic practices and inputs, such as pesticide and herbicide use and soil and water management regimes;
- evaluate producer decision-making with regard to the adoption of GE crops.

In a consensus report, the committee will present the findings of its study and identify future applications of plant and animal biotechnology that are likely to affect agricultural producers' decision-making in the future.

In interpreting its task, the committee chose to analyze the effects of GE crops on farm-level sustainability in terms of environmental, economic, and social effects. To capture the broad array of potential effects, the committee interpreted "farm level" as applying to both farmers who do not produce GE crops and those who do because genetic engineering is a technology of extensive scope, and its influences on farming practices have affected both types of farmers. Therefore, to the extent that peer-reviewed literature is available, the report draws conclusions about the environmental, economic, and social effects, both favorable and unfavorable, associated with the use of GE crops for all farmers in the United States over the last 14 years. The report encapsulates what is known about the effects of GE crops on farm sustainability and identifies where more research is needed. A full sustainability assessment of GE crops remains an ongoing task because of information gaps on certain environmental, economic, and social impacts.

Genetic-engineering technology continues to stir controversy around scientific issues and ideological viewpoints. This report addresses just the scientific questions and adopts an "evidentiary" standard of using peer-reviewed literature to form conclusions and recommendations. GE-trait developments may or may not turn out to be a cost-effective approach to addressing challenges confronting agriculture, but review of their impact and an exploration of what is possible are necessary to evaluate their relative efficacy. Therefore, the report details the challenges and opportunities for future GE crops and offers recommendations on how crop-management practices and future research and development efforts can help to realize the full potential offered by genetic engineering.

KEY FINDINGS

The order of findings in this summary reflects the structure of the report and does not connote any conclusions on the part of the committee regarding the relative strength or importance of the findings. In general, the committee finds that genetic-engineering technology has produced substantial net environmental and economic benefits to U.S. farmers compared

Copyright © National Academy of Sciences. All rights reserved.

Impact of Genetically Engineered Crops on Farm Sustainability in the United States
http://www.nap.edu/catalog/12804.html

with non-GE crops in conventional agriculture. However, the benefits have not been universal; some may decline over time, and the potential benefits and risks associated with the future development of the technology are likely to become more numerous as it is applied to a greater variety of crops. The social effects of agricultural biotechnology have largely been unexplored, in part because of an absence of support for research on them.

Environmental Effects

Generally, GE crops have had fewer adverse effects on the environment than non-GE crops produced conventionally. The use of pesticides with toxicity to nontarget organisms or with greater persistence in soil and waterways has typically been lower in GE fields than in non-GE, nonorganic fields. However, farmer practices may be reducing the utility of some GE traits as pest-management tools and increasing the likelihood of a return to more environmentally damaging practices.

Finding 1. When adopting GE herbicide-resistant (HR) crops, farmers mainly substituted the herbicide glyphosate for more toxic herbicides. However, the predominant reliance on glyphosate is now reducing the effectiveness of this weed-management tool.

Glyphosate kills most plants without substantial adverse effects on animals or on soil and water quality, unlike other classes of herbicides. It is also the herbicide to which most HR crops are resistant. After the commercialization of HR crops, farmers replaced many other herbicides with glyphosate applications after crops emerged from the soil (Figures S-1, S-2, and S-3). However, the increased reliance on glyphosate after the widespread adoption of HR crops is reducing its effectiveness in some situations. Glyphosate-resistant weeds have evolved where repeated applications of glyphosate have constituted the only weed-management tactic. Nine weed species in the United States have evolved resistance to glyphosate since the introduction of HR crops in 1996 compared with seven that have evolved resistance to glyphosate worldwide in areas not growing GE crops since the herbicide was commercialized in 1974. Furthermore, communities of weeds less susceptible to glyphosate are becoming established in fields planted with HR crops, particularly fields that are treated only with glyphosate.

Finding 2. The adoption of HR crops complements conservation tillage practices, which reduce the adverse effects of tillage on soil and water quality.

Farmers have traditionally used tillage to control weeds in their fields, interrupting weed lifecycles before they can produce seeds for the following year. However, using tillage to help manage weeds reduces soil quality and increases soil loss from erosion. Tilled soil forms a crust, which reduces the ability of water to infiltrate the surface and leads to runoff that can pollute surface water with sediments and chemicals. Conservation tillage, which leaves at least 30 percent of the previous crop's residue on the field, improves soil quality and water infiltration and reduces erosion because more organic matter is left on the soil surface, thereby decreasing disruption of the soil. The adoption of HR crops allows some farmers to substitute glyphosate application for some tillage operations as a weed-management tactic and thereby benefits soil quality and probably improves water quality, although definitive research on the latter is lacking. However, empirical evidence points to a two-way causal relationship between the adoption of HR crops and conservation tillage. Farmers who use conservation tillage are more likely to adopt HR crop varieties than those who use conventional tillage, and those who adopt HR crop varieties are more likely to practice conservation tillage than those who use non-GE seeds.

Finding 3. Targeting specific plant insect pests with Bt corn and cotton has been successful, and the ability to target specific plant pests in corn and cotton continues to expand. Insecticide use has decreased with the adoption of insect-resistant (IR) crops. The

Copyright © National Academy of Sciences. All rights reserved.

Impact of Genetically Engineered Crops on Farm Sustainability in the United States
http://www.nap.edu/catalog/12804.html

emergence of insect resistance to Bt crops has been low so far and of little economic or agronomic consequence; two pest species have evolved resistance to Bt crops in the United States.

Bt toxins, which are produced by the soil-dwelling bacterium *Bacillus thuringiensis*, are lethal to the larvae of particular species of moths, butterflies, flies, and beetles and are effective only when an insect ingests the toxin. Therefore, crops engineered to produce Bt toxins that target specific pest taxa have had favorable environmental effects when replacing broad-spectrum insecticides that kill most insects (including beneficial insects, such as honey bees or natural enemies that prey on other insects), regardless of their status as plant pests. The amounts of insecticides applied per planted acre of Bt corn and cotton have inverse relationships with the adoption of these crops over time (Figures S-4 and S-5), though a causative relationship has not been established or refuted because other factors influence pesticide-use patterns.

Since their introduction in 1996, the use of IR crops has increased rapidly, and they continue to be effective. Data indicate that the abundance of refuges of non-Bt host plants and recessive inheritance of resistance are two key factors influencing the evolution of resistance. The refuge strategies mandated by the Environmental Protection Agency, and the promotion of such strategies by industry, likely contributed to increasing the use of refuges and to delaying the evolution of resistance to Bt in key pests. Nevertheless, some populations of two generalist pests have evolved resistance to Bt crops in the United States, although the agronomic and economic consequences appear to be minor. With the introduction of multiple Bt toxins in new hybrids or varieties, the probability of resistance to Bt crops is further reduced.

FIGURE S-5 Pounds of insecticide applied per planted acre and percent acres of Bt cotton, respectively.
NOTE: The strong correlation between the rising percentage of Bt cotton acres planted over time and the decrease in insecticide pounds per planted acre suggests but does not confirm causation between these variables.
SOURCES: USDA-NASS, 2001; 2003, 2005, 2007, 2009a, b; Fernandez-Cornejo et al., 2009.

Finding 4. For the three major GE crops, gene flow to wild or weedy relatives has not been a concern to date because compatible relatives of corn and soybean do not exist in the United States and are only local for cotton. For other GE crops, the situation varies according to species. However, gene flow to non-GE crops has been a concern for farmers whose markets depend on an absence of GE traits in their products. The potential risks presented by gene flow may increase as GE traits are introduced into more crops.

Gene flow between many GE crops and wild or weedy relatives is low because GE crops do not have wild or weedy relatives in the United States or because the spatial overlap between a crop and its relatives is not extensive. How that relationship changes will depend on what GE crops are commercialized, whether related species with which they are capable of interbreeding are present, and the consequences of such interbreeding on weed management. Gene flow of approved GE traits into non-GE varieties of the same crops (known as adventitious presence) remains a serious concern for farmers whose market access depends on adhering to strict non-GE presence standards. Resolving this issue will require the establishment of thresholds for the presence of GE material in non-GE crops, including organic crops, that do not impose excessive costs on growers and the marketing system.

Impact of Genetically Engineered Crops on Farm Sustainability in the United States
http://www.nap.edu/catalog/12804.html

Economic Effects

The rapid adoption of GE crops since their commercialization indicates that the benefits to adopting farmers are substantial and generally outweigh additional technology fees for these seeds and other associated costs. The economic benefits and costs associated with GE crops extend beyond farmers who use the technology and will change with continuing adoption in the United States and abroad as new products emerge.

Finding 5. Farmers who have adopted GE crops have experienced lower costs of production and obtained higher yields in many cases because of more cost-effective weed control and reduced losses from insect pests. Many farmers have benefited economically from the adoption of Bt crops by using lower amounts of or less expensive insecticide applications, particularly where insect pest populations were high and difficult to treat before the advent of Bt crops.

The incomes of those who have adopted genetic-engineering technology have benefited from some combination of yield protection and lower costs of production. HR crops have not substantially increased yields, but their use has facilitated more cost-effective weed control, especially on farms where weeds resistant to glyphosate have not yet been identified. Lower yields were sometimes observed when HR crops were introduced, but the herbicide-resistant trait has since been incorporated into higher-yielding cultivars, and technological improvement in inserting the trait has also helped to eliminate the yield difference. In areas that suffer substantial damage from insects that are susceptible to the Bt toxins, IR crops have increased adopters' net incomes because of higher yields and reduced insecticide expenditures. Before the introduction of Bt crops, most farmers accepted yield losses to European corn borer rather than incur the expense and uncertainty of chemical control. Bt traits to address corn rootworm problems have lowered the use of soil-applied and seed-applied insecticides. In areas of high susceptible insect populations, Bt cotton has been found to protect yields with fewer applications of topical insecticides. More effective management of weeds and insects also means that farmers may not have to apply insecticides or till for weeds as often, and this translates into cost savings—lower expenditures for pesticides and less labor and fuel for equipment operations.

Finding 6. Adopters of GE crops experience increased worker safety and greater simplicity and flexibility in farm management, benefitting farmers even though the cost of GE seed is higher than non-GE seed. Newer varieties of GE crops with multiple GE traits appear to reduce production risk for adopters.

Farmers who purchase GE seed pay a technology fee—a means by which seed developers recover research and development costs and earn profits. GE seed is typically more expensive than conventional seed, and the net return in terms of higher yields and lower costs of production for a farmer considering adoption does not always offset the technology fee. However, studies have found that high rates of adoption of GE crops can be attributed in part to the value that farmers place on increased worker safety, perceived greater simplicity and flexibility in farm management (including more off-farm work opportunities), and lower production risk. Farmers and their employees not only face reduced exposure to the harsh chemicals found in some herbicides and insecticides used before the introduction of GE crops but have to spend less time in the field in applying the pesticides. Because glyphosate can be applied over a fairly wide

Copyright © National Academy of Sciences. All rights reserved.

Impact of Genetically Engineered Crops on Farm Sustainability in the United States
http://www.nap.edu/catalog/12804.html

timeframe, farmers who use HR crops have greater flexibility regarding when they treat weeds in their fields. Those benefits must be balanced with the risk that such flexibility in application timing may reduce crop-yield potential attributable to weed interference. Newer GE varieties that have multiple pest-control traits may result in more consistent pest management and thus less yield variability, a characteristic that has substantial value for risk-averse producers. The value of those benefits may provide additional incentives for adoption that counteract the extra cost of GE seed.

Finding 7. The effect GE crops have had on prices received by farmers for soybean, corn, and cotton is not completely understood.

Studies suggest that the adoption of GE crops that confer productivity increases ultimately puts downward pressure on the market prices of the crops. However, early adopters benefit from higher yields or lower production costs than nonadopters even with lower prices. The gains tend to dissipate as the number of adopters increases, holding technological progress constant. Thus, as the first adopters, U.S. farmers have generally benefited economically from the fact that GE crops were developed and commercialized in the United States before they were planted by farmers in other countries. The extent to which GE-crop adoption in developing countries will influence productivity and prices, and therefore U.S. farm incomes, is not completely understood. There is a paucity of studies of the economic effects of genetic-engineering technology in recent years even though adoption has increased globally.

Finding 8. To the extent that economic effects of GE-crop plantings on non-GE producers are understood, the results are mixed. By and large, these effects have not received adequate research.

Decisions made by adopters of GE crops can affect the input prices and options for both farmers who use feed and food products made with GE ingredients and farmers who have chosen not to grow GE seed or do not have the option available. The latter effects on those not using genetic-engineering technology have not been studied extensively. Livestock producers constitute a large percentage of corn and soybean buyers and therefore are major beneficiaries of any downward pressure on crop price due to the adoption of GE crops. Feed costs are nearly half the variable costs for livestock producers, so even moderate price fluctuations can affect their net incomes substantially. Livestock producers also benefit from increased feed safety due to reduced levels of mycotoxins in the grain. However, no quantitative estimation of savings to livestock operators due to the adoption of GE crops and the resulting effect on the profitability of livestock operations has been conducted. Similarly, a number of other economic effects predicted by economic theory have not been documented.

Favorable and unfavorable externalities are not limited to the cost and availability of inputs. To the extent that genetic-engineering technology successfully reduces pest pressure on a field and regionally, farmers of fields in the agricultural landscape planted with non-GE crops may benefit via lower pest-control costs associated with reductions in pest populations. However, nonadopters of genetic-engineering technology also could suffer from the development of weeds and insects that have acquired pesticide resistance in fields within the region planted to GE crops. When that happens, farmers might have to resort to managing the resistant pests with additional, potentially more toxic or more expensive forms of control, even though their practices may not have led to the evolution of resistance.

Copyright © National Academy of Sciences. All rights reserved.

Impact of Genetically Engineered Crops on Farm Sustainability in the United States
http://www.nap.edu/catalog/12804.html

Inadvertent gene flow from GE to non-GE varieties of crops can increase production costs. Gene flow occurs through cross-pollination between GE and non-GE plants from different fields, co-mingling of GE seed with non-GE seed, and germination of seeds left behind (volunteers) after the production year. Similarly, if GE traits cross into weedy relatives, weed-control expenses will be higher for all fields on to which the weeds spread, whether a farmer grows GE crops or not. In addition, gene flow of GE traits into organic crops could jeopardize crop value by rendering outputs unsuitable for high-value foreign or other markets that limit or do not permit GE material in food products; the extent of that effect has not been documented during the last 5 years. On the other hand, the segregation of GE traits from organic production may have benefited organic producers by creating a market in which they can receive a premium for non-GE products.

Social Effects

The use of GE crops, like the adoption of other technologies at the farm level, is a dynamic process that both affects and is affected by the social networks that farmers have with each other, with other actors in the commodity chain, and with the broader community in which farm households reside. However, the social effects of GE-crop adoption have been largely overlooked.

Finding 9. Research on the dissemination of earlier technological development in agriculture suggests that favorable and unfavorable social impacts exist from the dissemination of genetic-engineering technology. However, these impacts have not been identified or analyzed.

Because GE crops have been widely adopted rapidly, it is reasonable to hypothesize that there have been social effects on adopters, nonadopters, and farmers who use GE products, such as livestock producers. For example, based on earlier research on the introduction of new technologies in agriculture, it is possible that certain categories of farmers (such as those with less access to credit, those with fewer social connections to university and private-sector researchers, or those who grow crops for smaller markets) might be less able to access or benefit from GE crops. The introduction of genetic-engineering technology in agriculture could also affect labor dynamics, farm structure, community viability, and farmers' relationships with each other and with information and input suppliers. However, the extent of the social effects of the dissemination of GE crops is unknown because little research has been conducted.

Finding 10: The proprietary terms under which private-sector firms supply GE seeds to the market has not adversely affected the economic welfare of farmers who adopt GE crops. Nevertheless, ongoing research is needed to investigate how market structure may evolve and affect access to non-GE or single-trait seed. Furthermore, there has been little research on how increasing market concentration of seed suppliers affects overall yield benefits, crop genetic diversity, seed prices, and farmers' planting decisions and options.

During the 20th century, the U.S. seed industry evolved from small, family-owned businesses that multiplied seeds developed by university scientists to a market dominated by a handful of large, diversified companies. Universities still contribute to seed development, but seed

Copyright © National Academy of Sciences. All rights reserved.

Impact of Genetically Engineered Crops on Farm Sustainability in the United States
http://www.nap.edu/catalog/12804.html

companies have invested considerably in the research, development, and commercialization of patent-protected GE traits for large seed markets. Thus, corn, soybean, and cotton have received the bulk of private research attention in the last few decades. Large seed companies have not commercialized GE traits in many other crops because their market size has been insufficient to cover necessary research and development costs or because of concerns related to consumer acceptance and gene flow. Public research institutions continue to enhance the genetics of other crops, but full access to state-of-the-art technology (like genetic engineering) that may be beneficial to crops in smaller markets is often not available to public researchers because of patent protections.

Studies conducted in the first few years after the introduction of GE crops found no adverse effects on farmers' economic welfare from the consolidation of market power in the seed industry. However, the current developmental trajectory of GE-seed technology is causing some farmers to express concern that access to seeds without GE traits or to seeds that have only the specific GE traits that are of particular interest to farmers will become increasingly limited. Additional concerns are being raised about the lack of farmer input into and knowledge about which seed traits are being developed. Although the committee was not able to find published peer-reviewed material that documented the degree of U.S. farmers' access to non-GE seed and the quality of the seed, testimony provided to the committee suggests that access to non-GE or nonstacked seed may be restricted for some farmers or that available non-GE or nonstacked seed may be available in older cultivars that do not have the same yield characteristics as newer GE cultivars.

CONCLUSIONS AND RECOMMENDATIONS

Conclusion 1. Weed problems in fields of HR crops will become more common as weeds evolve resistance to glyphosate or weed communities less susceptible to glyphosate become established in areas treated exclusively with that herbicide. Though problems of evolved resistance and weed shifts are not unique to HR crops, their occurrence, which is documented, diminishes the effectiveness of a weed-control practice that has minimal environmental impacts. Weed resistance to glyphosate may cause farmers to return to tillage as a weed-management tool and to the use of potentially more toxic herbicides.

A number of new genetically engineered HR cultivars are currently under development and may provide growers with other weed management options when fully commercialized. However, the sustainability of those new GE cultivars will also be a function of how the traits are managed. If they are managed in the same fashion as the current genetically engineered HR cultivars, the same problems of evolved herbicide resistance and weed shifts may occur. Therefore, farmers of HR crops should incorporate more diverse management practices, such as herbicide rotation, herbicide application sequences, and tank-mixes of more than one herbicide; herbicides with different modes of action, methods of application, and persistence; cultural and mechanical control practices; and equipment-cleaning and harvesting practices that minimize the dispersal of HR weeds.

Recommendation 1. Federal and state government agencies, private-sector technology developers, universities, farmer organizations, and other relevant stakeholders should collaborate to document emerging weed-resistance problems and to develop cost-effective

Copyright © National Academy of Sciences. All rights reserved.

Impact of Genetically Engineered Crops on Farm Sustainability in the United States
http://www.nap.edu/catalog/12804.html

resistance-management programs and practices that preserve effective weed control in HR crops.

Conclusion 2. Given that agriculture is the largest source of surface water pollution, improvements in water quality resulting from the complementary nature of herbicide-resistance technology and conservation tillage may represent the largest single environmental benefit of GE crops. However, the infrastructure to track and analyze these effects is not in place.

Recommendation 2. The U.S. Geological Survey and companion federal and state environmental agencies should receive the financial resources necessary to document the water quality effects related to the adoption of GE crops.

Conclusion 3. The environmental, economic, and social effects on adopters and nonadopters of GE crops has changed over time, particularly because of changes in pest responses to GE crops, the consolidation of the seed industry, and the incorporation of GE traits into most varieties of corn, soybean, and cotton. However, empirical research into the environmental and economic effects of changing market conditions and farmer practices have not kept pace. Furthermore, little work has been conducted regarding the effects on livestock producers and nonadopters and on the social impacts of GE crops. Issues in need of further investigation include the costs and benefits of shifts in pest management for non-GE producers due to the adoption of GE crops, the value of market opportunities afforded to organic farmers by defining their products as non-GE crops, the economic impacts of GE-crop adoption on livestock producers, and the costs to farmers, marketers, and processors of the presence of approved or unapproved GE traits and crops in products intended for restricted markets. As more GE traits are developed and inserted into existing GE crops or into other crops, understanding the impacts on all farmers will become even more important to ensuring that genetic-engineering technology is used in a way that facilitates environment, economic, and social sustainability in U.S. agriculture.

Recommendation 3. Public and private research institutions should allocate sufficient resources to monitor and assess the substantial environmental, economic, and social effects of current and emerging agricultural biotechnology on U.S. farms so that technology developers, policymakers, and farmers can make decisions that ensure genetic engineering is a technology that contributes to sustainable agriculture.

Conclusion 4. Commercialized GE traits are targeted at pest control, and when used properly, they have been effective at reducing pest problems with economic and environmental benefits to farmers. However, genetic engineering could be used in more crops, in novel ways beyond herbicide and insecticide resistance, and for a greater diversity of purposes. With proper management, genetic-engineering technology could help address food insecurity by reducing yield losses through its introduction into other crops and with the development of other yield protection traits like drought tolerance. Crop biotechnology could also address "public goods" issues that will be undersupplied by the market acting alone. Some firms are working on GE traits that address public goods issues. However, industry has insufficient incentive to invest enough in research and development for those purposes when firms cannot collect revenue from innovations that generate net benefits

Copyright © National Academy of Sciences. All rights reserved.

Impact of Genetically Engineered Crops on Farm Sustainability in the United States
http://www.nap.edu/catalog/12804.html

beyond the farm. Therefore, the development of these traits will require greater collaboration between the public and private sectors because the benefits extend beyond farmers to the society in general. The implementation of a targeted and tailored regulatory approach to GE-trait development and commercialization that meets human and environmental safety standards while minimizing unnecessary expenses will aid this agenda (Ervin and Welsh, 2006).

Recommendation 4. Public and private research institutions should be eligible for government support to develop GE crops that can deliver valuable public goods but have insufficient market potential to justify private investment. Intellectual property patented in the course of developing major crops should continue to be made available for such public goods purposes to the extent possible. Furthermore, support should be focused on expanding the purview of genetic-engineering technology in both the private and public sectors to address public goods issues. Examples of GE-crop developments that could deliver such public goods include but are not limited to

- *plants that reduce pollution of off-farm waterways through improved use of nitrogen and phosphorus fertilizers,*
- *plants that fix their own nitrogen and reduce pollution caused by fertilizer application,*
- *plants that improve feedstocks for renewable energy,*
- *plants with reduced water requirements that slow the depletion of regional water resources,*
- *plants with improved nutritional quality that deliver health benefits, and*
- *plants resilient to changing climate conditions.*

Impact of Genetically Engineered Crops on Farm Sustainability in the United States
http://www.nap.edu/catalog/12804.html

1

Introduction

Historians often link the advent of human civilizations with the transition of human societies from food collection primarily through hunting and gathering to food production in established agricultural systems. In a pattern of parallel development, early agricultural systems began emerging in separate regions during the Neolithic period some 10,000 years ago (Mazoyer and Roudart, 2006). Crop-improvement practices based on identification and selection of the best plant varieties appear to date back to the early days of agriculture itself. Similarly, early pastoralists engaged in selective animal breeding. That those practices were recognized as important in the development of ancient human civilizations is apparent in the preservation of instructions on plant breeding in writing, such as in the works of Virgil and Theopastus (Vavilov, 1951). In the broadest sense, the term *biotechnology* can encompass a wide array of procedures used to modify organisms according to human needs. It can be argued that early agriculturalists engaged in a simple form of biotechnology (Kloppenburg, 2004) in developing the intention and the techniques to improve plant varieties and animal species.

Although the process of plant and animal improvement has been continuous throughout the history of agriculture, some historical periods can be identified as singularly transformative. For example, a major agricultural revolution took place in Europe from the 16th to the 19th century. It was characterized in part by the extensive use of plants and animals that had been imported from the Americas (Crosby, 2003) and by animal-drawn cultivation and the use of fertilizers, the latter permitting cereal and feed-grain cultivation without fallowing (Mazoyer and Roudart, 2006). That revolution led to important increases in the food supply and thus ultimately permitted increased population growth.

Another important change in agriculture resulted from the application of an increasingly scientific approach to plant breeding, which developed from the recognition of the cell as the primary unit of all living organisms in the 1830s (Vasil, 2008) and the work of Mendel (Kloppenburg, 2004). With the rediscovery of Mendel's principles of genetics in the early 1900s, progress in plant and animal breeding was accelerated. The continuous growth in crop yields and agricultural productivity during the 20th century owes much to those biological discoveries and to a series of mechanical and chemical innovations driven by agricultural research and development.

One of the more significant innovations in plant breeding during the 20th century was the development of hybrid crops, particularly corn, in the United States. Hybrid corn varieties, which are developed from crossing different inbred lines, out-yield pure inbred lines, though the seeds

Copyright © National Academy of Sciences. All rights reserved.

Impact of Genetically Engineered Crops on Farm Sustainability in the United States
http://www.nap.edu/catalog/12804.html

produced by hybrid varieties yield poorly. When corn hybrids were first developed, they had no discernible yield advantage over the existing open-pollinated corn varieties of the time (Lewontin, 1990). However, seed companies were motivated to develop high-yielding hybrid varieties; saving and planting the seeds of hybrid corn did not produce equal yields, so seed companies had a financial incentive to invest in these varieties. The research and development efforts devoted to hybrid corn produced tremendous yield improvements over the last 70 years. It is unclear if the same amount of investment could have resulted in similar yield increases for open-pollinated varieties; regardless, because of their limited potential for return on financial investment, efforts to develop high-yielding open-pollinated varieties were not made. Modern hybrids, which have been bred to allocate more of their energy to producing grain rather than stover (leaves and stalks), also demonstrate an ability to maintain high grain production in densely planted fields (Liu and Tollenaar, 2009), and they can exhibit increased tolerance to environmental stresses (such as drought, cold, and light availability).

Plant breeders in the 20th century also identified varieties of wheat and rice with shorter stalks and larger seed heads. They were crossed with relatives to create semidwarf wheat and rice varieties, which produced greater yields in part because they responded well to applications of nitrogen and did not lodge despite having heavier seed heads. The development of semidwarf wheat and rice spurred the Green Revolution of the 1960s and 1970s in developing countries (Conway, 1998). Such improvements in plant breeding increased global crop yields in rice and wheat substantially in countries with suitable growing conditions and markets.

Recent developments in scientific plant breeding have resulted from discoveries in molecular and cellular biology in the second half of the 20th century that laid the foundation for the development of genetically engineered plants. In 1973, the American biochemists Stanley Cohen and Herbert Boyer were among the first scientists to transfer a gene between unrelated organisms successfully. They cut DNA from an organism into fragments, rejoined a subset of those fragments, and added the rejoined subset to bacteria to reproduce. The replicated DNA fragments were then spliced into the genome of a cell from a different species, and this created a transgenic organism, that is, an organism with genes from more than one species. Before the advent of genetic engineering, plant tissue-culture technology expanded the array of available genetic material beyond what was possible with traditional plant breeding by manipulating the fertilization and embryos of crosses between more distantly related species (Brown and Thorpe, 1995). DNA-recombination techniques opened the possibility of augmenting plant genomes with desirable traits from other species and thus took the science of plant breeding to a stage in which improvement is constrained not by the limits of genetic traits within a particular species but rather by the limits of discovery of genes and their transfer from one species to another to confer desired characteristics on a particular crop.

COMMITTEE CHARGE AND APPROACH

The committee's study was the first comprehensive assessment of the impacts of the use of genetically engineered (GE) crops on farm sustainability in the United States. The most up-to-date, available scientific evidence from all regions was used to assemble a national picture that would reflect important variations among regions. Box 1-1 presents the formal statement of task assigned to the committee.

Copyright © National Academy of Sciences. All rights reserved.

Impact of Genetically Engineered Crops on Farm Sustainability in the United States
http://www.nap.edu/catalog/12804.html

BOX 1-1
Statement of Task Summary

An NRC committee will study the farm-level impacts of biotechnology, including the economics of adopting genetically engineered crops, changes in producer decision-making and agronomic practices, and farm sustainability.
The study will:

- review and analyze the published literature on the impact of GE crops on the productivity and economics of farms in the United States;
- examine evidence for changes in agronomic practices and inputs, such as pesticide and herbicide use and soil and water management regimes;
- evaluate producer decision-making with regard to the adoption of GE crops.

In a consensus report, the committee will present the findings of its study and identify future applications of plant and animal biotechnology that are likely to affect agricultural producers' decision-making in the future.

In conducting its task, the committee interpreted the term *sustainability* to apply to the environmental, economic, and social impacts of genetic-engineering technology at the farm level. That interpretation is in line with the federal government's definition of *sustainable agriculture*, which is "an integrated system of plant and animal production practices having a site-specific application that will over the long-term:

1. Satisfy human food and fiber needs.
2. Enhance environmental quality and the natural resource base upon which the agriculture economy depends.
3. Make the most efficient use of nonrenewable resources and on-farm resources and integrate, where appropriate, natural biological cycles and controls.
4. Sustain the economic viability of farm operations.
5. Enhance the quality of life for farmers and society as a whole." (U.S.C. Title 7 § 3103, 2009)

This definition conceives of sustainable farming systems that address salient environmental, economic, and social aspects and their interrelationships.

The report explores how GE crops contribute to achieving several of the conditions enumerated above. Farmers must continually adapt in response to environmental, economic, and social conditions by learning and adopting new practices. Adopting GE crops is one option some farmers make in adapting to changing conditions.

Though the three aspects of sustainability often interact with one another, the report organizes each in a separate chapter to facilitate access to the information. The chapter on production economics follows the environmental chapter because many of the economic gains and losses that farmers experience with GE crops result from changes occurring within the farm environment from GE-crop adoption. The chapter on social effects is brief because of a lack of published literature on the subject. Nevertheless, the committee deemed this aspect important to include for two reasons. First, social impacts are widely considered to be a necessary element in the definition of sustainability as noted earlier. Second, with the sizable shift in cropping

Copyright © National Academy of Sciences. All rights reserved.

Impact of Genetically Engineered Crops on Farm Sustainability in the United States
http://www.nap.edu/catalog/12804.html

practices and systems to genetic-engineering technology (and the prospect of more GE crops to come), the marked expansion of private-sector control of intellectual property related to seeds, and a growing concentration of private-sector seed companies, it is the committee's estimation that GE crops have had and will continue to have social repercussions at the farm and community levels. The committee agreed that the report should draw attention to need for research in this area. In this vein, the report highlights issues on which insufficient information is available for drawing firm conclusions. The final chapter summarizes the main findings of the assessment and discusses the potential for future GE crops to address emergent food, energy, and environmental challenges.

The committee interpreted the statement of task to be retrospective in nature, examining the sustainability effects of GE crops on U.S. farms since their commercialization. For that reason the committee focused in large part on the experiences of soybean, corn, and cotton producers because GE varieties of those crops have been widely adopted by farmers, those crops are planted on almost half of U.S. cropland, and most research on genetic-engineering technology in agriculture has targeted those three crops. However, the committee recognized that most farmers have been affected by the widespread adoption of GE crops, even if they have chosen not to adopt them or have not had the option to adopt them. The report examined the effects of genetic-engineering technology on those producers as well. Because the study was retrospective and focused on the experience of U.S. farmers, the adoption of GE crops in other countries entered into the analysis only if U.S. farmers have experienced effects of such adoption, and the committee restricted its speculations on the future applications and implications of genetic-engineering technology to the final chapter.

The National Research Council supported the study to expand its contributions to the understanding of agricultural biotechnology. Committee members were chosen because of their academic research and experience on the topic. Experts were selected from the fields of weed science, agricultural economics, ecology, rural sociology, environmental economics, entomology, and crop science. To prepare its report, the committee reviewed previous studies and scientific literature on farmers' adoption of genetic-engineering technology, the impacts of such technology on non-GE farmers, and environmental impacts of GE crops. It also examined historical and current statistical data on the adoption of GE crops in the United States. The committee acknowledges that GE crops in U.S. agriculture continue to stir controversy around scientific issues and ideological viewpoints. With this in mind, the committee kept its focus on scientific questions and adopted an evidentiary standard of using peer-reviewed literature upon which to base its conclusions and recommendations. It refrained from analyzing ideological positions, either in support of or against the technology, in order to remain as impartial as possible.

STUDY FRAMEWORK

An analysis of the farm-level sustainability impacts of GE crops requires a framework that integrates all salient factors that motivate their use. We use the principal theories applied to agricultural technology adoption to construct a framework that identifies the qualitative factors that affect U.S. farmers' decisions to use genetic-engineering technology. With an understanding of the adoption and use processes, we then outline an evaluation framework that spans environmental, economic, and social dimensions as noted above.

Copyright © National Academy of Sciences. All rights reserved.

Impact of Genetically Engineered Crops on Farm Sustainability in the United States
http://www.nap.edu/catalog/12804.html

Two main theories help in building a framework for analyzing a farmer's decision to adopt a particular GE crop. First, "diffusion" theory seeks to explain people's propensities to adopt innovations as communicated through particular channels and within particular social systems (Rogers, 2003). Second, "threshold" theory delves deeper into the economic influences on farmer decisions by considering the heterogeneity in farm sizes, in agronomic conditions (climate, soil, water availability, and pest pressure), in forms of human capital that influence learning by doing and using, and in operator values (Feder et al., 1985; Foster and Rosenzweig, 1995; Fischer et al., 1996; Marra et al., 2001; Sunding and Zilberman, 2001). Incorporating those factors allows a better qualitative understanding of the dynamics of the spread of the technologies across the landscape and of their impacts. Together, the diffusion and threshold theories point to five sets of factors that exert influences on a farmer's decision to use genetic-engineering technology:

1. Productivity (yield) effects.
2. Market structure and price effects.
3. Production input effects.
4. Human capital and personal values.
5. Information and social networks.

Productivity Effects

Genetic-engineering technology can directly and indirectly affect crop yields, either positively or negatively, as explained in Chapter 3 in more detail. The direct route stems from the effect on a cultivar after the insertion of one or more traits through genetic engineering. The indirect effect is related to the ability of a GE crop to decrease pest damage (Lichtenberg and Zilberman, 1986a). Just as natural-resource conditions, including pest pressures, vary among fields, farms, and regions, so will the indirect effects on yield and the rate of adoption of GE crops. The technologies tend to be adopted in locations whose agrophysical conditions—such as land quality, climate, and vulnerability to pests—lead to productivity gains (Marra et al., 2003; Zilberman et al., 2003). In addition to effects on quantity, genetic engineering may affect the quality of a crop, which influences its value.

Market-Structure and Price Effects

Farmers who are deciding whether to grow GE crops must consider their access to domestic and foreign markets. Differential access may stem from country regulations on the entry of GE crops into their markets or from lack of market infrastructure (for example, segmentation of GE and non-GE product chains). Farmers who choose to grow GE crops may experience higher or lower prices than if they grow non-GE crops. For example, if enough farmers adopt a GE crop and yields increase substantially because of direct or indirect effects, crop prices may be forced down by increased supplies, other characteristics remaining the same. Consumers of GE crops may benefit from the lower prices, though some consumers may be willing to pay more for non-GE crops for personal reasons, and this may create a premium for non-GE crops. Under other circumstances, global demand increases may absorb most or all of the increase in supply, in which case prices would not decline (see Chapter 3).

Impact of Genetically Engineered Crops on Farm Sustainability in the United States
http://www.nap.edu/catalog/12804.html

Market access and price effects alter farmers' revenues and profitability and thus their disposition to adopt GE crops. The organizational hierarchy of the commodity chain and the nature of farm policies can create structural conditions that act as impediments to or inducers of adoption of a technology (Mouzelis, 1976; Bonanno, 1991; Friedland, 2002; Kloppenburg, 2004). For example, the development of crops with more than one GE trait may create a structural condition for some farmers whereby they may have to pay for traits that they do not need in order to gain access to the traits that they desire (see Chapter 4).

Production-Input Effects

The adoption and use of GE crops can precipitate changes in the types, amounts, and timing of pesticide use and in the types, frequency, and timing of tillage operations; both can affect machinery requirements. Those changes are referred to as substitution effects; an example is the replacement of some pesticides with a GE crop (Lichtenberg and Zilberman, 1986b). A shift in labor requirements is another potentially important production-input effect (Fernandez-Cornejo and Just, 2007). The availability and quality of GE and non-GE seeds may affect a farmer's decision to use either. For example, the commercial success of the application of GE soybean and corn in the 1990s was accompanied by increased consolidation and vertical integration in the seed industry (Fernandez-Cornejo, 2004). Indeed, by 1997, two firms captured 56 percent of the U.S. corn-seed market, and this share has increased even more in recent years (see "Interaction of the Structure of the Seed Industry and Farmer Decisions" in Chapter 4) (Boyd, 2003). The changes in genetic-engineering technology and seed-industry structure may help to explain anecdotal statements about the reduced availability of some non-GE seed varieties in recent years (Hill, personal communication). However, the committee is not aware of any published research confirming the link between seed-industry structure and seed availability.

Human Capital and Personal Values

Every major study of agricultural-technology adoption has found that at least some aspects of human capital play a role in the process. Frequently, the more education or experience a farmer has, the more likely he or she is to adopt a new technology. Educational achievement and years of experience in farming are thought to be proxies for a potential adopter's ability to learn quickly how to adapt the new technology to the farm operation and to use it to its greatest advantage. As noted above, the process of learning and adaptation is critical to the development of more sustainable farming systems. Farmers also may hold personal values that affect their decisions to use GE crops beyond the financial effects that may flow from productivity, value, and production input. A person's values define preferences and have been shown to influence decisions on genetic-engineering development and applications (Piggott and Marra, 2008; Buccola et al., 2009). Examples of personal values include aversion to general and specific risks, preference for environmental stewardship, and ideological positions about agricultural systems. An example of the influence of risk aversion is some farmers' preference for GE crops if they reduce the variability of yields because they improve control of pests. Such risk reduction can motivate adoption of GE varieties by risk-averse farmers and may also lead to an increase in use of complementary practices, such as no-till planting (Alston et al., 2002; Piggott and Marra, 2007).

Impact of Genetically Engineered Crops on Farm Sustainability in the United States
http://www.nap.edu/catalog/12804.html

Information and Social Networks

Decisions of whether to adopt GE crops hinge on the quantity and quality of farmers' information about the characteristics and performance of the technologies. Information from formal sources, such as the agricultural media, on GE traits' technical aspects, economic implications, and prospects can shape farmers' views. Informal sources probably also speed or slow the adoption of GE crops (Wolf et al., 2001; Just et al., 2002). Social networks can have favorable or unfavorable effects not only on the adoption of technologies but also on the sharing of knowledge about GE and non-GE crops and on the development of new technologies and management strategies (Arce and Marsden, 1993; Busch and Juska, 1997; Hubbell et al., 2000). They can also mitigate potentially negative social impacts of GE-crop adoption. Recognition of the importance of social networks has been enhanced by studies of the processes associated with the use of alternative agricultural practices (Storstad and Bjørkhaug, 2003; Morgan et al., 2006). Insights derived from the study of social networks also may have great relevance to the development and dispersion of genetic-engineering technology.

Figure 1-1 portrays the influences of the different factors on GE-crop adoption decisions and the resultant impacts on environmental, economic, and social conditions. This conceptual model shows that factors under the control of the farmer, such as human capital, and outside their control, such as market prices, come together to influence the GE-crop adoption decision process, depicted by the central box in the figure. It also shows how the factors, up to this point presented as having distinct effects, may influence each other. Examples of potential interactions include the effects of information and social networks on personal values and production inputs and the effect of production-input substitution on productivity. Other impacts of decisions related to GE crops (for example, the environmental effect of pest population changes) may feed back to some influencing factors, such as production inputs. As discussed later in this chapter, empirical studies have found that factors in each of the categories have influenced GE-crop adoption patterns. However, it is not possible to rank the magnitude of influences in a general sense. Rather, we expect that the different factors will vary in influence across types of farms, geographic regions, and specific crop applications. For example, if a certain pest infestation is severe in a region, then the productivity gains from adopting a GE crop may far outweigh the influence of personal values of the adopter. In another case where pest pressures are moderate compared to other regions, functioning information and social networks may influence the speed and rate of adoption of genetic-engineering technology.

GENETICALLY ENGINEERED TRAITS IN CROPS

For agricultural crops, the first generation of genetic engineering has targeted traits that increase the efficacy of pest control. Since the introduction of GE crops, new seeds have provided pest control in one or more of three forms:

- Herbicide resistance.
- Insect resistance.
- Virus resistance.

The terms *resistance* and *tolerance* are often used interchangeably in the literature. *Tolerance* implies that a crop is affected by a pesticide but has a means to naturally survive the potential damage sustained. This report uses the more precise term *resistance* because altered genes either allow a plant to generate its own insecticide or prevent herbicides from damaging the plant (Roy, 2004).

GE herbicide-resistant (HR) crops contain transgenes that enable survival of exposure to particular herbicides. In the United States, crops are available with GE resistance to glufosinate and glyphosate, but most HR crops grown in the United States are resistant only to glyphosate, a nonselective chemical that has a low impact on the environment. Glyphosate inhibits the enzyme 5-enolpyruvyl-shikimate-3-phosphate synthase (EPSPS), which is part of the shikimate pathway in plants. The shikimate pathway helps produce aromatic amino acids; it is speculated that glyphosate kills a plant either by reducing aromatic amino acid production and adversely affecting protein synthesis or by increasing carbon flow to the glyphosate-inhibited shikimate pathway, causing carbon shortages in other pathways (Duke and Powles, 2008). The susceptibility of EPSPS to the chemical and the relative ease with which it is taken up by a plant make glyphosate an extremely effective herbicide. It presents a low threat of toxicity to animals in general because they do not have a shikimate pathway for protein synthesis (Cerdeira and Duke, 2006). Glyphosate also has low soil and water contamination potential because it binds readily to soil particles and has a relatively short half-life in soil (Duke and Powles, 2008).

Insect-resistant (IR) plants grown in the United States have genetic material from the soil-dwelling bacterium *Bacillus thuringiensis* (Bt) incorporated into their genome that provides protection against particular insects. Bt produces a family of endotoxins, some of which are lethal to particular species of moths, flies, and beetles. An insect's digestive tract activates the ingested toxin, which binds to receptors in the midgut; this leads to the formation of pores, cell lysis, and death. Individual Bt toxins have a narrow taxonomic range of action because their binding to midgut receptors is specific; the toxicity of Bt crops to vertebrates and many nontarget arthropods and other invertebrates in U.S. agricultural ecosystems is effectively absent. The first Bt crops that were introduced produced only one kind of Bt toxin. More recent varieties produce two or more Bt toxins; this enhances control of some key pests, allows control of a wider array of insects, and can contribute to delaying the evolution of resistance in target pests while reducing refuge size.

Gene sequences of pathogenic viruses have been inserted into crops to confer protection against related viruses—to make them virus-resistant (VR). Most transgenic VR plants resist viruses through gene silencing, which occurs when transcription of a transgene induces degradation of the genome of an invading virus. Potential unwanted environmental effects of VR crops include exchanges between viral pathogens and transgene products that could increase the virulence of viral pathogens, food allergenicity, and transgene movement through pollen, which

Copyright © National Academy of Sciences. All rights reserved.

Impact of Genetically Engineered Crops on Farm Sustainability in the United States
http://www.nap.edu/catalog/12804.html

can create VR weeds. Adverse environmental effects of commercialized VR plants have not been found (Fuchs and Gonsalves, 2008).

HR and IR crops, having been the principal targets of most efforts to develop GE crop varieties, account for the bulk of acres planted in GE crops in the United States. Consequently, this report focuses on farmers' experiences with these types of GE crops. HR varieties of soybean, corn, cotton, canola, and sugar beets and IR varieties of corn and cotton were grown commercially in 2009. Herbicide resistance and insecticide resistance are not mutually exclusive; a number of crop varieties that contain both types of resistance have been developed. GE corn and cotton may also express more than one type of Bt trait. Seeds with multiple GE characteristics are referred to as "stacked cultivars".

Herbicide resistance and insect resistance were commercialized because of the relative simplicity in gene transfer and the utility for farmers. The expression of those traits requires manipulation of the genetic code at only one site, a relatively straightforward process compared with such traits as drought tolerance, which involve the action of many genes. Furthermore, because corn, soybean, and cotton production accounts for the bulk of pesticide expenditures in the United States (Figure 1-2), herbicide resistance and insect resistance provided important market opportunities. Those GE crops fit easily into the traditional pest-management approach of mainstream U.S. agriculture: reliance on the continual emergence of technological advances to address pest problems, particularly after development of resistance to an earlier innovation. Therefore, the familiarity of the chemicals involved, the size of the market for the seeds of and pesticides for GE crops, and the ease of manipulation of the genes for the traits contributed to HR and IR seeds' being the first GE products to emerge in large-scale agriculture.

ADOPTION AND DISTRIBUTION OF GENETICALLY ENGINEERED CROPS

Crops with GE traits aimed primarily at pest control have been widely adopted in the United States by farmers of corn, cotton, soybean, canola, and sugar beet and have caused substantial changes in farm-management practices and inputs, such as changes in pesticide use. In 2008, almost half of U.S. cropland was planted with GE seed, even though the technology had been available to farmers only since the middle 1990s and only a few crops have experienced commercial success (USDA-NASS, 2009b). U.S. farmers planted 158 million acres of GE crops in 2009—nearly half of all the GE-crop acres in the world (James, 2009). Rates of adoption have been influenced by the type of crop, the trait expressed in the crop, and the pest pressures occurring on the farm. For example, adoption of cultivars with Bt traits has been most rapid and widespread in areas prone to insect infestations that can be curbed by the endotoxins present in GE crops.

The committee chose to concentrate its study on the farm-level effects of GE soybean, corn, and cotton because these crops are grown on nearly half of U.S. cropland (USDA-NASS, 2009b) and because over 80 percent of these crops are genetically engineered (Figure 1-3). The high level of adoption and the large-scale planting of those crops mean they have a substantially greater cumulative impact on farm-level sustainability compared to other GE crops, which may be widely adopted but are planted on few acres or may be adopted by only a small percentage of growers. Additionally, there are GE crops that have been commercialized but were not sold in 2009 for business or legal reasons. Those crops are discussed in the report, but they are not its primary focus (Box 1-2).

BOX 1-2
Other Commercialized Genetically Engineered Crops

GE varieties of crops other than corn, soybean, and cotton have been developed and produced in the United States. However, some are planted on relatively small acreage and often in specific locations (for example, papaya in Hawaii), and others are no longer available commercially (for example, GE potato). These are highlighted below, but they are not the focus of the report because those in production account for only a small percentage of U.S. agriculture in terms of land and revenue, and those not commercially available were only sold for a short time. The latter demonstrates commercial viability can depend on the willingness of farmers to adopt the product and the willingness of processors and consumers to accept it.

Minor Crops Widely Planted in Genetically Engineered Varieties by U.S. Farmers

Canola. HR canola was commercialized in the middle 1990s. It is widely grown in Canada but is a minor crop in the United States. However, since 2005, HR canola has accounted for almost half the acres planted in North Dakota, which makes up more than 90 percent of U.S. canola (USDA-NASS, 2009b). GE glyphosate-resistant and glufosinate-resistant canola cultivars accounted for 65 percent and 32 percent of the canola acres planted in the United States in 2006 (Howatt, personal communication).

Sugar beet. HR sugar beet was approved for commercial use in 1998, but concerns about marketplace acceptance precluded the commercial release of the transgenic cultivars (Duke, 2005). Transgenic glyphosate-resistant sugar beet was commercially grown in 2009 and reportedly was widely adopted (Stachler, personal communication). Economic studies suggested that the transgenic cultivars would improve profitability compared with conventional cultivars (Kniss et al., 2004; Gianessi, 2005). The potential for hybridization between HR sugar beet and weedy beet that occurs in the fields and nearby has led to concerns about future weed problems in Europe (where GE sugar beet is not commercialized), but hybridization is a minor problem in the United States (Stewart et al., 2003; Andersen et al., 2005). Indeed, spatial overlap between sugar beet production and weedy beet is limited to a few California counties (Calflora, 2009).

Papaya. Papaya is a small tree grown throughout the tropics for its fruit. Researchers at Cornell University and the University of Hawaii developed VR papaya by transforming the coat protein gene of the papaya ringspot virus to confer resistance against this devastating pathogen (Fuchs and Gonsalves, 2008). Transgenic papaya was first planted in 1998 in Hawaii, where it has contributed to sustaining the culture of this fruit. About 80 percent of papaya production in Hawaii is from transgenic plants (Fuchs and Gonsalves, 2008; Stokstad, 2008).

Minor Crops with Genetically Engineered Varieties Not Widely Adopted by U.S. Farmers

Squash. Transgenic VR squash lines were transformed with the coat protein gene of the watermelon mosaic virus, zucchini yellow mosaic virus, and cucumber mosaic virus (Fuchs and Gonsalves, 2008). The ZW-20 squash line is resistant to the watermelon and zucchini yellow mosaic virus, and CZW-3 resists the watermelon, zucchini yellow, and cucumber mosaic viruses. ZW-20 and CZW-3 were deregulated in 1994 and 1996, respectively, and commercially grown soon thereafter. Those lines were also crossed to other squash cultivars to produce new lines of VR squash. Transgenic squash accounted for about 12 percent of total U.S. squash production in 2005. Most acreage of transgenic squash is in New Jersey, Florida, Georgia, South Carolina, and Tennessee (Fuchs and Gonsalves, 2008).

Sweet corn. Sweet corn was planted on 617,350 acres in 2008 (USDA-NASS, 2009a). A little less than half, or 246,600 acres, were planted for the fresh market; sweet corn from the remaining acres was for processing. Of the fresh market acres, about 20,000 were planted to GE varieties with high Bt protection against corn earworm and European corn borer and moderate protection against fall armyworm (see Table 1-2; Lynch et al., 1999; Mason, personal communication). Bt sweet corn varieties are typically marketed directly to the consumer;

Copyright © National Academy of Sciences. All rights reserved.

Impact of Genetically Engineered Crops on Farm Sustainability in the United States
http://www.nap.edu/catalog/12804.html

processors have been reluctant to purchase sweet corn with GE traits because possible consumer aversion to GE crops could have negatively affected purchases of other products under their brand names (Bradford and Alston, 2004). Commercialized Bt sweet corn also has been engineered to resist glufosinate; however, glufosinate is not registered for use with Bt sweet corn because of concerns about consumer acceptance (Fennimore and Doohan, 2008).

Commercialized Genetically Engineered Crops Not Presently Available

Tomato.[a] The Flavr Savr tomato, developed by the company Calgene, was commercialized in 1994. The genetics of the tomato were engineered to slow the softening of the vegetable during ripening. The trait was developed in a tomato variety usually used for processing. However, a public opposition campaign against GE tomatoes caused some large processors to refuse to purchase the Flavr Savr variety for their products. In response, Calgene tried to sell the variety as a fresh-market tomato, but the vegetable bruised easily. That characteristic caused problems in production, transportation, and distribution. Furthermore, the Flavr Savr did not taste better than its cheaper competitors. Production of the variety was discontinued. Another GE tomato, developed for processing by the company Zeneca, was grown in California in the middle 1990s. Those tomatoes had a similar GE trait for delayed ripening and were processed into tomato paste for sale in the United Kingdom. However, consumer opposition to GE products caused Zeneca to discontinue the sale of the tomato paste in 1999.

Potato. A Bt potato resistant to the Colorado potato beetle was commercialized in 1995. Three years later, the technology developer, Monsanto, introduced a stacked variety that combined the Bt trait with virus resistance. Researchers found the Bt trait protected the potato from insect damage at all stages of the beetle's life (Perlak et al., 1993), and Monsanto scientists noted a large potential for reduction in the use of pesticides to treat insect and virus problems (Kaniewski and Thomas, 2004). However, Monsanto discontinued the sale of GE potatoes in 2001. The cultivars failed to capture more than 2–3 percent of the market for two reasons. First, a new insecticide that controlled the Colorado potato beetle and other pests came on the market at around the same time as GE potatoes; most farmers chose the insecticide over the GE trait (Nesbitt, 2005). Second, potato processors experienced a public-pressure campaign against the use of GE potatoes (Kilman, 2000; Kaniewski and Thomas, 2004). As food companies pledged to use non-GE potatoes in their products, farmers responded to processors' contracts for conventional varieties. Thus, although GE potatoes were technologically successful, they did not survive in the marketplace.

Alfalfa. Alfalfa is an important crop in the United States and is widely cultivated over a broad geographic range (USDA-NASS, 2009b). GE glyphosate-resistant alfalfa was commercialized in 2005, and about 198,000 acres was planted in 2006 (Weise, 2007). However, legal action over concerns about the risk of introgression of the transgene into nontransgenic alfalfa and the inability to mitigate this risk resulted in the termination of further seed sales and planting of glyphosate-resistant alfalfa (Charles, 2007) until USDA completed an environmental impact statement. That statement was released for public comment in December 2009.

Corn

The first GE variety of corn, which was commercialized in 1996, expressed a Bt toxin that targeted European corn borer, southwestern corn borer, and several other pests (see Table 1-2). GE corn with resistance to glyphosate was released in 1997, followed by a variety with resistance to glufosinate in the next year (Dill, 2005). An IR variety with a different Bt toxin to combat corn rootworm (*Diabrotica* spp.) was introduced in 2003.

Adoption of HR corn proved slower than that of soybean: only 8 percent of the acreage was planted to HR corn in 2001 (Table 1-3, Figure 1-5). The low adoption rate of HR corn in 2001 was consistent among all U.S. regions. The narrow window of time for glyphosate application to be effective against early-season weed pressure in corn may have deterred farmer adoption (Tharp and Kells, 1999; Johnson et al., 2000; Gower et al., 2003; Knežević et al., 2003; Dalley et al., 2004; Cox et al., 2005). Growers probably relied on traditional strategies for pre-emergence herbicide weed control rather than risk missing the glyphosate application window and ending up with weedier fields and reduced corn yields. Furthermore, lack of market access for HR corn to the European Union provided an added deterrent against early adoption of HR corn in the late 1990s and early 2000s.

Variable insect pressure also delayed the adoption of IR corn, and this resulted in planting of only 19 percent of the acreage to IR corn in 2001 (Table 1-3, Figure 1-5). European corn borer is a key pest in the western Corn Belt region (Pilcher et al., 2002; Hyde et al., 2003; Mungai et al., 2005) but causes only a sporadic problem in the eastern Corn Belt region (Baute et al., 2002; Ma and Subedi, 2005; Cox et al., 2009). Consequently, IR corn acreage ranged from 23 to 30 percent in Iowa, Kansas, Minnesota, Missouri, Nebraska, and South Dakota but from 6 to 11 percent in

Impact of Genetically Engineered Crops on Farm Sustainability in the United States
http://www.nap.edu/catalog/12804.html

Indiana, Michigan, Ohio, and Wisconsin in 2001 (Table 1-3). Farmers in regions without consistent corn borer infestations probably chose not to adopt IR corn.

TABLE 1-2 Insect Pests of Corn Targeted by Bt Varieties

Common Name	Latin Binomial
Primary Pest	
European corn borer	*Ostrinia nubilalis*
Southwestern corn borer	*Diatraea grandiosella*
Western corn rootworm	*Diabrotica virgifera virgifera*
Northern corn rootworm	*Diabrotica barberi*
Corn earworm	*Helicoverpa zea*
Fall armyworm	*Spodoptera frugiperda*
Black cutworm	*Agristis ipsilon*
Secondary Pest	
Mexican corn rootworm	*Diabrotica virvifera zeae*
Southern cornstalk borer	*Diatraea crambidoides*
Stalk borer	*Papaipema nebris*
Lesser corn stark borer	*Elasmopalpus lignosellus*
Sugarcane borer	*Diatraea saccharalis*
Western bean cutworm	*Richia albicosta*

NOTE: This pest categorization does not describe specific pest pressures in different states or regions. For example, the sugarcane borer is a primary pest of corn in Louisiana.

Impact of Genetically Engineered Crops on Farm Sustainability in the United States
http://www.nap.edu/catalog/12804.html

In 2002, stacked hybrids were introduced, and this led to a further increase in acreage of GE corn. The increasing rate of adoption of stacked hybrids—2 percent in 2002 and 46 percent in 2009, with all major corn states above 30 percent (Table 1-3)—reflects the popularity of these traits and the lack of nonstacked GE traits in the seed marketplace. By 2009, 85 percent of U.S. corn acreage was planted with some type of GE seed; more than half these acres were in stacked varieties (Figure 1-5). In addition, by 2009, all major corn-growing states had GE acreage exceeding 70 percent except Ohio (67 percent); thus, adoption of IR corn is no longer region-specific (Table 1-3). Farmers' preference for multiple traits explains in part the lower rates of adoption of HR-only and IR-only varieties of corn compared with the rates of adoption of HR soybean (Figure 1-4).

Corn rootworm is a destructive and consistent pest in all regions of the United States that have continuous corn fields (and in some regions where corn is planted in fields after soybean). Bt corn for control of corn rootworm, especially western corn rootworm, has contributed to increased acreage of GE corn since its introduction in 2003 because growers preferred IR corn to the use of soil-applied insecticides or the use of insecticide and fungicide applied to seed at 1.25 mg of active ingredient[1] per seed. Bt corn hybrid seed for corn rootworm control is sold with only 0.25 mg of active ingredient per seed of insecticide and fungicide for control of secondary pests[2] and soil-borne pathogens. Growers can choose to add this feature for an additional cost to non-GE or HR corn hybrid seed. Thus, GE corn with the Bt trait for corn rootworm control and lower levels of seed-applied insecticide and fungicide substituted for the control tactics in continuous corn in the 1980s and 1990s of soil-applied insecticides for rootworm control and seed-applied products with higher toxicity[3] for secondary pest control, which growers had to manually apply to the seed. In-plant resistance for rootworm control with low levels of insecticide already applied to the seed by professional seed handlers for control of secondary corn pests is safer for the farmers who plant the crops and for the environment.

[1]The *active ingredient* is the material in the pesticide that is biologically active. The active ingredient is typically mixed with other materials to improve the pesticide's handling, storage, and application properties.

[2]Examples include click beetles (*Alaus oculatus*), scarab beetles (*Scarabaeus sacer*), seed corn maggot (*Delia platura),* and wireworms *(Melanotus* spp).

[3]Examples include O,O-diethyl 0-2-isopropyl-6-methyl(pyrimidine-4-yl) phosphorothioate (commonly marketed as Diazinon); N-trichtoromethylthio~cyclohexene-1,2-dicarboximide (Captan); and gamma-hexachlorocyclohexane (Lindane).

Cotton

Commercialized in 1996, IR cotton rapidly gained substantial market share because of its control of tobacco budworm, pink bollworm, and cotton bollworm (Table 1-5). GE glyphosate-resistant cotton, introduced in 1997, also proved popular with farmers because weed management has traditionally been more challenging in cotton than in many other field crops (Jost et al., 2008). The stacked Bt-glyphosate-resistant variety was introduced in 1997. By 2001, GE cotton had captured 69 percent of the acreage: 32 percent HR-only, 13 percent IR-only, and 24 percent stacked varieties (Table 1-4, Figure 1-6). Farmers in the southeast Cotton Belt adopted GE varieties more rapidly (78–91 percent in Arkansas, Georgia, Louisiana, Mississippi, and North Carolina) compared with those in Texas (49 percent) and California (40 percent), reflecting the lower insect pressure in the latter two states, especially California (only 11 percent IR and 2 percent stacked varieties).

TABLE 1-4 Insect Pests of Cotton Targeted by Bt Varieties

Common Name	Latin Name
Primary Pest	
Cotton bollworm	*Helicoverpa zea*
Tobacco budworm	*Heliothis virescens*
Pink bollworm	*Pectinophora gosypiella*
Secondary Pest	
Salt marsh caterpillar	*Estigmene acrea*
Cotton leaf perforator	*Bucculatrix thurberiella*
Soybean looper	*Pseudoplusia includens*
Beet armyworm	*Spodoptera exigua*
Fall armyworm	*Spodoptera frugiperda*
Yellowstriped armyworm	*Spodoptera ornithogalli*
European corn borer	*Ostrinia nubilalis*

NOTE: This pest categorization does not describe specific pest pressures in different states or regions. For example, the cotton bollworm and tobacco budworm are minor pests of cotton in Arizona.

A new HR variety introduced in 2006 provided growers with a wider window for glyphosate application and the possibility of using higher glyphosate dosages (Mills et al., 2008). At around the same time, IR cotton with two Bt endotoxins was commercialized and offered improved control of cotton bollworm, increased protection against such secondary pests as beet armyworm and soybean looper, and advantages in resistance management (Mills et al., 2008; Siebert et al., 2008). The introduction of the improved traits alone or in stacked cultivars contributed to the increase in GE cotton to 88 percent in 2009; 23 percent HR-only, 17 percent IR-only, and 48 percent stacked (Table 1-5). As in 2001, farmers in the southeastern states had a higher adoption rate of GE cotton in 2009 (91 percent or greater) than Texas (81 percent) and California (73 percent). Pink bollworm and cotton bollworm are not major insect pests in California, so adoption of IR cotton (8 percent) and stacked varieties (11 percent) are particularly low; HR cotton (54 percent) makes up most of GE cotton in California.

An Early Portrait of Farmers who Adopt Genetically Engineered Crops

A study of cotton farmers' planting decisions in four southeastern U.S. states in 1996 and 1997 provided early evidence on the various factors that influenced the choice to adopt transgenic cotton (Marra et al., 2001). The growers were asked about their human capital (stock of knowledge and ability), farm-specific characteristics, reasons for adopting or not adopting Bt cotton in 1996, and the pest-control regimens that they used on both their conventional and their Bt cotton acres (if applicable), including amounts and types of insecticides applied and their

Copyright © National Academy of Sciences. All rights reserved.

Impact of Genetically Engineered Crops on Farm Sustainability in the United States
http://www.nap.edu/catalog/12804.html

costs. Comparing the farmers' actions on fields planted to Bt and non-Bt cotton on the same farm controlled for variation in management, land quality, and machinery complement.

The study found that one measure of human capital that was associated with a higher likelihood of adopting Bt cotton was experience (number of years of growing cotton). The age of the farmer was not significant. The propensity to adopt because of higher profit potential of genetic-engineering technology—related to higher yields, decreased costs, or both—was also affirmed by the responding farmers. They reported higher yields on their Bt acres than on their non-Bt acres (6.58 lb/acre more on fields with Bt cotton than those without in the Upper South and 16.43 lb/acre more in the Lower South) and large reductions in pesticide costs in both regions (about $6.00/acre less for fields with Bt cotton in the Upper South and about $10.00/acre less in the Lower South). Similarly, farmers who had previously experienced a high degree of pest infestation or pest resistance to currently used pesticides were more inclined to grow Bt cotton. Adopters reported higher past boll damage (7 percent higher on average compared with nonadopters) and higher incidence of past pest resistance to conventional insecticides (31 percent reported pest resistance compared with 18 percent of nonadopters in the combined sample). Those findings on human capital, yields, and the influence of pest problems are in accord with the explanations for adoption put forth by the diffusion and threshold theories.

Farm characteristics can also play a role in the decision to adopt a new technology. If the technology requires a high initial investment (such as for new machinery), farmers with more acres over which to spread the fixed costs might be more likely to adopt. Although the production technology itself is considered to be scale-neutral (i.e., the technology should not have differential impacts based on the size of the farm operation into which it is adopted), adopters in the study in both regions tended to have much larger farms and to farm more cotton acres than nonadopters; this supports the idea that the costs of learning may not be scale-neutral and thus that there is a possibility that differential farm-level social impacts have been associated with the adoption of GE crops (explained further in Chapter 4).

In 2001, farmers in Indiana, Illinois, Iowa, Minnesota, and Nebraska were surveyed to analyze the differences between adopters and nonadopters in farm and farmer characteristics (Wilson et al., 2005). The responses revealed that farmers growing corn on farms of less than 160 acres planted a greater percentage to GE corn for European corn borer control (54.5 percent) than farmers growing corn on farms of over 520 acres (39.2 percent). The same small–large differential held for aerial application of an insecticide (73.8 percent of farmers with less than 160 acres versus 57.3 percent with more than 520 acres); this suggests that smaller farmers place greater reliance on both chemical and GE controls of European corn borer than larger farmers. Just over one-fifth of the farmers (21.1 percent) reported a yield increase with the use of transgenic corn for European corn borer in all five states, from 11.2 percent in Indiana to 29.9 percent in Minnesota; 2.8 percent reported a yield decrease; and the rest reported no change in yield or that they did not know if there was a change or not. The surveyed farmers' greatest concerns were the ability to sell GE grain (59.3 percent), a market-access factor, and the additional technology fee (57.3 percent), a production-input factor that affected profits. Finally, the responding farmers indicated that a reduction in exposure to chemical insecticide (69.9 percent of the farmers), a personal health concern, and a reduction in insecticides in the environment (68.5 percent), a personal value, were the primary benefits of transgenic corn.

A more recent study of GE-crop adoption pertains to soybean (Marra et al., 2004). Table 1-6 presents the average total number of operated acres, the proportion of operated acres owned, age, education, and income (by category) for the different classes of adopters with the results of

Copyright © National Academy of Sciences. All rights reserved.

Impact of Genetically Engineered Crops on Farm Sustainability in the United States
http://www.nap.edu/catalog/12804.html

pairwise t-test results. The t-test results show that adopters (both partial and full) in this survey tended to be younger and operated more acres than nonadopters. Income, education, and percentage of operated acres the farmer owned do not show statistically significant differences among classes of adopters (Marra et al., 2004).

TABLE 1-6 National Soybean Survey Descriptive Statistics by Adoption Category

Farm Characteristics	Nonadopters	Partial Adopters	Full Adopters
Total Operated Acres	916.9[a]	1237.5[b]	1193.4[b]
(N)	(44)	(66)	(136)
Proportion of Acres Owned	0.6[a]	0.5[a]	.05[a]

Total Income (by category)	3.3[a]	2.8[a]	3.0[a]
(N)	(34)	(49)	(103)

NOTE: If a superscript letter is different, the mean for this class of adopters is statistically significantly different from the others in that category.
NOTE: Income categories ranged from 1= <$50,000/year to 5 = >$500,000/year.
SOURCE: Marra et al., 2004.

The importance of social networks in influencing patterns of adoption of GE crops has been highlighted in another recent study of the adoption of Bt corn in the Midwest. It described how farmers, whom the author of the study termed *reflexive producers*, negotiate between the advice and claims of experts, who do not farm, and local forms of knowledge that are conveyed by members of farmer networks. The study found that farmers' determination of whether pest problems that require the use of Bt corn exist depended more on local than on expert knowledge (Kaup, 2008).

DETERRENTS TO GENETICALLY ENGINEERED TRAIT DEVELOPMENT IN OTHER CROPS

Soybean, corn, and cotton represent a substantial number of acres planted in the United States, but they do not reflect the diversity of American agriculture. GE varieties have not been developed by private firms for most U.S. crops, in part because the small markets for these crops will not generate sufficient returns on the necessary investment in research, technology commercialization, and marketing infrastructure. Furthermore, concern about selling food with GE-derived ingredients in some markets and the resistance of some grower organizations have limited the commercial application of genetic-engineering technology to just a few crops.

Impact of Genetically Engineered Crops on Farm Sustainability in the United States
http://www.nap.edu/catalog/12804.html

Market Conditions Influencing the Commercialization of Genetically Engineered Varieties

Most research in and development of GE crops are conducted by private firms. Private companies must produce profits for their shareholders, so the marketability of a crop plays a determining role in decisions as to which GE crops are brought to commercialization. Market size, trait value, regulatory costs, environmental concerns, and technology access influence biotechnology firms' decisions to develop and sell GE seeds.

The market for seeds must be large enough to warrant the investment in commercialization. If markets are too small or are characterized by farmers with low ability to pay for the technology, the benefits to firms are too low to induce them to introduce GE varieties. That is one of the reasons that specialty crops have largely been overlooked in genetic engineering. The VR papaya, for example, was developed through public research. In addition, the number of researchers in these types of crops is considerably smaller and the marketing infrastructure less extensive than for soybean, corn, and cotton. That lack of resources, the diversity of species, the relatively short marketing season, and the small number of planted acres combine to deter private-sector investment in genetic-engineering technology for specialty crops (Bradford and Alston, 2004). To collect sufficient returns, firms instead invest in widely grown crops that have long storage life and that have year-round marketing potential. That generally means that farmers growing such crops have access to genetic-engineering technology, whereas the option is not available to farmers growing specialty crops or crops that are not widely grown in the United States.

The cost of regulatory compliance to ensure that GE crops do not pose unacceptable food safety and environmental risks has become an important component of the overall cost of new biotechnologies (Kalaitzandonakes et al., 2007). These costs may have contributed to limiting the development of GE minor crops, as was the case with pesticide development during the 1970–1990 period. As Ollinger and Fernandez-Cornejo (1995) found, "pesticide regulations have encouraged firms to focus their chemical pesticide research on pesticides for larger crop markets and abandon pesticide development for smaller crop markets." Obtaining regulatory clearance of GE crops in the United States is a long process, and the cost per crop can be very high. Furthermore, for crops with wild, weedy relatives (e.g., wheat), the potential for gene flow raises their environmental risk and expense (see "Gene Flow and Genetically Engineered Crops" in Chapter 2). Large private firms have concluded that investment in less widely grown crops does not generate adequate returns to justify the development and regulatory cost of bringing them to market.

Research and development in genetic-engineering technology have been stimulated by the development of patent protection for GE organisms. Changes in intellectual-property rights (IPR) law in the 1970s and 1980s are largely responsible for creating a profitable environment for biotechnology research. However, that protection may also create constraints on the development of GE varieties of more crops. Companies that control the patents may be unwilling to provide licenses or offer licenses at affordable prices to public-sector researchers or other companies that would like to develop seeds for smaller markets. A similar restriction may occur when university scientists patent genetic material that becomes essential for development of GE crops by other university scientists. Thus, the mechanism that generated the incentives to develop and commercialize genetic engineering may limit its applicability to most crops (Alston, 2004). The influence of IPR on the commercialization of genetically engineered crops will be discussed further in Chapter 4.

Impact of Genetically Engineered Crops on Farm Sustainability in the United States
http://www.nap.edu/catalog/12804.html

Marketing decisions are also influenced by perceived consumer acceptance of GE products. If technology providers have reason to believe that a GE crop will not be purchased by consumers, the technology will not be commercialized regardless of the potential benefits of the technology to producers. Indeed, a product may even be decommercialized if consumer avoidance, or the fear of it, is high enough. For example, consumer concerns and competing pest-control products caused the GE potato to be discontinued (see Box 1-2). The perceived potential loss of markets has also postponed the commercialization of GE wheat (this is covered further in Chapter 4). Consumers appear to be more accepting of products that are further removed from direct consumption, although additional research is needed in this regard (Tenbült et al., 2008). Thus, companies have been more willing to invest in corn and soybean, which are used primarily for animal feed and processed products, and cotton, a fiber crop. Even though wheat and rice are grains (like corn), are widely planted, and have a considerable storage life, their proximity to the consumer in the food supply chain has contributed to additional pressures on the private sector, which may explain firms' wariness to introduce genetic-engineering technology into them (Wisner, 2006).

Resistance to Genetic-Engineering Technology in Organic Agriculture

As outlined above, genetic-engineering technology is not available to farmers of most crops. However, some producers have chosen not to adopt the technology regardless of its accessibility. That attitude is typified by organic production in the United States.

As American agricultural practices incorporated greater use of synthetic chemicals in the 1950s and 1960s, organic production gained popularity as an alternative farming system. By the 1980s, the organic movement was large enough to justify the establishment of national certification standards. The proliferation of standards, inconsistency in labeling, difficulty in marketing, and inability to police violators of standards prompted organic groups to push for passage of the Organic Foods Production Act (OFPA) of 1990 (Rowson, 1998). The OFPA authorized a National Organic Program (NOP) in the U.S. Department of Agriculture (USDA) to define organic farming practices and acceptable inputs. The act established an advisory group, the National Organic Standards Board (NOSB), to provide recommendations to USDA on the structure and guidelines of the NOP. The NOSB viewed GE organisms as inconsistent with the principles of organic agriculture and recommended their exclusion (Vos, 2000). Opponents of genetic-engineering technology in organic production raised concerns about food safety and environmental effects. They also argued that organic agriculture is based on a set of values that places a high priority on "naturalness" (Verhoog et al., 2003), a criterion that in their view genetic engineering did not meet.

The proposed rule that was issued in 1997 deemed GE seeds permissible in organic agriculture; subsequently, USDA received a record number of public comments, almost entirely in objection to the proposal (Rowson, 1998). In response to the opposition, USDA rewrote the standards. When the NOP final rule went into effect in 2001, GE plants were not considered to be compliant with standards of organic agriculture (Johnson, 2008).

FROM ADOPTION TO IMPACT

The assessment framework described earlier in this chapter spans all the qualitative dimensions necessary to evaluate the potential sustainability of genetic-engineering technology. Therefore, this report's structure covers environmental, economic, and social changes, and the following chapters report progress and conclusions in these realms.

Environmental Effects

The landscape-level environmental effects of GE crops, both potential improvements and risks, did not receive extensive study when such crops were first planted widely (Wolfenbarger and Phifer, 2000; Ervin et al., 2001; Marvier, 2002). Since then, many studies on nontarget effects, including further studies requested by the U.S. Environmental Protection Agency, have accumulated. Other studies and analyses have related adoption of GE crops to changes in pesticide regimens and tillage practices. However, longitudinal data are still needed to better understand the effects of changes in farm management on environmental sustainability, such as on water quality or on resistance to glyphosate in weeds. Comprehensive evidence on other environmental dimensions—such as some aspects of soil quality, biodiversity, water quality and quantity, and air-quality effects—is also sparse. The environmental effects of farmers' adoption of genetic-engineering technology are discussed in Chapter 2.

Economic Effects

The economic effects of genetic-engineering technology in agriculture, which are addressed in Chapter 3, stem from effects on crop yields; the market returns received for the products; reductions or increases in production inputs and their prices, such as the costs of GE seeds and pesticides; and such other effects as labor savings that permit more off-farm work or that result in changes in yield risk. Those effects have received considerable study, particularly in the early stages of adoption of GE crops. However, recent information is sparse even though new GE varieties continue to be introduced. Less farm-level economic analysis has been conducted, perhaps because of the near dominance of the technologies in soybean, cotton, and corn production, because serious production or environmental problems have not surfaced, and because there is less interest for conducting additional research in a well-studied arena. More extensive studies of some economic effects, such as those on yield, have been conducted more recently in developing countries than in mature markets such as the United States.

Social Effects

The social effects of the adoption or nonadoption of genetic-engineering technology have not been studied as extensively as those attributed to previous waves of technological development in agriculture, even though earlier studies demonstrated that revolutionary agricultural technologies generally have substantial impacts at the farm or community level (Berardi, 1981; DuPuis and Geisler, 1988; Buttel et al., 1990) and that there was a high expectation that genetic-engineering technology would also have substantive and varied social impacts (Pimentel et al., 1989). It is thus surprising that there has been relatively little research on the ethical and

Impact of Genetically Engineered Crops on Farm Sustainability in the United States
http://www.nap.edu/catalog/12804.html

socioeconomic effects of the adoption of agricultural biotechnology at the farm or community level (e.g., Buttel, 2005). A few studies have explored the economic effects of structural changes (integration and concentration) in the seed and agrichemical industries (Hayenga, 1998; Brennan et al., 2000; Fulton and Giannakas, 2001; Fernandez-Cornejo and Schimmelpfennig, 2004; Fernandez-Cornejo and Just, 2007). However, though the issue of how farmers might be socially impacted by the increasing integration of seed and chemical companies was first raised more than 20 years ago (Hansen et al., 1986), the organizations responsible for conducting or sponsoring research on the effects of genetic-engineering technology have generally fallen short of promoting the comprehensive and rigorous assessment of the possible social and ethical effects of GE-crop adoption. That responsibility rests not only with federal agencies (Kinchy et al., 2008) but with state governments, universities, nongovernment organizations, and the private for-profit sector. The absence of such research reduces our ability to document what the effects of the adoption of genetic-engineering technology have been on farm numbers and structure, community socioeconomic development, and the health and well-being of farm managers, family members, and hired farm laborers. A particularly significant question that has not been adequately assessed is whether the adoption of GE crops has exacerbated, alleviated, or had a neutral effect on the steady decline of farm numbers and the vitality of rural communities often associated with the industrialization of U.S. agricultural production. Because of the comparative dearth of empirical research findings on the social impacts of GE-crop adoption in the United States, we offer in Chapter 4 a discussion of the potential effects of the introduction of genetic-engineering technologies on farming-system dynamics in the form of testable hypotheses and piece together the ancillary literature on documented social effects, such as legal disputes.

CONCLUSION

Genetic-engineering technology has been built on centuries of plant-breeding experiments, research, and technology development. Commercialized applications have focused on pest management, primarily through resistance to the herbicide glyphosate and the incorporation of endotoxins that are lethal to some insect pests. Those traits have provided farmers of soybean, corn, and cotton additional tools for combating pests. The popularity of GE crops is evidenced by their widespread adoption by farmers. In the following three chapters, we examine how their adoption has changed or reinforced farming practices and what implications the changes have for environmental, economic, and social sustainability at the farm level. At the close, we identify remaining challenges and opportunities for GE crops in the United States and draw conclusions and recommendations for increasing their contributions to farm sustainability.

2

Environmental Impacts of Genetically Engineered Crops at the Farm Level

The environmental impacts of planting genetically engineered (GE) crops occur within the context of agriculture's general contribution to environmental change. Agriculture has historically converted biologically diverse natural grasslands, wetlands, and native forests into less diverse agroecosystems to produce food, feed, and fiber. Effects on the environment depend on the intensity of cultivation over time and space; the inputs applied, including water, fertilizer, and pesticides; and the management of inputs, crop residue, and tillage. With 18 percent of the land area in the United States planted to crops and another 26 percent devoted to pastures (FAO, 2008), the huge scale of these impacts becomes obvious. In general, tillage, crop monoculture, fertilizers, and pesticide use often have adverse effects on soil, water, and biodiversity. Agriculture is the leading cause of water-quality impairment in the United States (USDA-ERS, 2006). No-tillage systems, crop rotations, integrated pest management, and other environmentally friendly management practices may ameliorate some of the adverse impacts, but the tradeoff between agricultural production and the environment remains. With agricultural lands approaching 50 percent of U.S. land, developing more ecologically and environmentally sound agricultural management practices for crops, soil, and water is a central challenge for the future (Hanson et al., 2008). Against that backdrop, we evaluate the impact of GE crops on the environmental sustainability of U.S. farms.

This chapter examines the changes in farm practices that have accompanied the adoption of GE crops and the evidence on how such adoption affects the environment. It addresses impacts at the individual farm level and also at the landscape level, given that impacts from individual farms accumulate and affect other farms and their access to communal natural resources in the region. The use of GE crops has altered farmers' agronomic practices, such as tillage, herbicides, and insecticides; these alterations have implications for environmental sustainability both on and off the farm, which are evaluated to the extent possible at this point in time (Box 2-1). In particular, we examine the effects of the adoption of GE crops on soil quality, biodiversity, and water quality.

BOX 2-1
Limitations to Evaluating the Magnitude of Environmental Effects

Although environmental risk assessment is conducted for all GE varieties before regulatory approval, in some cases, the absence of environmental monitoring at the landscape level prevents calculating the magnitude of effects (e.g., water quality) following commercialization. Where monitoring data on agricultural practices are available (e.g., tillage practices, pesticide use), simple correlations of the adoption rates with trends in agricultural practices do not capture the complexity required to quantify the magnitude of any environmental effect. The lack of spatially-explicit data linking the use of GE crops with data-monitoring agricultural practices stymies any accurate calculation of the magnitude of environmental effects at national or even regional levels (NRC, 2002). Environmental consequences of agricultural practices can vary greatly at a sub-regional scale. For example, the adoption of a herbicide-resistant crop may facilitate use of no-till practices, but the environmental effects of no-till practices depend on existing soil texture, structure, and erosion potential for each individual farm. Though models may exist to quantify soil retention given erosion potential, what amount of retention can be attributed to HR crops requires two additional calculations:

1. Quantifying to what extent HR crops caused the adoption of conservation tillage practices, given that there is a two-way relationship, and
2. Spatially linking the adoption of HR crops with data on the occurrence of Highly Erodible Land, something not feasible without spatially-explicit data.

Similarly, weed and pest control measures fluctuate from year to year and crop to crop, as have the choices of active ingredients. Determining the extent to which adoption of GE crops replaced specific pesticides over time requires incorporating a suite of factors, such as changes in pest pressure or pest-management strategies (e.g., see footnote on boll weevil eradication program), tillage practices, technology, and public policy (e.g., pesticide regulation, government programs) (Fernandez-Cornejo et al., 2009). Spatial data on the evolution of weed resistance are also lacking, thus preventing any calculation of environmental consequences of the declining effectiveness of glyphosate with glyphosate-resistant crops.

ENVIRONMENTAL IMPACTS OF HERBICIDE-RESISTANT CROPS

The adoption of herbicide-resistant (HR) crops has affected the types and number of herbicides and the amount of active ingredient applied to soybean, corn, and cotton. This section first examines the substitution of glyphosate for other herbicides that has taken place and how the use of HR crops has interacted with tillage practices. It then assesses ecological effects of those changes on soil quality, water quality, arthropod biodiversity, and weed communities. Lastly, the implications for weed management in cropping systems with HR crops are considered, especially for systems in which glyphosate-resistant weeds evolve.

Herbicide Substitution

A higher proportion of herbicide-resistant GE soybean has been planted than of any other GE crop in the United States. Adoption has exceeded 90 percent of the acres planted to soybean by U.S. farmers (Figure 2-1). HR cotton acreage reached 71 percent in 2009 (Figure 2-2), while

Impact of Genetically Engineered Crops on Farm Sustainability in the United States
http://www.nap.edu/catalog/12804.html

planted HR corn acres were 68 percent that year (Figure 2-3). The HR crops planted thus far have altered the mix of herbicides used in cropping systems and allowed the substitution of glyphosate for other herbicides. Figures 2-1 through 2-3 summarize the trends in the use of glyphosate and other herbicides on corn, soybean, and cotton (expressed in pounds per planted acre of these crops) and the adoption of HR corn, soybean, and cotton (Fernandez-Cornejo et al., 2009). It is important to recognize that, depending on the metrics used, the substitution of glyphosate for other herbicides has resulted in the use of fewer alternative herbicides by growers of HR crops. However, glyphosate is often applied in higher doses and with greater frequency than the herbicides it replaced. Thus, the actual amount of active ingredients (glyphosate and other herbicides) applied per acre actually increased from 1996 to 2007 in soybean (Figure 2-1) and cotton (Figure 2-2) but decreased over the same period in corn (Figure 2-3).

Glyphosate is reported to be more environmentally benign than the herbicides that it has replaced (Fernandez-Cornejo and McBride, 2002; Cerdeira and Duke, 2006). It binds to soil rapidly (preventing leaching), it is biodegraded by soil bacteria, and it has a very low toxicity to mammals, birds, and fish (Malik et al., 1989). Glyphosate can be detected in the soil for a relatively short period of time compared to many other herbicides, but is essentially biologically unavailable (Wauchope et al., 1992). Formulations that contain the surfactant polyoxyethylene amine can be toxic to some amphibians at environmentally-expected concentrations and may affect aquatic organisms under some environmental conditions (Folmar et al., 1979; Tsui and Chu, 2003; Relyea and Jones, 2009); however, these formulations are labeled for terrestrial uses only with restrictions with respect to waterways. The greater use of postemergence glyphosate applications has been accompanied by modifications of agronomic practices, particularly with regards to weed management and tillage. The interactions of those practices have implications for environmental sustainability.

Tillage Practices

Tillage is one process used by farmers to prepare the soil before planting. In conventional tillage, all postharvest residue is plowed into the soil to prepare a clean seedbed for planting and to reduce the growth of weeds; in conservation tillage, at least 30 percent of the soil surface is left covered with crop residue after planting. In the 1970s and 1980s, innovations in cultivators and seeders enabled farmers to plant seeds at a reasonable cost with residue remaining on the field. Those developments encouraged the adoption of one form of conservation tillage called no-till, in which the soil and surface residue from the previously harvested crop are left undisturbed as the next crop is seeded directly into the soil without tillage. After soil-conservation policy was incorporated into the Food Security Act of 1985, conservation tillage accelerated in the 1990s (Figure 2-4). The introduction of HR soybean and cotton has supported the trend because the use of glyphosate allowed weeds to be controlled after crop emergence without the need for tillage to disrupt weed development before or after planting. Indeed, in the last 10 years, the use of conservation tillage has continued to increase, with the exception that it has remained constant in the case of corn (Figure 2-4).[1]

The adoption of conservation tillage practices by U.S. soybean growers increased from 51 percent of planted acres in 1996 to 63 percent in 2008 (Figure 2-4), or an addition of 12 million

[1]More information on different types of tillage systems can be found in Appendix B.

Impact of Genetically Engineered Crops on Farm Sustainability in the United States
http://www.nap.edu/catalog/12804.html

acres. The adoption of no-till practices accounted for most of the increase and was used on 85 percent of these additional 12 million acres. Over the same time period, the acreage planted to soybean increased at most nine million acres. In cotton there was a doubling of the percentage of acres managed using conservation tillage from 1996 to 2008, and no-till is the predominant conservation tillage practice (Figure 2-4). Cotton acreage declined over the same time period. For corn between 1996 and 2008, an additional 4.8 million acres of corn were planted. At the same time, the use of conservation tillage practices remained at a fairly constant 40 percent of planted acreage (Figure 2-4). No-till practices increased by 4 percent over the same time period (4.3 million acres) but this was disproportionate relative to overall increases in conservation tillage practices (1.9 million acres), indicating that farmers converted from other conservation tillage practices to no-till.

According to U.S. Department of Agriculture (USDA) survey data for 1997, a larger share of acreages planted to HR soybean was managed with conservation tillage than was planted to conventional soybean (Fernandez-Cornejo and McBride, 2002)—about 60 percent versus about 40 percent (Figure 2-5). The difference in the use of no-till between adopters and nonadopters of HR soybean was even more pronounced: 40 percent of acres planted with HR soybean were under no-till, double the corresponding share of acres of non-GE soybean under no-till management practices (Fernandez-Cornejo and McBride, 2002).

From the perspective of farmer decision-making, the availability of HR technology may affect the adoption of conservation tillage, and the use of conservation tillage may affect the decision to adopt HR crops. Several economists have tried to understand how closely the two decisions are linked. An econometric model developed to address the simultaneous nature of the decisions was used to determine the nature of the relationship between the adoption of GE crops with HR traits and no-till practices on the basis of 1997 national survey data on soybean farmers (Fernandez-Cornejo et al., 2003). Farmers using no-till were found to have a higher probability of adopting HR cultivars than farmers using conventional tillage, but using HR cultivars did not significantly affect no-till adoption. That result suggested that farmers already using no-till incorporated HR cultivars seamlessly into their weed-management program; but the commercialization of HR soybean did not seem to encourage the adoption of no-till, at least at the time of the survey.

More recently, however, Mensah (2007) found a two-way causal relationship on the basis of more recent data. Using a simultaneous-adoption model and 2002 survey data on soybean farmers, Mensah found that farmers who adopted no-till were more likely to adopt HR soybeans *and* that farmers who adopted the HR technology were more likely to adopt no-till practices.

In the case of cotton, the evidence also points toward a two-way causal relationship. Roberts et al. (2006) evaluated the relationship between adoption of HR cotton and conservation tillage practices in Tennessee from 1992 to 2004. Using two methods,[2] they found that the adoption of HR cotton increased the probability that farmers would adopt conservation tillage and conversely that farmers that had previously adopted conservation tillage practices were more likely to adopt HR cotton. Thus, the adoption of no-till practices and the adoption of HR cotton are complementary practices.

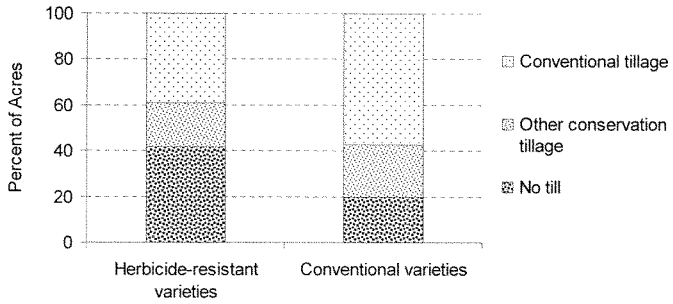

FIGURE 2-5 Soybean acreage under conservation tillage and no-till, 1997.
SOURCE: Adapted from Fernandez-Cornejo and McBride, 2002.

Kalaizandonakes and Suntornpithug (2003) also studied the simultaneous adoption of HR and stacked cotton varieties and conservation tillage practices on the basis of farm-level data. They concluded that conservation tillage practices both encouraged the adoption of HR and stacked cotton varieties and were encouraged by their adoption. Using state-level data for 1997–2002 and using a simultaneous-equation econometric model, Frisvold et al. (2007) studied the diffusion of HR cotton and conservation tillage. They found strong complementarity between the two practices and rejected the null hypothesis that the diffusion of one is independent of the diffusion of the other. They also observed that an increase in the probability of adoption of HR cotton increased the probability of adoption of conservation tillage and vice versa.

Thus, most empirical evidence points to a two-way causal relationship between the adoption of HR crops and conservation tillage.[3] Farmers using conservation tillage practices are more likely to adopt HR crop varieties than those using conventional tillage, and those adopting HR crop varieties are more likely to change to conservation tillage practices than those who use non-HR cultivars. The analytical techniques used do not reveal the relative strength of each causal linkage, so it is not clear which factor (adoption of HR varieties or use of conservation tillage) has a greater influence on the other.

Soil Quality

The relationship between the adoption of conservation tillage practices and the adoption of HR crops is relevant to farm sustainability because conservation tillage has fewer adverse environmental impacts than conventional tillage (reviewed by Uri et al., 1999). On the farm, conservation tillage reduces soil loss from erosion, increases water infiltration, and can improve

[3]Most published evidence is for the cases of soybean and cotton given that extensive adoption of HR corn is relatively more recent (HR corn adoption only exceeded 20 percent of corn acreage in 2005).

Impact of Genetically Engineered Crops on Farm Sustainability in the United States
http://www.nap.edu/catalog/12804.html

soil quality and moisture retention (reviewed by Uri et al., 1999; Holland, 2004). Corn and soybean are grown in regions where highly erodible land is common, and conversion to conservation tillage for these crops results in substantial reduction in soil loss and wind erosion even on non-highly erodible land (Uri et al., 1999). Leaving more crop residue on fields strengthens nutrient cycling and increases soil organic matter, a key component of soil quality (reviewed by Blanco-Canqui and Lal, 2009). Soil organisms decompose plant residue, and this, in turn, cycles nutrients and improves soil structure. In general, soil organisms have greater abundance or biomass in no-till systems than in conventional tillage systems because soil is disturbed less (reviewed by Wardle, 1995; Kladivko, 2001; Liebig et al., 2004).

In addition to tillage, the use of herbicides can affect soil quality through their impact on soil organisms, so interpreting the effects of HR crops on soil quality requires an understanding of how tillage practices interact with herbicide use to influence the soil microorganism community. In laboratory studies, glyphosate can inhibit or stimulate microbial activity, depending on soil type and glyphosate formulation (Carlisle and Trevors, 1986, and references therein). Some microorganisms can use glyphosate as a substrate for metabolism (increased activity); whereas others are susceptible to the herbicide because they have an enzyme 5-enolpyruvyl-shikimate-3-phosphate synthase pathway that glyphosate inhibits. When species-level responses were measured, roots of glyphosate-resistant soybean and corn treated with glyphosate had significantly more colonies of the fungus *Fusarium* than did non-HR cultivars or HR cultivars not treated with glyphosate (Kremer and Means, 2009). In contrast, fluorescent *Pseudomonas* populations, an antagonist of fungal pathogens like *Fusarium*, were significantly lower in soybean that were both glyphosate resistant and treated with glyphosate compared to untreated HR cultivars or a non-HR cultivar treated with other herbicides (Kremer and Means, 2009). Those results indicate a change in the antagonistic relationship between *Fusarium* and *Pseudomonas* attributable to the formulation of glyphosate used. Whether magnitude of change in this antagonistic relationship would have consequences on soil quality of disease control was not a part of the study.

With respect to general microbial activity, three studies in the United States have detected no uniform changes in soil organism profiles in association with tillage or with the use of glyphosate on glyphosate-resistant cropping systems (Liphadzi et al., 2005; Weaver et al., 2007; Locke et al., 2008). Soil microorganisms in fields planted with glyphosate-resistant corn and soybean varieties were similar with and without tillage (Liphadzi et al., 2005). HR fields treated with glyphosate and non-GE fields treated with other herbicides were also similar in soil microbe activity (Liphadzi et al., 2005). On tilled, experimental plots of glyphosate-resistant soybean, transient changes in the soil microbial community were detected in the first few days after application of glyphosate compared to no application (Weaver et al., 2007), but the differences disappeared after 7 days. When there was continuous cotton cropping, soil quality did not differ between HR and non-HR systems. In contrast, soil under continuous HR-corn cropping contained more carbon and nitrogen than soil with non-HR corn (Locke et al., 2008), which would be considered a benign change. Differences in carbon and nitrogen contents could have been due to glyphosate use, but they were also probably influenced by changes in the detrital food web associated with the higher biomass of winter weeds in the HR-corn cropping system (Locke et al., 2008). Subtle differences in the structure of the soil microbial community were also detectable in those same experiments; the significance of the differences for soil quality were not discussed. Thus, species-level studies suggest that glyphosate can alter the microbial composition in the rhizosphere. General studies of the interaction of tillage and glyphosate use in

Copyright © National Academy of Sciences. All rights reserved.

Impact of Genetically Engineered Crops on Farm Sustainability in the United States
http://www.nap.edu/catalog/12804.html

HR crops have indicated transient benign effects of glyphosate and neutral, or in one case favorable, effects of conservation tillage on the soil communities in HR crops.

Water Quality

Conservation tillage practices can have off-farm benefits for water quality that are potentially more important than onsite productivity effects (Foster and Dabney, 1995). Because conservation tillage practices improve soil-water infiltration, the volume of runoff is less than when conventional tillage is used. Reduced tillage and no-till practices can improve water quality by reducing the amounts of sediments and sediment-associated chemicals in runoff from farm fields into surface water. Similarly, lower volumes of runoff can decrease the transport of soil nutrients and agricultural inputs, such as fertilizers and pesticides, although the decrease will vary with soil type, tillage practice, and nutrient or pesticide input. For example, although the concentration of herbicide in runoff from no-till fields can be higher than when other conservation tillage practices are used, the total amount of herbicide in runoff may be similar because runoff volume is reduced (Fawcett et al., 1994; Locke and Bryson, 1997; Mickelson et al., 2001; Shipitalo and Owens, 2006; Zeimen et al., 2006). That phenomenon has been observed with the use of glyphosate in no-till fields (Shipitalo et al., 2008).

Studies have suggested that the use of glyphosate poses less risk to water quality than the use of other herbicides; this is attributable in part to the production systems typically used in GE crops and to the physical chemistry and relatively low toxicity of glyphosate (Estes et al., 2001; Wauchope et al., 2002; Peterson and Hulting, 2004). However, there are no regional-scale analyses of the effects of HR-crop adoption on water quality. One study conducted in a small Ohio watershed that compared herbicide runoff in HR and non-HR soybean fields found that the amount of glyphosate in the runoff was nearly one-seventh that of the herbicide metribuzin and about half that of alachlor, even though glyphosate was applied to soybean twice and alachlor and metribuzin once to soybean (Shipitalo et al., 2008). Those results are consistent with known characteristics of glyphosate, which strongly absorbs to soil and has a half-life in soil of 6–60 days, depending on soil characteristics. Microbial processes degrade glyphosate into two metabolites: sarcosine and aminomethylphosphonic acid (AMPA). Sarcosine degrades quickly to carbon dioxide and ammonia. AMPA is more persistent than glyphosate in the soil environment but is considered equally or less toxic (reviewed by Giesy et al., 2000). Numerous studies have documented the occurrence of glyphosate and AMPA in surface waters (Kolpin et al., 2006), but they have rarely been found in groundwater (Borggaard and Gimsing, 2008). Concentrations of glyphosate reported in surface water have not exceeded the maximum contaminant level (MCL) for drinking water set by the U.S. Environmental Protection Agency (EPA); in accordance with World Health Organization recommendations, MCLs have not been set for AMPA (WHO, 2005).

Shifts to conservation tillage attributable to the availability of HR crops have contributed to reductions in soil loss and probably in herbicide runoff. The magnitude and spatial distribution of the benefits is not precisely known, but the implications are that those are important environmental benefits of these cropping systems. However, as discussed later in this chapter (see "Other Shifts in Weed Communities"), some of the environmental benefits may be threatened in the future.

Impact of Genetically Engineered Crops on Farm Sustainability in the United States
http://www.nap.edu/catalog/12804.html

Arthropod Biodiversity

Changes in herbicide use and tillage practices like those accompanying the adoption of HR crops can affect such organisms as natural enemies of pests or pollinators, which provide ecological services to agriculture. Weeds provide an ecological disservice to farms by competing with crop plants for nutrients and light even at low population densities, but weeds can also support a broad array of nonpest species. Pollinators feed on nectar or use some weeds as hosts for their larval stage; weed species can be food for herbivores that in turn are preyed on by predators that also control pests of crops. In particular, more effective weed management could decrease the abundance of beneficial organisms, depending on the mobility of a species and how closely its resource base is associated with weed abundance. In contrast, the increase in no-till practices that leave more plant material undisturbed in fields may increase the resource base for beneficial insects.

Evidence indicates that the planting of HR cultivars does not consistently affect the weed diversity and abundance that support beneficial species. Whether a farmer used a GE crop or a conventional crop, better weed control has generally reduced the numbers of arthropods and other organisms in corn, sugar beet, and rapeseed fields (Hawes et al., 2003) and decreased the abundance of the predatory big-eyed bug (*Geocoris punctipes*) in soybean fields (Jackson et al., 2003; Jackson and Pitre, 2004). When HR crops improved weed management (decreased weeds), populations of natural enemies and pollinators decreased (Hawes et al., 2003). When conventional weed-management tactics (such as the use of the herbicide atrazine) were more effective at weed control on non-HR corn relative to HR corn, beneficial insect abundance was greater within the HR side of the field where more weeds occurred (Hawes et al., 2003). Subsequent analyses of these same data in more depth have revealed detailed associations between properties of the weed community and the accompanying arthropod food web (Hawes et al., 2009) and strengthened the conclusion that weed management accounts for the relationships observed. However, weed management was not the largest influence on the abundance of beneficial organisms. Rather, there were differences of a factor of 3–10 in abundance among different crops and between early and late in the growing season, compared with differences of a factor of 2 associated with weed management (Hawes et al., 2003).

Weed Biodiversity and Weed Shifts

Crop-production practices inevitably influence the composition of the weed community. Typically, only a few weed species are economically important in a particular crop-production system (Owen, 2001; Tuesca et al., 2001). When a production practice changes, for example, a change in herbicide, it may ultimately select for weed biotypes that are resistant to that herbicide (Baker, 1991). Other elements of production practices that have selective effects on the weed community include harvesting techniques, irrigation, fertilization, planting dates, soil amendments, and tillage (Hilgenfeld et al., 2004; Murphy and Lemerle, 2006; Owen, 2008).

The stronger the selective force of those practices (e.g., the level of disturbance caused by tillage), the more consistent the selective force (e.g., continuous planting of the same crop as opposed to annual crop rotations), and the simpler the selective force (e.g., the recurrent use of one herbicide), the greater the effect on the composition of the weed community (Owen, 2001). Changes in the kinds of weeds that are important locally are termed *weed shifts* (which implies changes in weed species composition) (Givnish, 2001); in the following discussion, weed shifts

Copyright © National Academy of Sciences. All rights reserved.

Impact of Genetically Engineered Crops on Farm Sustainability in the United States
http://www.nap.edu/catalog/12804.html

are the ecological process by which an initial weed community is replaced by a new community, including better-adapted species, in response to changes in agricultural practices. Weed shifts are generally followed by a period of stability, given the longevity of weed seeds in the soil, as long as the agricultural systems that resulted in the shift remain constant (Buhler, 1992; Buhler et al., 1997). They are a common and inevitable result of agriculture and are not unique to the adoption of HR crops, but it is essential to understand and manage them well if agriculture is to be productive and sustainable. Such shifts are particularly relevant for managing weeds in HR-crop systems, in which tillage practices and herbicide use both play major roles in shaping the weed community.

Herbicide Resistance in Weeds

The International Survey of Herbicide Resistant Weeds (ISHRW) provides a historical account and extensive list of weeds that have evolved resistance to herbicides (Heap, 2010). Although the ISHRW reflects the efforts of many weed scientists in reporting weed populations that have herbicide resistance, the voluntary basis of the contributions likely results in underestimation of the extent of resistance to herbicides, including glyphosate. The evolution of herbicide-resistant weeds is not unique to the herbicides for which HR traits exist. Currently, 195 species (115 dicots and 80 monocots) have evolved resistance to at least one of 19 herbicide mechanisms of action in at least 347 herbicide-resistant weed biotypes distributed over 340,000 fields (Heap, 2010).

Glyphosate, first commercialized in 1974, has been extensively used for weed control in perennial crops (fruits, trees, nuts, and vines), along roadsides and irrigation canal banks, and in urban areas and national parks (Powles, 2008). The first case of evolved resistance to glyphosate was reported in 1996 in rigid ryegrass (*Lolium rigidum*) (Powles et al., 1998). The glyphosate-resistant population originated in an orchard in a large winter cropping region of southern Australia, where glyphosate had been used intensively for the control of rigid ryegrass for more than 15 years. Since the initial report, at least six other weed species have been reported as resistant to glyphosate in environments where glyphosate-resistant crops were not planted (Powles, 2008; Heap, 2010).

Emergence of Glyphosate-Resistant Weeds in Herbicide-Resistant Crop Fields

Eight or nine species have evolved resistance to glyphosate independently in glyphosate-resistant crops over 13 years in the United States (from 1996 to 2009) (Heap, 2010). Gene flow between HR crops and closely related weed species does not explain the evolution of glyphosate resistance in U.S. fields because sexually compatible weeds are absent where corn, cotton, and soybean are grown in the United States. However, the nearly exclusive reliance on glyphosate for weed control, a practice accelerated by the widespread introduction of glyphosate-resistant crop varieties, has caused substantial changes in weed communities. The first report of glyphosate resistance associated with a GE glyphosate-resistant crop involved horseweed (*Conyza canadensis*) in Delaware (VanGessel, 2001); once resistance evolved, growers found it difficult to control this weed in no-till glyphosate-resistant soybean (VanGessel, 2001). Since the initial report in 2000, glyphosate-resistant populations of horseweed have been documented throughout the Mid-Atlantic, Mid-South, Mississippi Delta, and Midwest states (Heap, 2010). The weed

Copyright © National Academy of Sciences. All rights reserved.

Impact of Genetically Engineered Crops on Farm Sustainability in the United States
http://www.nap.edu/catalog/12804.html

grows particularly well in no-till production systems, producing a large number of wind-carried seeds that are dispersed over long distances (Buhler and Owen, 1997; Ozinga et al., 2004).

Subsequent to that discovery in 2000, other weed species have evolved resistance to glyphosate in glyphosate-resistant crops in the United States (Table 2-1). They include two species of pigweed, Palmer amaranth (*Amaranthus palmeri*) and waterhemp (*Amaranthus tuberculatus*),[4] which have become economically important in glyphosate-resistant cotton and soybean production (Zelaya and Owen, 2000, 2002; Culpepper, 2006; Culpepper and York, 2007; Legleiter and Bradley, 2008). Infested areas are increasing rapidly in the Southeast, the Mississippi Delta (Palmer amaranth and Johnsongrass, *Sorghum halepense*), and the Midwest (waterhemp) (Culpepper and York, 2007; Legleiter and Bradley, 2008). Glyphosate-resistant populations of giant ragweed (*Ambrosia trifida*) have been reported in several states (Leer, 2006), primarily in or adjacent to glyphosate-resistant soybean. Kochia (*Kochia scoparia*) with evolved resistance to glyphosate has recently been identified in Kansas (Heap, 2010). Another weed, common lambsquarters (*Chenopodium album*) (Kniss et al., 2004, 2005; Schuster et al., 2007; Scursoni et al., 2007) may have also evolved glyphosate-resistant biotypes (Boerboom, 2005), but it has not yet appeared on the ISHRW list.

TABLE 2-1 Weeds That Evolved Resistance to Glyphosate in Glyphosate-Resistant Crops in the United States

Species	Crop	Location	Acreage[a]
Amaranthus palmeri (Palmer amaranth)	Corn, cotton, soybean	Georgia, North Carolina, Arkansas, Tennessee, Mississippi	200,000–2,000,000
Amaranthus tuberculatus (waterhemp)	Corn, soybean	Missouri, Illinois, Kansas, Minnesota	1,200–11,000
Ambrosia artemisiifolia (common ragweed)	Soybean	Arkansas, Missouri, Kansas	<150
Ambrosia trifida (giant ragweed)	Cotton, soybean	Ohio, Arkansas, Indiana, Kansas, Minnesota, Tennessee	2,000–12,000
Conyza canadensis (horseweed)	Corn, cotton, soybean	14 states	> 2,000,000
Kochia scoparia (kochia)	Corn, soybean	Kansas	51-100
Lolium multiflorum (Italian ryegrass)	Cotton, soybean	Mississippi	1000–10,000
Sorghum halepense (Johnsongrass)	Soybean	Arkansas	Unknown

[a]Minimum and maximum acreages are based on expert judgments provided for each state. The estimates were summed and rounded to provide an assessment of the minimum and maximum acreages in the United States. These values indicate orders of magnitudes but do not provide precise information on abundance of resistant weeds.

Other Shifts in Weed Communities

Factors other than the evolution of glyphosate resistance affect the composition of weed species in the field. Changes in the tillage system used in growing HR crops are probably the most important factor in promoting weed shifts because disturbance is a primary selective force (Buhler, 1992). In addition, weeds that escape glyphosate applications by germinating after the last application can have an advantage in glyphosate-resistant crops (Hilgenfeld et al., 2004; Owen and Zelaya, 2005; Puricelli and Tuesca, 2005; Scursoni et al., 2007; Wilson et al., 2007; Owen, 2008). Table 2-2 lists weed species that have been found to be naturally tolerant to the conditions prevalent in the fields where glyphosate-resistant crops are grown and have become more abundant after the widespread adoption of these crops. Shifts in local weed communities have been observed more frequently in glyphosate-resistant cotton and soybean than in glyphosate-resistant corn, probably because glyphosate-resistant cotton and soybean are more widely cultivated than glyphosate-resistant corn (Culpepper, 2006). However, where glyphosate-resistant corn and glyphosate-resistant soybean are commonly rotated (e.g., in the Midwest), strong selection pressure exists for the evolution of glyphosate-resistant weeds because the management tactics vary so little between the two crops.

Farmers' Response to Glyphosate Resistance in Weeds

The evolution of glyphosate resistance in some kinds of weeds and other weed shifts can diminish the technical and economic efficiency of weed control. However, because glyphosate allows producers to control a wide array of weeds conveniently and economically, they have been reluctant to stop using glyphosate-resistant crops and glyphosate when facing control problems arising from a few glyphosate-resistant or naturally glyphosate-tolerant weed species. For controlling problematic weeds, they prefer increasing the magnitude and frequency of glyphosate applications, using other herbicides in addition to glyphosate, or increasing their use of tillage.

TABLE 2-2 Weeds Reported to Have Increased in Abundance in Glyphosate-Resistant Crops

Species	Crop	Location	Reference
Acalypha spp. (copperleaf)	Soybean	—	Owen and Zelaya, 2005; Culpepper, 2006
Amaranthus tuberculatus (waterhemp)	Soybean	—	Owen and Zelaya, 2005
Amaranthus palmeri (Palmer amaranth)	Cotton	—	Culpepper, 2006
Annual grasses	Cotton	—	Culpepper, 2006
Chenopodium album (common lambsquarters)	Soybean	Iowa, Minnesota	Owen, 2008
Commelina communis (Asiatic dayflower)	Cotton, soybean	Midwest, Midsouth, Southeast	Owen and Zelaya, 2005; Culpepper, 2006; Owen, 2008
Commelina benghalensis (tropical spiderwort)	Cotton	Southeast, Georgia	Owen, 2008; Mueller et al., 2005
Cyperus spp. (nutsedge)	Cotton	—	Culpepper, 2006
Equisetum arvense (field horsetail)	Herbicide-resistant crops	—	Owen, 2008
Oenothera biennis (evening primrose)	Herbicide-resistant crops	Iowa	Owen, 2008
Oenothera laciniata (cutleaf evening primrose)	Soybean	—	Culpepper, 2006
Pastinaca sativa (wild parsnip)	Herbicide-resistant crops	Iowa	Owen, 2008
Phytolacca americana (pokeweed)	Herbicide-resistant crops	—	Owen, 2008
Ipomoea spp. (annual morning glory)	Cotton	—	Culpepper, 2006

For example, soybean growers in Delaware continued planting glyphosate-resistant soybean even in the presence of widespread glyphosate resistance in horseweed (Scott and VanGessel, 2007). Most producers addressed the problem by applying an herbicide with a different mode of action, increasing the frequency of glyphosate applications, or using tillage before planting. Some 76 percent of growers estimated that resistance in horseweed increased their management costs by more than $2.02/acre, and 28 percent reported cost increases of over $8.09/acre (Scott and VanGessel, 2007). Similarly, a survey of 400 corn, soybean, and cotton producers in 17 states found that most would not limit the use of glyphosate-resistant crops when facing problematic glyphosate-resistant weeds (Foresman and Glasgow, 2008). Instead, producers planned to increase the rotation of herbicides, the use of tank-mixes, or the amount of tillage. They expected that additional measures for the control of glyphosate-resistant weeds would cost $13.90–16.30/acre (Foresman and Glasgow, 2008).

In an economic analysis of weed-management costs with a hypothetical reduction of control with glyphosate in three regions of the United States, the projected cost of new resistance-

Copyright © National Academy of Sciences. All rights reserved.

Impact of Genetically Engineered Crops on Farm Sustainability in the United States
http://www.nap.edu/catalog/12804.html

management practices for horseweed was $12.33/acre in a cotton–soybean–corn rotation in western Tennessee (Mueller et al., 2005). Additional costs were due to a shift from no-till to conventional tillage for cotton and the need for new preplant herbicides for soybean. The projected cost of new herbicide resistance-management practices for waterhemp was $17.91/acre in a corn–soybean rotation in southern Illinois; this cost resulted from use of different pre-emergence and postemergence herbicides for soybean (Mueller et al., 2005). For cotton grown in Georgia, the extra cost of controlling shifts in tropical spiderwort (*Commelina benghalensis*), a weed that is naturally tolerant to glyphosate, was predicted to be $14.91/acre; an additional herbicide application after cotton emergence explained this cost (Mueller et al., 2005).

Those studies indicate that the evolution of glyphosate resistance and weed shifts could lead to two important changes in practices: increased use of herbicides generally and reductions in conservation tillage (Mueller et al., 2005). Such changes would also increase weed-management costs and reduce producers' profits, and the environmental consequences of those practices, if they were widely adopted by producers of HR crops, would negate the environmental benefits previously achieved.

In summary, most glyphosate-resistant weeds in HR crops are of economic importance in row crops grown in the Southeast and Midwest. The number of weed species evolving resistance to glyphosate is growing (Figure 2-6), and the number of locations with glyphosate-resistant weeds is increasing at a greater rate, as more and more acreage is sprayed with glyphosate. Though the number of weeds with resistance to glyphosate is still small compared to other common herbicides,[5] the shift toward glyphosate-resistant weed biotypes will probably become an even more important component of row-crop agriculture unless production practices (such as recurrent use of glyphosate) change dramatically (Gressel, 1996; Owen and Zelaya, 2005; Johnson et al., 2009).

Implications of Weed Shifts in Herbicide-Resistant Cropping Systems

As noted above, because the adoption of HR crops has facilitated an increase in conservation tillage and reduced the number of herbicides that growers use to control weeds, the selection pressures affecting weed communities has changed. Unsurprisingly, managing weeds through glyphosate applications to HR crops favors the evolution of glyphosate resistance in weeds occurring in these crop fields (Shaner, 2000; Mueller et al., 2005; Foresman and Glasgow, 2008; Powles, 2008). Addressing the problem of resistance—a problem not unique to HR crops—requires careful thought about management practices and other potential solutions based on a clear understanding of how genes that code for resistance are distributed throughout a population of a weed species.

Principles of Population Genetics Underlying Resistance in Weeds

Similar concepts have been used to understand the evolution of resistance to glyphosate in weeds and to the Bt toxin in insects. Population-genetic models and empirical data on factors that

[5]For example, 38 weeds have developed resistance to some acetyl-CoA carboxylase (ACCase), and resistance to some acetolactate synthase (ALS) inhibitors has been documented in 107 worldwide.

affect how resistance evolves have been applied to the management of both herbicide-resistant weeds and Bt-resistant insects (Jasieniuk et al., 1996; Werth et al., 2008). However, strategies for delaying the evolution and spread of resistance are not the same because there are important underlying differences in the population genetics of herbicide resistance and insect resistance.

Resistance to herbicides, and in particular to glyphosate, is often conferred by a single nuclear gene (Jasieniuk et al., 1996; Powles and Preston, 2006). Herbicide resistance in weeds is rarely recessive;[6] in all cases studied, resistance to glyphosate was additive to dominant, that is, individuals with a single resistance allele can survive applications of glyphosate (Jasieniuk et al., 1996; Zelaya et al., 2004; Powles and Preston, 2006; Zelaya et al., 2007; Neve, 2008). Furthermore, even if resistance is recessive in some weeds, many weeds are self-pollinating, so a recessive gene for resistance could become homozygous in only a few generations and thus confer resistance to all offspring (Gould, 1995; Jasieniuk et al., 1996). Some agronomically important weeds (such as, pigweed) are dioecious (having separate male and female plants) and thus are cross-pollinated. They have demonstrated the ability to evolve resistance to glyphosate although the genetics of the process have not been described.

Finally, even though the seeds of some weed species can disperse over long distances (Shields et al., 2006), dispersal of viable pollen generally occurs over short distances (Jasieniuk et al., 1996; Roux et al., 2008). Therein lies an important difference between weeds and insects and hence the availability of strategies, such as refuges, to control weed resistance. For all the reasons described above, maintaining a refuge—an area where susceptible weeds are not

[6]Plants carry two alleles (forms) of the same gene for glyphosate resistance. Each allele exerts influence on the nature of that trait; saying that resistance is recessive means that one allele is not sufficient to confer resistance. Offspring that inherit one allele with the resistant trait and one without will not be resistant, while offspring that inherits two of the same form of the allele that confers resistance will be resistant.

exposed to glyphosate and would persist to interbreed with resistant biotypes—cannot be expected to lower the heritability of herbicide resistance in weeds as it lowers the heritability of Bt resistance in insects targeted by Bt crops (Jasieniuk et al., 1996). The refuge strategy for Bt-resistant insects is discussed later in this chapter (see "Evolution and Management of Insect Resistance").

Although the use of refuges cannot be expected to delay the evolution of glyphosate resistance in weeds, the spread of herbicide resistance can be delayed by reducing the selective differential (the difference in survival and other fitness traits) between individuals with and without resistance alleles (Gressel and Segel, 1990; Jasieniuk et al., 1996; Werth et al., 2008). That can be accomplished by using control practices that kill weeds that have the resistance alleles. For example, the use of tank-mixes that contain two or more herbicides with different modes of action may be effective if the herbicides have high efficacy in controlling the target weeds. Similarly, herbicides with different modes of action or methods that combine herbicides and mechanical weed control (tillage) may be used sequentially to control the same generation (i.e., emergence cohort) of weeds.

The selective differential between individuals with and without resistance alleles can also be reduced by rotating the types of herbicides used to control the target weeds so that selection for resistance to a specific herbicide occurs only in alternate growing seasons (Jasieniuk et al., 1996; Roux et al., 2008). When no fitness costs[7] are associated with resistance, the rotation of herbicides contributes to equalizing the fitness of individuals that are resistant to and susceptible to a herbicide during seasons when the herbicide is not used. Models suggest that the evolution of resistance to the rotated herbicides will be delayed by 1 year for each year that the rotation tactic is used (Maxwell and Jasieniuk, 2000). When fitness costs are associated with resistance to a herbicide (Gressel and Segel, 1990; Jasieniuk et al., 1996; Baucom and Mauricio, 2004), the fitness of individuals that have resistance alleles is lower than the fitness of individuals that do not during seasons when the herbicide is not used. Therefore, herbicide rotation contributes to reducing the selective differential between individuals with and without resistance alleles over time, which may delay the evolution of resistance (Jasieniuk et al., 1996; Roux et al., 2008).

Reduction in the selective differential can be accomplished by rotating the type of crops grown in a field between growing seasons; this may result in drastic changes in the types of herbicides used. Changes in ecological conditions associated with cultivation of different crops could favor declines in particular weed species (which could be resistant or tolerant to glyphosate) or induce competitive disadvantages in herbicide-resistant weeds through negative cross-resistance, in which resistance to one chemical confers hypersensitivity to another chemical (Gressel and Segel, 1990; Boerboom, 1999; Owen and Zelaya, 2005; Beckie et al., 2006; Murphy and Lemerle, 2006).

Developing Weed-Management Strategies for Herbicide-Resistant Crops

How might the various strategies be used in the context of HR cropping systems? Tank-mixes and sequences of herbicides to extend the useful life of herbicides could be employed if

[7]Some genes that confer resistance affect the biological or physiological viability of an organism adversely in absence of a pesticide, and carriers of such a gene tend to become rarer in the population over time. The fitness cost is the extent to which such a penalty on fitness exists.

Impact of Genetically Engineered Crops on Farm Sustainability in the United States
http://www.nap.edu/catalog/12804.html

crop cultivars that are resistant to two or more herbicides are developed; this strategy is currently favored by biotechnology companies (Duke, 2005; Behrens et al., 2007; Green et al., 2008; Green, 2009). As for using crop rotations, the increasingly common practice of farmers throughout the United States of using glyphosate as the primary or only weed-management tactic in rotations of different glyphosate-resistant crops limits the application of the rotation strategy, even if the change in crop-induced ecological changes might improve weed management. A possible solution could be to combine the rotation of two or more HR cultivars that each can tolerate only one herbicide with the use of a different herbicide at each rotation. For example, different varieties of GE canola (*Brassica napus* L.) grown in the prairie provinces of Canada were engineered for resistance to glufosinate or glyphosate. That allowed producers to include two types of HR canola into a canola–wheat–barley rotation so that canola resistant to glufosinate or glyphosate would be grown only once every 4 years in a particular field (Powles, 2008). In contrast with corn, soybean, and most cotton production, growing crop species like canola, in which hybridization between the crop and weedy relatives is possible, poses a risk of gene flow between the HR crop and the weedy relatives (Beckie et al., 2003; Légère, 2005; see also "Gene Flow Between Genetically Engineered Crops and Related Weed Species").

The same rotation strategy could be used with HR crops that are resistant to two (or more) herbicides; the same crop would be grown twice during the rotation" cycle, but each of the two herbicides that it can resist would be applied only every other year. Genes that confer resistance to some acetyl-CoA carboxylase (ACCase) inhibitors, synthetic auxins (e.g., 2, 4-D), acetolactate synthase (ALS) inhibitors, dicamba, glufosinate, glyphosate, and hydroxyphenylpyruvate dioxygenase (HPPD) inhibitors are the most likely candidates for production of the next generation of HR varieties that are resistant to multiple herbicides (Duke, 2005; Behrens et al., 2007; Green, 2009). So far, weed resistance to glufosinate and HPPD inhibitors has not been reported. Weed resistance to dicamba has not been reported in corn, cotton, or soybean but has appeared in other crops in the United States (Heap, 2010). However, weed resistance to some ACCase inhibitors, synthetic auxins, and ALS inhibitors has been reported in corn, cotton, and soybean (Heap, 2010). Moreover, most weed species that have evolved resistance to glyphosate in fields of HR crops (Table 2-1) also have evolved resistance to ALS inhibitors (Heap, 2010).

From the point of view of herbicide-resistance management and the long-term efficacy of an HR crop, it may be better to engineer a crop for resistance to herbicides that can efficiently control most weeds associated with the crop. For example, genes that confer resistance to ALS inhibitors, to which many weed species are already resistant, could be inferior to genes that confer resistance to dicamba, glufosinate, and HPPD inhibitors to produce durable HR corn, cotton, and soybean resistant to two or more herbicides. Similarly, care should be taken to engineer crops for resistance to specific ACCase inhibitors and synthetic auxins that will still be effective in controlling weeds associated with future HR crops.

If crops that are resistant to multiple herbicides—including ALS inhibitors, ACCase inhibitors, synthetic auxins, and glyphosate—are widely planted, continued use of the herbicides in fields that contain weeds already resistant to some of them could involve a risk of selecting for high levels of multiple herbicide resistance. The ability of weeds to evolve biotypes that have multiple herbicide resistance has already been demonstrated in waterhemp populations in Illinois and Missouri that are resistant to three herbicide mechanisms of action (Patzoldt et al., 2005; Legleiter and Bradley, 2008). Evolved multiple resistance will exacerbate problems of controlling some key herbicide-resistant weeds, and local and regional spatially explicit information on the distribution of weeds that are resistant to glyphosate and other herbicides

Copyright © National Academy of Sciences. All rights reserved.

Impact of Genetically Engineered Crops on Farm Sustainability in the United States
http://www.nap.edu/catalog/12804.html

could be useful in helping to manage such a situation (Werth et al., 2008). Tank-mixes and sequencing herbicides rely on redundancy to be effective. Models assessing sequential use of herbicides only, or of herbicides and mechanical weed control, indicate that a low frequency of alleles conferring resistance to herbicides and high weed mortality are critical factors for these strategies to substantially delay the evolution of weed resistant to glyphosate in HR crops (Neve et al., 2003; Neve, 2008; Werth et al., 2008).

In conclusion, regardless of the specific herbicide for which HR crops are genetically engineered, only appropriate stewardship by the grower will delay the evolution of resistance to the herbicide. Resistance management is voluntary in the United States for all pesticides except Bt produced by Bt crops (Berwald et al., 2006; Thompson et al., 2008). Given the rapid increase in and expansion of weeds that are resistant to glyphosate in HR crops, herbicide-resistance management needs national attention. As discussed previously, the rapid evolution of weed resistance to glyphosate has probably been a consequence of growers' management decisions that favored the use of glyphosate as the primary, if not sole, tactic to control weeds despite efforts in the private and public sectors to strongly recommend alternative strategies (Johnson et al., 2009). Without changes in production practices, the increase in weeds resistant to glyphosate will likely increase weed-management expenses for farmers. The evolution of herbicide resistance and other weed shifts associated with the adoption of GE crops requires the development and use of more effective weed-management strategies and tactics (Beckie, 2006; Murphy and Lemerle, 2006; Green et al., 2008; Gustafson, 2008; Powles, 2008; Werth et al., 2008).

Diversification of weed-management strategies can be accomplished by integrating several weed-control tactics: herbicide rotation, herbicide application sequences, and the use of tank-mixes of more than one herbicide; the use of herbicides that have different modes of action, methods of application, and persistence; cultural and mechanical control practices; and equipment-cleaning and harvesting practices that minimize the dispersal of herbicide-resistant weeds. Although the strategies to mitigate weed shifts are readily identified, they have largely been ignored because of the scale of commercial agriculture, which favors the simplicity, convenience, and short-term success of herbicide use over more time-consuming strategies that can be burdensome to implement on farms (Shaner, 2000; Mueller et al., 2005; Johnson and Gibson, 2006; Sammons et al., 2007; Owen, 2008). Furthermore, increased reliance on glyphosate for weed control in glyphosate-resistant crops has reduced the price of other herbicides in the United States and has limited efforts to develop new herbicides (Shaner, 2000; Duke, 2005). Companies are increasingly focused on expanding the use of currently registered herbicides, which can be achieved by commercializing GE crops that are resistant to more than one herbicide (Duke, 2005; Green, 2007, 2009). Delaying the evolution of resistance to herbicides that are used with HR crops and minimizing other weed shifts are particularly important in this context because new herbicides may not be readily available to replace ones that become ineffective when resistance evolves. Therefore, farmers would benefit from focusing on more diverse, longer-term weed-management strategies to preserve the effectiveness of HR crops and to minimize the possibility of more expensive control tactics in the future.

ENVIRONMENTAL IMPACTS OF INSECT-RESISTANT CROPS

The adoption of Bt crops has changed insect-management strategies for most corn and cotton farmers in the United States. Those changes have implications for pest populations, soil

Copyright © National Academy of Sciences. All rights reserved.

Impact of Genetically Engineered Crops on Farm Sustainability in the United States
http://www.nap.edu/catalog/12804.html

conditions, and the management of insect pests in the future. The following section evaluates the impact of insect-resistant (IR) crop adoption on pest populations, on nontarget insects, and on soil quality. It also investigates resistance-management strategies and concerns related to the continued effectiveness of IR crops.

Levels of Insecticide Use

Insecticide Use in Corn

Insecticide use in corn (in pounds per acre) has steadily declined since 1997 as the adoption of Bt corn (which reached 50 percent of corn acres planted in 2007) has increased (Figure 2-7). Bt corn was introduced in the mid-1990s to control the European corn borer (*Ostrinia nubilalis*). Because chemical control of the European corn borer was not always profitable (and timely application was difficult) before the introduction of Bt corn, many farmers accepted yield losses rather than incur the expense and uncertainty of chemical control. For those farmers, the introduction of Bt corn resulted in yield gains rather than pesticide savings (Fernandez-Cornejo and Caswell, 2006). However, a new type of Bt corn introduced in 2003 to protect against corn rootworm (*Diabrotica* spp.), which was previously controlled with chemical insecticides and crop rotation, has provided substantial insecticide savings (Fernandez-Cornejo and Caswell, 2006).

Insecticide Use in Cotton

Cotton has the highest traditional use of insecticides per acre and the highest rate of adoption of Bt crops, reaching almost 60 percent in 2007, 12 years after Bt cotton was first commercialized (Figure 2-8). Insecticide use has fallen (in pounds per acre) over the same period, but fluctuations in total cotton insecticide applications have also been strongly affected by the boll weevil eradication program[8] (Fernandez-Cornejo et al., 2009).

[8]Since the 1970s, cotton growers and governments have worked toward eradicating the boll weevil, a beetle that affects cotton and that is not directly affected by Bt cotton. Different cotton-growing regions joined the program in different years. Typically, the first year of participation entails heavy application of pesticides (generally malathion). In subsequent years, the boll weevil population is monitored and treated as needed. A new wave of cotton-growing regions began participating in 1993. The spike in cotton insecticide applications in 1999 and 2000 coincides with the entry of 2 million cotton acres into the program in Texas (Fernandez-Cornejo et al., 2009).

Regional Pest Reductions

Corn and cotton that produce Bt toxins can cause high mortality in insect pest populations in which Bt-resistance alleles are rare. For example, mortality in pink bollworm (*Pectinophora gossypiella*) and tobacco budworm (*Heliothis virescens*) on Cry1Ac cotton is virtually 100 percent throughout the growing season (Tabashnik et al., 2000; Showalter et al., 2009) . However, mortality in the moths *Helicoverpa armigera* and *Helicoverpa zea*[9] on Cry1Ac cotton is typically lower than 95 percent and declines during the growing season (Kennedy and Storer, 2000; Olsen et al., 2005; Tabashnik et al., 2008; Showalter et al., 2009). Crops that produce more than one Bt toxin generally cause higher mortality than crops that produce a single toxin although declines in mortality during the growing season may still be observed (Adamczyk et al., 2001; Bommireddy and Leonard, 2008; Mahon and Olsen, 2009; Showalter et al., 2009).

Because Bt crops can cause high pest mortality, it has been postulated that one effect of the widespread use of Bt crops is a reduction in some pest populations regionally (Kennedy et al., 1987; Alstad and Andow, 1995; Roush, 1997; Gould, 1998; Kennedy and Storer, 2000; Storer et

[9] *Helicoverpa armigera* and *Helicoverpa zea* are known by many common names, depending on the host plant. *Helicoverpa armigera* is referred to as old world bollworm or cotton bollworm (when it feeds on cotton), pod borer (when it feeds on chickpea or pigeon pea), tomato fruit borer (when it feeds on tomato), and corn earworm (when it feeds on corn). *Helicoverpa zea* is often called cotton bollworm, corn earworm, or tomato fruitworm.

Impact of Genetically Engineered Crops on Farm Sustainability in the United States
http://www.nap.edu/catalog/12804.html

al., 2003). According to that idea, an area-wide decline in pest abundance could occur because replacing non-Bt crop fields with Bt crop fields eliminates suitable habitats for the pests. If females lay eggs on Bt plants and on non-Bt host plants, laying eggs on Bt plants could substantially reduce the number of surviving offspring produced by females and cause a decline in pest density (Riggin-Bucci and Gould, 1997; Carrière et al., 2003; Shelton et al., 2008). Models have suggested that the suppression of pest populations is more likely as mortality induced by Bt crops increases, the abundance of Bt crops and female movement between patches of Bt and non-Bt plants increase, and the net reproductive rate in patches of non-Bt hosts decreases (Carrière et al., 2003). However, polyphagous pest species (those able to feed on multiple types of plants) often exploit crops sequentially during the growing season, tracking changes in host suitability (Kennedy and Storer, 2000). In some cropping systems, the feeding options of such pests might be limited to only a Bt crop for a few generations, when it is the only suitable resource available. Thus, Bt crops could affect pest population dynamics even when the crops are relatively rare (Kennedy et al., 1987; Wu et al., 2008).

Long-term monitoring of insect-pest density before and after commercialization of Bt crops has provided evidence that deployment of Bt crops influences pest population dynamics regionally. Table 2 3 contains the results of pest-monitoring studies in the United States and China. Most of the studies covered a single region where spatially explicit data on the distribution of Bt crops were not available, but in one study of pink bollworm population density in Arizona from 5 years before to 5 years after introduction of Bt cotton, the abundance of Bt and non-Bt cotton fields in 15 cotton-growing regions was quantified with geographical information system technology (Carrière et al., 2003). In regions with less than an average of 65 percent Bt cotton in the second 5-year period, the introduction of Bt cotton had no consistent effect on population density of pink bollworm; in regions with more than 65 percent Bt cotton, the introduction of Bt cotton decreased pink bollworm population density, and the extent of the decline increased as the percentage of Bt cotton increased. Those data are consistent with modeling results and suggest that pest-population suppression occurs if the area of Bt crops exceeds a threshold percentage of Bt cotton (Carrière et al., 2003). Another recent study of the European corn borer conducted in five major U.S. corn-producing states indicated that suppressive effects of Bt corn depended on the extent of adoption of the technology (Hutchison et al., 2007).

Storer et al. (2008) noted that producers, extension agents, and pesticide appliers reported less serious insect-pest control problems in non-Bt crops, such as soybean and vegetables, after the regional suppression of the European corn borer and the corn earworm (*H. zea*) by Bt corn in Maryland. As a comparison to the U.S. experience, a study conducted in six provinces of China from 1997 to 2006 documented a progressive decline in the population density of cotton bollworm (*H. armigera*) after the introduction of Bt cotton (Wu et al., 2008) (Table 2-3). The significant suppression of cotton bollworm occurred not only in Bt and non-Bt cotton but in corn, peanut, soybean, and vegetables. Wu et al. (2008) proposed that the regional decline of cotton bollworm populations could reduce insecticide use in crops other than cotton. Nevertheless, the economic consequences of the regional suppression of pests by Bt crops have been investigated only for European corn borer in five U.S. Corn Belt states (Hutchison et al., 2007). It was estimated that regional declines in European corn borer population densities during the last 14 years in those states saved at least $3.9 billion for producers of non-Bt corn and $6.1 billion for producers of Bt and non-Bt corn combined. Further detailed spatially explicit studies of the association between the distribution of Bt crops and pest problems on different scales will be helpful in improving understanding of how the use of Bt crops can reduce pest abundances (Marvier et al., 2008).

The use of Bt crops sometimes changes pest-management practices enough to increase problems related to pests that are not killed by Bt toxins. For example, substantial reductions in the use of synthetic insecticides on Bt cotton favored outbreaks of mirids and leafhoppers in China (Wu et al., 2002; Men et al., 2005). Those pests had been well controlled by insecticides before the introduction of Bt cotton. Similarly, lower use of insecticides in Bt cotton probably contributed to the higher stink bug damage in cotton in some southern U.S. states although the regional increases in stink bug populations were probably influenced by other factors as well (Greene et al., 2001; Greene et al., 2006). Changes in pest-management practices in connection with Bt crops can also have favorable consequences for the control of some pests that are not killed by Bt toxins. For example, a reduction in insecticide use on Bt cotton was sometimes associated with greater predator abundance and better pest control in cotton aphid in the United States (see section "Natural Enemies").

Reversal of Insect Resistance to Synthetic Insecticides

The deployment of Bt crops is known to promote a reversal of pest resistance to synthetic insecticides, but this has not yet been observed in United States. In northern China, the reduction in use of insecticides on Bt cotton contributed to restoring cotton bollworm (*H. armigera*) susceptibility to some synthetic insecticides (Wu et al., 2005; Wu, 2007) although fitness costs associated with insecticide resistance likely helped to increase susceptibility. Similarly, resistance to pyrethroid insecticides declined considerably in tobacco budworm (*H. virescens*) after the introduction of Bt cotton in southern Tamaulipas, Mexico (Terán-Vargas et al., 2005). The renewed efficacy of insecticides provided more pest-management options to producers in those regions. However, such reversals in insecticide resistance do not always occur. For example, the planting of Bt cotton in Louisiana did not change the high levels of pyrethroid resistance in tobacco budworm (*H. virescens*) and cotton bollworm (*H. zea*) (Bagwell et al., 2001), and *H. zea* resistance to pyrethroids increased substantially after the planting of Bt cotton in several regions of Texas (Pietrantonio et al., 2007).

Impact of Genetically Engineered Crops on Farm Sustainability in the United States
http://www.nap.edu/catalog/12804.html

Effects on Nontarget Species

Bt toxins are considered acutely toxic to a relatively narrow array of invertebrate taxa when compared with broad-spectrum insecticides because toxicity through direct ingestion of a Bt toxin is typically restricted to insects in the same order as the target pest (Schnepf et al., 1998; Glare and O'Callaghan, 2000; van Frankenhuyzen and Nystrom, 2002; Mendelsohn et al., 2003). For example, the endotoxins Cry1Aa, Cry1Ab, and Cry1Ac kill mainly particular moths and butterfly species, while Cry3Aa and Cry3Bb mainly kill particular beetle species. Furthermore, because Bt toxins are specific, they cause different mortality within targeted insect orders. For example, the cotton cultivar Bollgard I®, which produces the toxin Cry1Ac and targets lepidopteran pests, kills virtually 100 percent of pink bollworm and tobacco budworm (*H. virescens*), between 24–95 percent of cotton bollworms *H. zea* and *H. armigera*, and less than 4 percent of fall armyworm (*Spodoptera frugiperda*) and beet armyworm (*Spodoptera exigua*) (Showalter et al., 2009). Field studies have revealed relatively few adverse effects of Bt crops on arthropods that are not closely related to the target pests (Cattaneo et al., 2006; Romeis et al., 2006). In contrast, broad-spectrum insecticides, such as pyrethroids and organophosphates had consistent, adverse effects on a wide array of nontarget arthropods (Cattaneo et al., 2006; Romeis et al., 2006).

Although the high specificity of Bt crops for the control of target pests is consistent with integrated pest management, they may have effects on beneficial organisms. For example, the larvae of nontarget moths or butterflies in the landscape surrounding farms may be susceptible to Bt toxins that target pests in this group, but they would need to eat the Bt plant material to be affected. Bt corn byproducts that enter streams may affect aquatic insects in related taxa (Rosi-Marshall et al., 2007). The abundance of some natural enemies may decrease when their host or prey species are susceptible to Bt toxins and as a result become rare or nutritionally less suitable (Romeis et al., 2006).

Quantifying and predicting the effects of Bt crops on nontarget invertebrate species has been the subject of considerable work. As compiled by Marvier et al. (2007) and Naranjo (2009), research on the nontarget effects of Bt crops includes 135 laboratory studies of nine Bt crops and 22 Bt Cry proteins or protein combinations and 63 field studies of five Bt crops and 13 Bt proteins. In total, field and laboratory studies of at least 99 and 185 invertebrate species, respectively, have been conducted although not with equal effort. Most of the field studies have been of corn and cotton. Individual study results vary, so evidence-based generalizations are elusive in the absence of formal approaches. A review of recent syntheses provides an overview of the generalizations that have emerged thus far from those efforts.

For cotton and corn, whether Bt crop fields have more or fewer nontarget invertebrates depends on whether one compares the Bt crop to a conventional counterpart that received insecticide treatments (Marvier et al., 2007; Wolfenbarger et al., 2008; Naranjo, 2009). Collectively, studies have indicated that a higher total abundance of arthropods occurred in Bt fields than in conventional fields sprayed with insecticides and a lower abundance than in conventional fields with no insecticide treatment (Marvier et al., 2007). For Bt corn, the magnitude of the effect also depended on whether studies tested Bt176 (no longer registered for use) or the MON810 (commercially used) Bt events. Lower abundance of specific taxa was found in Bt fields than in unsprayed, non-Bt fields; the taxa in question included moths, butterflies, beetles, and true bugs on cotton and wasps on corn. Differences in the availability of prey or in survival may explain those results (Marvier et al., 2007).

Impact of Genetically Engineered Crops on Farm Sustainability in the United States
http://www.nap.edu/catalog/12804.html

Bt potato crop fields without insecticide use contained higher abundances of predators, natural enemies as a whole, and nontarget pests compared to conventional potato fields, whether or not insecticides were applied to the conventional fields (Wolfenbarger et al., 2008).

Natural Enemies

Maintenance of healthy populations of predators of crop pests is a desirable goal for ensuring long-term environmental sustainability of farms. Decreasing the numbers of predators, which in practice will be related to the overall biodiversity in an area and to on-farm pest control (Landis et al., 2008), would be undesirable. Even in systems where a single predator may suffice as a biocontrol agent, redundancy is an important tool for ensuring ecosystem services.

The few studies comparing biological control (by parasitism and predation rates) between Bt and conventional crops have suggested that control of nontarget pests on Bt crops was enhanced on cotton (Head et al., 2005) or similar on cotton (Naranjo, 2005) and corn (Pons and Starý, 2003; Naranjo, 2005) and that control of target pests on Bt crops was enhanced on cotton (Head et al., 2005), similar on cotton (Sisterson et al., 2004b; Naranjo, 2005) and corn (Orr and Landis, 1997; Sisterson et al., 2004b; Naranjo, 2005), or reduced on corn (Siegfried et al., 2001; Bourguet et al., 2002; Manachini, 2003; cited by Naranjo, 2009). Maintenance of biological control of nontarget pests in one study occurred in Bt cotton fields in spite of about a 20 percent reduction in the abundance of some common predators (Naranjo, 2005). When Bt crops have completely replaced insecticide-treated conventional crops, studies have consistently reported higher numbers of predators on cotton, corn, and potato. When Bt crops have replaced non-insecticide-treated conventional crops, results studies have consistently indicated slightly fewer predators on Bt cotton and no detectable difference on Bt corn (Wolfenbarger et al., 2008; Naranjo, 2009).

Field studies of parasitoids have overemphasized specialist species of the target pest of Bt corn, so generalizations to parasitoids as a group are premature. The studies have revealed a pattern similar to that of predators: fewer parasitoids in conventional corn fields sprayed with insecticides and no detectable difference between Bt corn fields and conventional corn fields not treated with insecticides. Laboratory studies indicate that effects of Bt toxins on parasitoids depend on whether they are fed prey that are susceptible to Bt toxins (Zwahlen et al., 2000; Dutton et al., 2002; Schuler et al., 2003; Schuler et al., 2004; Romeis et al., 2006). Syntheses of laboratory studies of 14 parasitoid species indicate a favorable or neutral effect on life-history traits when they were fed prey that had ingested a Bt toxin but were not affected by it (high-quality prey). Conversely, studies have shown longer development times, lower reproduction, and lower survival if the parasitoids were fed prey that had ingested a Bt toxin that was toxic to them (low-quality prey) (Naranjo, 2009).

The adoption of Bt cotton increases abundances of natural enemies and hence the potential for biological control when it completely replaces insecticide treatments. Moth larvae were responsible for a large fraction of cotton insect losses before the adoption of Bt cotton, but cotton-insect losses caused by these larvae have become less important now that Bt cotton has been widely adopted. The five major insect pests of cotton in the United States in 2008 were lygus bugs (1 percent yield loss), bollworms and budworms (0.76 percent yield loss), stink bugs (0.75 percent yield loss), thrips (0.52 percent yield loss), and cotton fleahoppers (0.23 percent yield loss) (Williams, 2008). Among those, only bollworms and budworms are controlled by Bt cotton, so the use of Bt cotton rarely eliminates all insecticide applications. Actual farm-level

Impact of Genetically Engineered Crops on Farm Sustainability in the United States
http://www.nap.edu/catalog/12804.html

reductions in insecticide use for Bt cotton would probably increase the abundance of nontarget insects less consistently (e.g., Cattaneo et al., 2006; Sisterson et al., 2007) than what has been observed in experimental studies in which the use of Bt cotton completely replaced insecticide treatments.

Pollinators and Other Valued Insects

The honey bee (*Apis mellifera*) is one of the agricultural sector's most important pollinators. Laboratory toxicity studies of honey bees have consistently found no evidence that Bt pollen or Bt proteins decrease honey-bee larval or adult survival (Duan et al., 2008) even at toxin concentrations well beyond what would be encountered in the field. There have been laboratory or field studies of few other species (Wolfenbarger et al., 2008; Naranjo, 2009); no consistent effect on development time (eight studies) or survival (20 studies) has been detected in laboratory tests, but effects varied widely among studies, particularly for development time (Naranjo, 2009). Laboratory studies collectively have indicated longer development time and lower survival of valued insect herbivores, a category that includes charismatic species (e.g., monarch butterfly larvae), and moths of economic importance (e.g., the silkworm) (Naranjo, 2009).

Summary of Nontarget Effects

The abundance of natural enemies on Bt crops can be greater than, the same, or lower than on non-Bt crops. The magnitude of the benefit depends on the extent to which a Bt crop substitutes for the use of insecticide treatments of non-Bt crops and on whether insecticides for other pests are used on the Bt crop. Honey-bee adults and larvae were not harmed by Bt pollen or Bt proteins, but too few pollinators have been studied to support generalizations about the group as a whole. As the sophistication of GE-crop varieties increases and the functional roles of arthropods become understood more fully, it should be possible to develop strategic pest-management systems that maintain high crop productivity while avoiding effects on nontarget moths, butterflies, and beetles.

Soil Quality

Overall, it appears that current Bt crops have no greater or less effect on soil quality than the crops that they have replaced. Many peer-reviewed studies have addressed the nontarget impacts of Bt crops on soil organisms. Specifically, studies have considered the effects of plant residues on the soil community because plants are the primary source of carbon in soils. If Bt toxins affect soil microorganisms, rates of decomposition and nutrient cycling may be altered. Studies have also focused on the consequences of Bt-containing root exudate. Root exudate influences the soil community, especially the community of distinct, specialized soil microorganisms associated with roots.

Most assessments of the effects of Bt insecticidal proteins on soil microorganisms and other organisms have found that these proteins do not substantially alter microbial populations and measured functions (Icoz and Stotzky, 2008). Over four years of continuous corn cultivation, Bt plant residues and root exudates had no consistent or persistent effect on a breadth of

Copyright © National Academy of Sciences. All rights reserved.

Impact of Genetically Engineered Crops on Farm Sustainability in the United States
http://www.nap.edu/catalog/12804.html

microorganisms or their enzymatic activity in the soil, but differences were detected according to plant species, variety, and age as well as other environmental factors (Icoz et al., 2008). With respect to macroorganisms, Lang et al. (2006) found no significant differences in earthworm or springtail population density or biomass between soils with Bt and with non-Bt corn or between soils with corn treated and not treated with insecticide (baythroids) at five sites during 4 years of corn cultivation. Instead, the site and the sampling years had a greater influence on earthworm population density and biomass than the presence of the Cry protein. Those results corroborate other laboratory and field studies of the effect of Bt toxins on survival, growth, and reproduction of an array of soil invertebrates, including woodlice, springtails, and mites (Ahl Goy et al., 1995; Saxena and Stotzky, 2001a; Zwahlen et al., 2003; Clark et al., 2006; Vercesi et al., 2006; Krogh et al., 2007). Similarly, Birch et al. (2007) detected transient and site-specific reductions in the biomass of oribatid mites and total microarthropods in fields under Bt and non-Bt corn. However, the differences between populations under different non-Bt corn varieties were often of the same magnitude as those between Bt and non-Bt corn; this led to the conclusion that the effects in the field were varietal effects and not due specifically to the Bt trait (Cortet et al., 2006).

When the effects of Bt toxins on nematodes were studied, season, soil tillage, soil type, crop type, and cultivar influenced nematode number to a greater extent than whether the corn was a Bt variety. Under field cultivation for Bt-crops with the Cry3Bb1 protein and non-Bt crops, no effect was detected on the abundance of the nematode *Caenorhabditis elegans* on corn (Al-Deeb et al., 2003, corn) or on the relative abundance of species of nematodes in the soil with eggplant (Manachini, 2003; eggplant, cited by Icoz and Stotzky, 2008). When soils from Bt corn with the Cry1Ab protein and non-Bt corn in cultivation were compared, there were no effects on nematode communities and diversity (Manachini, 2003; cited by Icoz and Stotzky, 2008) or on the nematode *Pratylenchus* spp. (Lang et al., 2006). However, in experiments in cultivated Bt and non-Bt corn fields, adverse effects on growth and abundance of *C. elegans* were observed (Manachini, 2003; Lang et al., 2006; cited by Icoz and Stotzky, 2008), and a lower abundance of natural populations occurred transiently in Bt fields and consistently at one Bt site (Griffiths et al., 2005; Griffiths et al., 2006).

Similarly, the Cry1Ab insecticidal protein for European corn borer control had less effect on the bacterial community structure than other environmental factors (Baumgarte and Tebbe, 2005). In one study, a transient decrease occurred in the numbers of protozoa in soil with Bt corn under field conditions (Griffiths et al., 2005); otherwise, no toxic effects of the Cry proteins on protozoa have been observed (Donegan et al., 1995; Saxena and Stotzky, 2001a; Griffiths et al., 2005; Icoz and Stotzky, 2008). No changes in microbial activity and other assays (i.e., nitrogen mineralization potential, short-term nitrification, and soil respiration rate) occurred when soils cropped with corn that produced the Cry3Bb toxin for corn rootworm protection were compared with soils cropped with the nontransgenic isoline (Devare et al., 2004; Devare et al., 2007). Those studies have indicated that Bt and non-Bt crops have comparable effects on soil bacteria and protozoa.

Rates of residue decomposition and the associated accumulation of soil organic matter affect soil productivity and soil ecological functions; therefore, if residues of Bt corn differ from residues of non-Bt corn in decomposition rates, there might be long-term implications for soil quality and soil carbon sequestration. Reduced decomposition rates might increase the time that Bt toxins remain in the environment. Chemical bonds in lignins are more resistant to microbial decomposition than other chemical bonds in plant cells. Some studies have demonstrated higher

Copyright © National Academy of Sciences. All rights reserved.

Impact of Genetically Engineered Crops on Farm Sustainability in the United States
http://www.nap.edu/catalog/12804.html

lignin content in Bt corn hybrids compared to their respective isolines (or near-isolines) (Saxena and Stotzky, 2001b; Poerschmann et al., 2005), but other studies have found no differences (Jung and Sheaffer, 2004). Decomposition rates have more importance for soil quality than relative lignin contact. In some laboratory research, plant residue of Bt hybrids decomposed at a lower rate in soil than residue of non-Bt hybrids (Flores et al., 2005), but field studies have not detected differences in decomposition rates (Lehman et al., 2008). Similarly, Hopkins and Gregorich (2003) reported no differences in carbon dioxide production from Bt and non-Bt corn in soil over a 43-day incubation period. No differences in mass losses in the field were detected between Bt-glyphosate–resistant and glyphosate-resistant cotton lines, indicating that there were no differences in the rate of decomposition or change in nutrient content in the litter over the 20-week experiment (Lachnicht et al., 2004). When the whole soil organism community was allowed to access the residue, the decomposition of Bt and non-Bt residue was similar (Zwahlen et al., 2007). Tarkalson et al. (2008) also reported no differences in residue decomposition rates or in mass of total carbon remaining over time between Bt and non-Bt corn hybrids observed in a field study although the study did detect differences in rates of decomposition for leaf, stalk, and cob plant parts. Finally, after seven years of continuous corn cultivation, no differences between Bt and non-Bt corn treatments were detected in total carbon or nitrogen in soil, indicating that plant decomposition rates were similar (Kravchenko et al., 2009). On the basis of those studies, the plant residue from Bt and non-Bt corn hybrids decomposed at similar rates and would have similar effects on soil quality and on potential carbon sequestration.

Evolution and Management of Insect Resistance

Evolution of Resistance

Insects can adapt to toxins and other tactics used to control them (Palumbi, 2001; Onstad, 2008). When Bt crops were first considered for commercial introduction, EPA recognized their potential to reduce human and environmental exposure to broad-spectrum insecticides, increase growers' ability to manage pests and improve crop quality, and increase profits at the farm and industry levels (Berwald et al., 2006; Matten et al., 2008). Those benefits had already been demonstrated by sprayed Bt insecticides that are critical pest-management tools for many fruit and vegetable crops in the United States (K. Walker et al., 2003). As the regulatory agency overseeing the introduction of biological pesticides, EPA concluded that the potential for rapid evolution of insect resistance to Bt toxins produced by GE crops was a threat to the benefits provided by Bt crops and to the efficacy of Bt sprays in organic and conventional production systems (Matten et al., 2008; Thompson et al., 2008). Accordingly, it mandated the use of a refuge strategy (described later in this chapter) to delay the evolution of resistance in major insect pests controlled by Bt corn and cotton (US-EPA, 2008a).

Extensive monitoring of 11 major lepidopteran pests of corn and cotton over the last 14 years has revealed that some populations of one moth species, cotton bollworm (*Helicoverpa zea*), evolved resistance to the Bt toxins Cry1Ac and Cry2Ab found in some cotton cultivars in the United States (Tabashnik and Carrière, 2008; Tabashnik et al., 2008; Tabashnik et al., 2009a). In addition, some populations of fall armyworm evolved resistance to Cry1F corn in Puerto Rico (Matten et al., 2008), and some populations of corn stem borer (*Busseola fusca*) evolved resistance to Cry1Ab corn in South Africa (van Rensburg, 2007; Kruger et al., 2009).

Copyright © National Academy of Sciences. All rights reserved.

Impact of Genetically Engineered Crops on Farm Sustainability in the United States
http://www.nap.edu/catalog/12804.html

That resistance has evolved in only three pest species in the last 14 years suggests that the refuge strategy has successfully delayed the evolution of resistance to Bt toxins (Tabashnik et al., 2008; Tabashnik et al., 2009a). Comparisons between pests that have and have not evolved resistance to Bt crops suggest that recessive inheritance of resistance and abundant refuges of non-Bt host plants are two key factors that delay the evolution of resistance (Tabashnik et al., 2008; Tabashnik et al., 2009a). In accordance with these findings, EPA demands that GE seed companies require producers to plant refuges to delay the evolution of resistance where such refuges are deemed necessary and develop compliance assurance programs (Thompson et al., 2008). The promotion of precise resistance-management guidelines by the industry has undoubtedly contributed to increasing the use of refuges for managing the evolution of resistance to Bt crops in the United States. In some regions, compliance to the mandated refuge strategies has been high since the introduction of Bt crops (Carrière et al., 2005). However, levels of compliance have substantially and regularly declined in other parts of the country, possibly because the use of Bt crops has increased globally and producers can no longer rely on non-Bt users to provide refuges for their farms (Jaffe, 2009).

Although the theory, resistance-monitoring data, and experimental work conducted in the laboratory suggest the refuge strategy has been useful, detailed field experiments are still needed to demonstrate how the refuge strategy can delay the evolution of resistance to Bt crops. There is usually a delay between the introduction of a novel pesticide and the rapid rise in the number of species that have evolved resistance to it (Georghiou, 1986). That is illustrated in a comparison of the cumulative number of cotton pests that evolved resistance to Bt toxins in crops and to the insecticide dichlorodiphenyltrichloroethane (DDT) after the introduction of these pest-management tools in the United States (Figure 2-9).

After commercialization of Bt cotton in 1996, its use increased rapidly in the United States. Similarly, the use of DDT in cotton increased rapidly after it became widely commercially available in 1946. For example, 90 percent of agricultural DDT applications in the United States targeted cotton pests in 1962 (Walker et al., 2003). Similar to Bt cotton that produces high concentrations of Bt toxins over much of the growing season, DDT was applied repeatedly in cotton and retained toxicity for extended periods (US-EPA, 2000). The recessive mutations *kdr* and super-*kdr* confer recessive resistance to DDT in many agricultural pests (Davies et al., 2007; APRD, 2009); this is similar to the inheritance of resistance to Bt toxins in cotton, which is often recessive (Tabashnik et al., 2008).

With respect to the evolution of resistance, Bt cotton and DDT differ in at least two important ways. First, DDT kills a wide array of insects regardless of their feeding habits whereas Bt cotton kills only some lepidopteran pests that feed on the cotton. Second, no refuge strategy was mandated to manage the evolution of insect resistance to DDT. Those differences suggest that the evolution of DDT resistance in cotton pests should have been more rapid than the evolution of resistance to Bt cotton. However, the cumulative number of cotton pests that evolved resistance to Bt cotton and the number that evolved resistance to DDT after their introduction in the United States have been strikingly similar (Figure 2-9). That comparison indicates that it may still be too soon to claim that the refuge strategy has substantially delayed the accumulation of pests resistant to Bt. While seed companies are in a better position to commercialize more efficient Bt cultivars for delaying the evolution of resistance (see below), the possibility remains that the accumulation of resistant pests could accelerate. Thus, complacency in the implementation of resistance-management strategies is not warranted (Hurley and Mitchell, 2008; Jaffe, 2009; Tabashnik et al., 2009a).

Principles of Population Genetics Underlying the Refuge Strategy

Population-genetic models and empirical data on factors that affect the evolution of insect resistance to Bt crops have been central in the development of the refuge strategy. Models generally assume that resistance to a toxin produced by Bt crops is conferred by mutations at a single locus (gene location) (Gould, 1998; Tabashnik and Carrière, 2008). That is a reasonable assumption because resistance to the intense selection imposed by Bt crops and insecticides is likely to involve genes that have major effects (Carrière and Roff, 1995; McKenzie, 1996). Furthermore, most of the observed cases of evolved resistance to Bt crops have involved mutations at a single locus (Gahan et al., 2001; Morin et al., 2003; Yang et al., 2007; Pereira et al., 2008). For simplicity, models assume the presence of one allele that confers susceptibility and one allele that confers resistance even if more than one allele at a single locus can confer resistance to Bt crops (Morin et al., 2003; Yang et al., 2007).

The refuge strategy relies on two basic principles. The first principle is that the dominance of resistance[10] is reduced by increasing the dose of Bt toxins (Gould, 1998; Tabashnik et al., 2004). When the concentration of a Bt toxin in a plant is low, the resistance trait in the insect population is nonrecessive, but when it is high, the resistance trait in the insect population becomes recessive, and resistance becomes rarer. Accordingly, resistance to commercialized GE crops

[10]The *dominance of resistance* depends on the response of heterozygotes compared to the response of homozygous-susceptible individuals and homozygous-resistant individuals. If heterozygotes respond like homozygous-susceptible individuals, resistance is recessive; if heterozygotes respond like homozygous-resistant individuals, resistance is dominant.

Impact of Genetically Engineered Crops on Farm Sustainability in the United States
http://www.nap.edu/catalog/12804.html

that produce high concentrations of Bt toxins is recessive in many, but not all, target pests (Tabashnik et al., 2008). The refuge strategy requires the presence of refuges of non-GE host plants in or near Bt crop fields (US-EPA, 2008b, a). For refuges to be effective, the susceptible insects produced in refuges must be in sufficient numbers and mate with the rare resistant pests that survive on GE crops. With effective refuges and recessive resistance, most hybrid offspring produced by resistant pests that survive on Bt crops are killed when they feed on GE crops. That reduces the heritability of resistance (the degree of genetic similarity between resistant parents that survive on Bt crops and their offspring) and delays its evolution (Gould, 1998; Sisterson et al., 2004a; Tabashnik and Carrière, 2008).

The second principle underlying the refuge strategy is that the evolution of resistance can be delayed or prevented by reducing the selective differential between individuals with and without resistance alleles (Gould, 1998; Carrière and Tabashnik, 2001; Andow and Ives, 2002; Tabashnik et al., 2005; Crowder and Carrière, 2009). The selective differential between resistant and susceptible individuals can be affected by crop-management practices, such as increasing refuge size that increases relative fitness of susceptible individuals (Mitchell and Onstad, 2005; Onstad, 2008). In fields of Bt crops, where resistant individuals are more abundant than susceptible individuals, the selective differential between resistant and susceptible individuals can be reduced by such crop-management practices as pheromone mating disruption and the elimination of crop residues that contain insects (Andow and Ives, 2002; Yves Carrière et al., 2004).

The selective differential between resistant and susceptible individuals can also be affected by pest biology and genetics. Fitness costs associated with resistance to Bt toxins occur in environments that lack Bt toxins if individuals with one or more resistance alleles have lower fitness than individuals without such alleles (Gassmann et al., 2009). Fitness costs of Bt resistance are found in many species and select against resistance in environments where Bt toxins are absent; this selection counterbalances selection that favors an increase in resistance in fields of Bt crops (Gassmann et al., 2009). Fitness costs expressed in heterozygous individuals are nonrecessive; costs expressed only in homozygous resistant individuals are recessive. Nonrecessive fitness costs can delay the evolution of resistance more effectively than recessive fitness costs because alleles that confer resistance to Bt crops are often rare (Gould et al., 1997; Andow et al., 2000; Tabashnik et al., 2006; Mahon et al., 2007), so most resistance alleles in pests targeted by Bt crops are carried by heterozygous individuals. With nonrecessive fitness costs, the fitness of resistant heterozygous individuals is lower than the fitness of susceptible individuals in refuges, and such costs can strongly select for a decline in resistance despite the fact that selection favors resistant individuals on Bt crops (Gassmann et al., 2009). In other words, recessive costs that influence only the rare homozygous resistant individuals are less effective in delaying resistance than nonrecessive costs that influence the more abundant resistant heterozygous individuals.

Incomplete resistance occurs when the fitness of resistant individuals is lower on Bt cultivars than on corresponding non-Bt cultivars (Carrière and Tabashnik, 2001). It occurs because the individuals that do survive on Bt crops are nevertheless affected adversely by Bt toxins (for example, larvae take a long time to develop on the Bt crop, and the resulting moths are smaller and less fecund). Incomplete resistance is found in many species and contributes to delaying the evolution of resistance by reducing the selective differential between resistant and susceptible individuals (Carrière and Tabashnik, 2001; Tabashnik et al., 2005; Crowder and Carrière, 2009).

Impact of Genetically Engineered Crops on Farm Sustainability in the United States
http://www.nap.edu/catalog/12804.html

The Pyramid Strategy

The first IR crops produced a single Bt toxin. More recently, the "pyramid" strategy has used GE crops that produce two distinct Bt toxins for delaying pest resistance. The pyramid strategy is based on the principle that insects are killed on two-toxin plants as long as they have a susceptibility allele at a resistance locus—a phenomenon called redundant killing (Gould, 1998; Roush, 1998). As resistance alleles are generally rare, the only genotype that has high survival on a cultivar that produces two or more Bt toxins is expected to be extremely rare. Accordingly, the refuge strategy is considered more effective in reducing the heritability of resistance when crops produce more than one Bt toxin than when they produce a single Bt toxin (Gould, 1998; Roush, 1998; Gould et al., 2006). Models suggest that the pyramid strategy is most effective when the majority of susceptible pests are killed by the GE crop, resistance to each Bt toxin is recessive, fitness costs and refuges are present, and selection with one Bt toxin does not cause cross-resistance to another (Gould, 1998; Zhao et al., 2005; Gould et al., 2006). Cross-resistance to Bt occurs when a genetically based decrease in susceptibility to one toxin decreases susceptibility to other toxins.

Changes in Refuge Strategy in the United States

In a process that aims to use scientific knowledge to balance economic and environmental considerations, refuge strategies for Bt corn and cotton mandated by EPA have been improved since the commercialization of these GE crops in 1996. EPA specifies the area, configuration, and types of refuges to be used with specific Bt crops. Changes in refuge requirements have been based on input from academe, farmers, and industry. Some of the changes have made refuge requirements more stringent, while others have eliminated refuge requirements. For example, refuge distance requirements for the use of Bt cotton against pink bollworm were unspecified from 1996 to 2000, unless the percentage of Bt cotton in a county exceeded 75 percent in the previous year (US-EPA, 1998; Carrière et al., 2001). However, on the basis of the principle that refuges must be near Bt crops to promote the desired mating between susceptible and resistant insects, new regulations enacted in 2001 limited the distance between refuges and Bt cotton regardless of the percentage of Bt cotton in the previous year (Tabashnik et al., 1999; Carrière et al., 2001; US-EPA, 2001; Y. Carrière et al., 2004). Since 2006, in response to a proposal from cotton growers to eradicate pink bollworm in Arizona, EPA has allowed use of mass release of sterile pink bollworm moths as an alternative to non-Bt cotton refuges (US-EPA, 2006a).

In another example, in response to a proposal from Monsanto, the refuge requirement of non-Bt cotton cultivars was abolished from Texas to the Mid-Atlantic to manage resistance of tobacco budworm (*Heliothis virescens*) and cotton bollworm (*Helicoverpa zea*) to Monsanto's pyramided Bt cotton cultivar that produces the toxins Cry1Ac and Cry2Ab (US-EPA, 2007) and subsequently to a cultivar from Dow AgroSciences producing Cry1Ac and Cry1F. The proposal included new data and modeling results that indicated that weeds and non-Bt crops other than cotton might provide sufficient refuges to delay Bt resistance in the two mobile, polyphagous pests (US-EPA, 2006b). The 2007 change by EPA meant that refuges of non-Bt cotton are no longer required for millions of acres of the Monsanto cotton cultivar grown in large areas of the United States. Assuming that no other factors changed (e.g., the technology fee), that action would improve the net benefits to farmers of growing the GE cotton and increase its adoption (Luna V et al., 2001; Matus-Cádiz et al., 2004) at least in the short term. However, it is

Copyright © National Academy of Sciences. All rights reserved.

Impact of Genetically Engineered Crops on Farm Sustainability in the United States
http://www.nap.edu/catalog/12804.html

noteworthy that decreased susceptibility to both Cry1Ac and Cry2Ab in cotton bollworm (*H. zea*) has indicated that this pest is evolving resistance to cotton producing those toxins in the United States (Tabashnik et al., 2008; Tabashnik et al., 2009b).

It appears likely that most Bt crops commercialized in the future by biotechnology companies will produce two or more Bt toxins for the control of individual insect pest species (Bravo and Soberón, 2008; Matten et al., 2008). That could improve the durability of Bt crops if few other major insect pests targeted by Bt crops evolve resistance before the replacement of one-toxin crops by pyramids, and if populations of pests that are resistant to single-toxin Bt crops remain rare. EPA promotes the replacement of one-toxin Bt cultivars with two-toxin Bt cultivars on the basis of recognition that the evolution of resistance is more effectively delayed with a pyramid strategy than with one-toxin crops (Matten et al., 2008). Another incentive to eliminating the use of one-toxin Bt cultivars when two-toxin Bt cultivars are introduced is that results from simulation models and small-scale laboratory experiments indicate that the evolution of resistance to two-toxin cultivars is accelerated when plants that produce two Bt toxins are grown near plants that produce just one toxin (Roush, 1998; Gould, 2003; Zhao et al., 2005).

So far, the complete replacement of one-toxin with two-toxin Bt cultivars has occurred only in Australia (Baker et al., 2008). The Transgenic and Insecticide Management Strategy committee, which comprises growers, consultants, researchers, seed companies, and chemical industry, has overseen the development, implementation, and evaluation of resistance-management strategies for Bt cotton in Australia (Fitt, 2003). Cotton that produces the Bt toxin Cry1Ac for the control of cotton bollworm (*Helicoverpa armigera*) was replaced by cotton producing Cry1Ac and Cry2Ab in 2004. That allowed producers to reduce the area of refuges from 70 percent with Cry1Ac cotton to as low as 5 percent with Cry1Ac and Cry2Ab cotton (Baker et al., 2008). The exclusive use of a pyramid strategy for managing the evolution of Bt resistance in insect pests might allow producers to use more Bt crops while maintaining efficient resistance management (Mahon et al., 2007; Baker et al., 2008). However, an allele conferring high levels of resistance to Cry2Ab has been found in relatively high frequency (0.0033) in field populations of cotton bollworm (*H. armigera*), and individuals homozygous for this allele can survive on mature cotton producing the toxins Cry1Ac and Cry2Ab (Mahon et al., 2007; Mahon and Olsen, 2009). This indicates that a key assumption of the pyramid strategy is not met (i.e., redundant killing), and thus that caution should be used to manage the evolution of cotton bollworm resistance to Cry1Ac and Cry2Ab cotton in Australia.

Agricultural and Environmental Impacts of Insect Resistance to Bt Crops

The refuge strategy was mandated in the United States not only to slow the evolution of resistance to Bt cultivars but also to protect the effectiveness of Bt sprays. Susceptibility to sprays with many Bt toxins in pests that evolve resistance to single-toxin Bt crops will depend on several factors, including the level of resistance, the variety and concentration of the toxins in the sprays, and the extent of cross-resistance to different toxins. If a spray contains one or more toxins to which the pest has evolved resistance or cross-resistance, susceptibility to the spray could be decreased (Tabashnik et al., 1993; Moar et al., 1995). Nonetheless, sprays containing one or more toxins that kill pests that are resistant to other toxins can be useful against such pests (Tabashnik et al., 1993; Liu et al., 1996; Akhurst et al., 2003; Wang et al., 2007).

Copyright © National Academy of Sciences. All rights reserved.

Impact of Genetically Engineered Crops on Farm Sustainability in the United States
http://www.nap.edu/catalog/12804.html

Along with other insecticidal compounds with different modes of action, many sprayed Bt insecticides commonly used in the United States contain at least two Cry toxins that differ substantially from each other in amino acid sequence and that bind to different target sites in the larval midgut (Schnepf et al., 1998; Ferré and Van Rie, 2002; Crickmore et al., 2009). The few pests that have evolved resistance to Bt crops could remain susceptible to sprayed Bt insecticides that contain many Bt toxins, as long as the evolution of resistance to the toxins in Bt crops does not involve strong cross-resistance to all the toxins in Bt sprays. Cross-resistance between Bt toxins that differ substantially in amino acid sequence is usually weak or nil, but exceptions occur in important pests that are targeted by Bt crops, including cotton bollworm (*H. zea*) (Hernández-Martínez et al., 2009; Tabashnik et al., 2009b). However, the possibility of cross-resistance in corn stem borer and fall armyworm has not been investigated extensively. The agricultural and environmental impacts of cross-resistance between single-toxin Bt crops and multitoxin Bt sprays will also depend on the extent to which the two approaches are used to control a given pest and on pest movement between Bt crops and areas where Bt sprays are used.

EPA requires remedial action plans to address cases of resistance, which can involve cessation of use of a particular Bt cultivar in a specific area (US-EPA, 1998; Carrière et al., 2001; US-EPA, 2001). Sales of corn that produce the Bt toxin Cry1F were suspended voluntarily in Puerto Rico after the evolution of resistance to Cry1F in fall armyworm (Matten et al., 2008). In the absence of published information on the distribution of resistance and on the presence of cross-resistance and fitness costs, it is not possible to assess whether the evolution of resistance to Cry1F in fall armyworm threatens the sustainability of other Bt crops or sprayed Bt insecticides in Puerto Rico. Furthermore, the economic and environmental consequences of Bt resistance are difficult to assess because little information is available on the profitability of Cry1F corn in Puerto Rico and on how withdrawal of Cry1F corn in Puerto Rico has affected insecticide use.

In contrast, the evolution of resistance of cotton bollworm (*H. zea*) to Cry1Ac cotton in the United States did not have serious agronomic, economic, or environmental consequences. That is because resistance did not affect many bollworm populations, Cry1Ac cotton still provides some control of Cry1Ac-resistant insects, synthetic insecticides were used in conjunction with Cry1Ac cotton from the onset to control bollworm, and the widespread use of cotton that produces both Cry1Ac and Cry2Ab in the states where resistance occurred provided effective control of insects that were resistant to Cry1Ac (Tabashnik et al., 2008). Data on increased bollworm survival on cotton plants that produce Cry1Ac and Cry2Ab in the field or on the consequences of field-evolved resistance to Cry2Ab are lacking (Tabashnik et al., 2009b). Although there is strong evidence of resistance to Cry1Ac in some populations of bollworm in the Southeast (Tabashnik and Carriere, 2009; Tabashnik et al., 2009a), a subset of the data has been contested by some scientists (Moar et al., 2008), and EPA has not commented on the situation.

GENE FLOW AND GENETICALLY ENGINEERED CROPS

This section presents an overview of the potential of gene flow to weedy relatives for crops for which GE varieties have been developed (though not all of these varieties have been commercialized). The movement of herbicide resistance into weedy relatives present on farm fields can influence farmers' weed-management strategies. Gene flow between GE and non-GE crops could accelerate the evolution of pest resistance to Bt crops, if many Bt plants are routinely present in refuges of non-Bt crops (Heuberger et al., 2009; Krupke et al., 2009). The following

Impact of Genetically Engineered Crops on Farm Sustainability in the United States
http://www.nap.edu/catalog/12804.html

section specifically considers factors that affect gene flow via cross-pollination within crops, on which the coexistence of GE and non-GE crops depends. Chapter 3 addresses other sources of gene flow, such as co-mingling of seed and germination of volunteer seeds left behind, and the economic consequences of gene flow between GE and non-GE varieties.

Gene Flow Between Genetically Engineered and Non-Genetically Engineered Crops

The potential for cross-pollination between GE and non-GE crops depends on the plant species (Ellstrand, 2003a). In particular, the reproductive strategy of a crop determines the degree of gene flow between GE and non-GE crops; open-pollinated crops (such as corn) have the greatest probability of cross-pollination between GE and non-GE cultivars. Even in self-pollinated plants, out-crossing occurs occasionally, the rate depending on the particular species and environment. In soybean, for example, out-crossing is occasional (Palmer et al., 2001; Abud et al., 2004; Abud et al., 2007). In contrast, corn is freely out-crossing, so the cross-pollination of non-GE cultivars with pollen from GE varieties depends on the distance from the source and other factors. Models of pollen dispersal in corn and the consequent gene flow may have low precision, particularly in light of the small amounts of pollen that move more than 800 ft and the substantial impacts of climate (Ashton et al., 2000).

Among the factors that control gene flow between populations of wind-pollinated plants are distance from the pollen source and pollen shed density, time required for pollen movement, wind speed and direction, air temperature, and relative humidity (Luna V et al., 2001; Westgate et al., 2003). Pollen viability declines quickly with desiccation. Even if pollen is dispersed over great distances, it may, if dried out, not be viable. Similarly, the occurrence of GE pollen in a non-GE corn field does not necessarily mean that pollination will occur (Feil and Schmid, 2002). Nonetheless, the distances needed to prevent any cross-pollination in corn or other open-pollinated crops are so great that they are not practical in current commercial agricultural systems (Luna V et al., 2001; Matus-Cádiz et al., 2004).

Insect-mediated cross-pollination between GE and non-GE crops occurs in those species for which insects typically are the agents of transfer of pollen between individuals (Van Deynze et al., 2005; Llewellyn et al., 2007). Canola and cotton are modally out-crossing as a result of pollinator activity, whereas soybean is usually self-pollinated but is visited by insects seeking its pollen (Ahrent and Caviness, 1994; Walklate et al., 2004; Heuberger and Carrière, 2009). In a recent study that monitored cross-pollination of seed-production fields of non-Bt cotton (some HR, some not) by Bt cotton, both the density of flower-foraging honey bees in seed production fields and the area of Bt cotton at a distance of 2,460 ft from the non-Bt cotton fields affected cross-pollination (Heuberger and Carrière, 2009). It had been documented that most cross-pollination in cotton occurs over distances of less than 160 ft (McGregor, 1976; Free, 1993; Xanthopoulos and Kechagia, 2000; Zhang et al., 2005). Nevertheless, foraging honey bees can easily travel two miles or more (Beekman and Ratnieks, 2000); this suggests that the 2,460-ft radius at which pollen from Bt cotton influenced out-crossing of non-Bt cotton resulted from movement of foraging honey bees from Bt to non-Bt cotton fields. Accordingly, the results of Heuberger and Carrière (2009) indicate that small-scale gene-flow studies may miss occasional long-distance cross-pollination between GE and non-GE insect-pollinated crops.

As the adventitious presence of GE traits is widespread in the seed supply of non-GE crops, gene flow between non-GE and GE crops may commonly involve cross-pollination by plants from the same field (i.e., adventitious plants). Heuberger and Carrière (2009) found adventitious

Copyright © National Academy of Sciences. All rights reserved.

Impact of Genetically Engineered Crops on Farm Sustainability in the United States
http://www.nap.edu/catalog/12804.html

Bt cotton plants in 67 percent of seed-production fields of non-Bt cotton. They demonstrated that adventitious Bt plants resulted both from human error (inadvertent planting of Bt cotton in non-Bt cotton fields) and from contamination in seed bags. After accounting for the effect of the area of Bt cotton surrounding a seed production field and the abundance of foraging honey bees, the density of adventitious Bt plants was positively associated with out-crossing rates in seed-production fields. Most models of pollen transfer between crop varieties have not considered the adventitious presence of GE plants in non-GE fields and may therefore fall short of making accurate predictions of the abundance of GE traits in supposedly non-GE plants.

Canola is not a major crop in the United States, but substantial acreage is planted in North Dakota, which accounted for more than 87 percent of U.S. canola planted in 2009 (USDA-NASS, 2009b). Gene flow between GE and non-GE canola is well documented in the large canola-growing region of western Canada; it can be facilitated by the transient populations of canola established each year outside agricultural fields (Knispel et al., 2008). Genetically engineered HR canola cultivars are the dominant type, and in 2006, glyphosate-resistant and glufosinate-resistant canola cultivars accounted 65 percent and 32 percent, respectively, of U.S. canola acres planted (Howatt, 2008, personal communication). Given that there are two GE herbicide-resistance traits (glyphosate and glufosinate) and a non-GE imidazolinone-resistant trait, introgression of these traits can result in multiple-herbicide resistance in a single plant (Knispel et al., 2008). The occurrence of multiple-herbicide-resistant volunteer canola increases the difficulties of management (Beckie et al., 2004; Beckie, 2006; Beckie et al., 2006). In addition to the problem of deploying special management techniques for HR weeds, adventitious presence of a GE trait in a non-GE field of canola has economic consequences.

Alfalfa is an important crop in the United States and is widely cultivated over a broad geographic range (USDA-NASS, 2008). GE glyphosate-resistant alfalfa was commercialized in 2005, and about 198,000 acres were planted in 2006 (Weise, 2007). However, in 2007, it once again became a regulated item, a decision that was upheld by the Court of Appeals in 2008. USDA Animal and Plant Health Inspection Service (APHIS) was ordered to conduct an environmental impact statement (EIS) because of "the significant threat of gene flow and the development of Roundup-resistant weeds that requires further study and analysis in an EIS" (*Geertson Farms Inc.*, 2009).[11] APHIS released the draft EIS for public comment in December 2009.

Sugar beet (*Beta vulgaris*) cultivars with the GE trait that confer resistance to glyphosate have been commercialized and were widely adopted by growers in the United States. However, in September 2009, the Northern California District Court ruled that USDA violated the National Environmental Protection Act when it deregulated HR sugar beets, and USDA is required by the court to prepare an environmental impact statement to adequately consider the impacts of GE sugar beets on other sugar beet growers as well as farmers growing table beets and swiss chard, two crops with which sugar beets may cross pollinate (*Center for Food Safety v. Thomas J. Vilsack*, 2009).

[11]Roundup is the trademarked name of glyphosate sold by Monsanto.

Impact of Genetically Engineered Crops on Farm Sustainability in the United States
http://www.nap.edu/catalog/12804.html

Gene Flow between Genetically Engineered Crops and Related Weed Species

In locations where crop varieties occur with wild or weedy populations of the same or closely related species, interbreeding between a crop and its relatives may lead to exchange of genes between the cultivars or species involved. Such hybridization is common in plants generally and is a key process for the evolution of new plant species. When gene flow occurs between crops and their wild relatives, an agronomic characteristic may move into the wild populations. Environmental sustainability on farms might be affected by the consequences of such gene flow between crops and wild relatives if the gene flow reduces genetic diversity available for crop improvement. However, only a few crops (sunflower, pecan, blueberry, and some squashes) were domesticated within the borders of the United States, so most crops planted on U.S. farms do not pose a risk to the conservation of genetic diversity in related native species and landraces. When crop species coexist with weedy relatives, gene flow might result in a weed-management issue and any accompanying economic and environmental effects. At least 15 crop species have been documented to hybridize with weedy relatives in the United States (Keeler et al., 1996). For HR traits, hybridization is a mechanism by which herbicide resistance might evolve in related weeds if HR crops are able to interbreed with related weedy species occurring in the same location (see the canola example in "Developing Weed-Management Strategies in Herbicide-Resistant Crops" earlier in this chapter).

In the United States for corn and soybean, the most common GE crops grown, no genetically compatible relatives or weedy strains exist; therefore, movement of GE traits into related weed species is not an issue. Wild populations of cotton (*Gossypium hirsutum*) exist along the Gulf Coast and a wild relative (*Gossypium tomentosum*) is in Hawaii. Gene flow is unlikely because the United States prohibits the commercial sale of Bt cotton in those areas. In Hawaii, test varieties and nursery stock can be produced, but with restrictions to minimize gene flow (e.g., US-EPA, 2005). In contrast, the use of HR crops in the same areas is apparently not more restricted than in the rest of the United States (USDA-APHIS, 2008).

Hybridization between the allotetraploid canola (*Brassica napus*) and one of its diploid weedy parents, turnip mustard (*Brassica rapa*) are extensive, and the hybrids are usually about 60 percent pollen fertile (Warwick et al., 2003; Légère, 2005; Simard et al., 2006), thus facilitating the spread of a GE trait into the weeds. GE herbicide-resistant traits have been reported to persist in populations of turnip mustard as they have in several other species of weeds (Warwick et al., 2003; Owen and Zelaya, 2005; York et al., 2005; Warwick et al., 2008). In addition, hybridization is possible between canola and species of a few related genera of mustards, some of them weedy (Warwick et al., 2000; FitzJohn et al., 2007) and occurs spontaneously when they are grown together in an experimental garden. For these reasons, canola has been designated as a moderate-risk crop with regard to the potential for gene flow to its weedy relatives (Stewart et al., 2003), and farm-level effects may occur in canola-growing regions as discussed earlier. The extent to which they have economic impacts and affect environmental sustainability will depend on how the weeds are managed.

Gene flow has been demonstrated from sugar beet to near-relative weeds, *B. macrocarpa* and *B. vulgaris* subsp. *maritima* (Andersen et al., 2005). Thus, the introgression of HR traits from GE sugar beets to weedy beets (*B. vulgaris*) and sea beets (*B. vulgaris* subsp. *maritima*) should be considered a moderate risk (Stewart et al., 2003), but the consequences of gene flow would occur on a very small spatial scale in the United States. Co-occurrence of those species with sugar beet cultivation was limited to two California counties (Kern and Imperial) in 2006

Copyright © National Academy of Sciences. All rights reserved.

Impact of Genetically Engineered Crops on Farm Sustainability in the United States
http://www.nap.edu/catalog/12804.html

(Calflora, 2009). Weedy beets are sporadic and local in the United States and not considered a major problem, as they are in Europe, where the species is native.

Transgenic virus-resistant squash has been available commercially since 1995 and was estimated to have been planted on an average of 12 percent of the 58,400 acres in squash production in 2005 (Quemada et al., 2008). Wild populations of *Cucurbita pepo* occur in south and central regions of the United States (Cowan and Smith, 1993) and can be an agricultural weed (Oliver et al., 1983). Gene flow between conventional cultivars of domesticated *C. pepo* and its wild populations is known to occur (Kirkpatrick and Wilson, 1988; Decker-Walters et al., 2009). Data are not available yet on the extent to which transgenes may exist in wild populations. As of 2005, the opportunity for gene flow across a large spatial scale appeared low because the majority of transgenic squash cultivation occurs outside the range of the wild populations of *C. pepo* (Quemada et al., 2008). The consequences of any gene flow to wild populations depend on virus incidence, the expression of the transgene in the wild populations (Spencer and Snow, 2001; Fuchs et al., 2004a; Fuchs et al., 2004b; Laughlin et al., 2009; Sasu et al., 2009)

Concerns about the consequences of a transfer of GE traits to wild or weedy populations and how to effectively mitigate those consequences have delayed the release of GE sunflower (*Helianthus annuus*, a species that was domesticated in the United States), creeping bentgrass (*Agrostis stolonifera*, a popular turf grass introduced from Europe), and rice (*Oryza sativa*, a species native to Asia with related, intercompatible weeds introduced into some rice fields with the crop). For sunflower, the potential for transgene movement to weedy relatives is quite high and thus the consequences of gene flow on weed management presents an environmental concern about the commercial development of transgenic sunflower (Snow and Palma, 1997; Snow, 2002; Ellstrand, 2003b; Stewart et al., 2003). Wild sunflowers are weeds in row-crop fields, including corn, soybean, domesticated sunflower, wheat, and small grains (Bernards et al., 2009). In a multiyear study conducted across the High Plains of the United States in a number of commercial sunflower-production fields, it was observed that approximately 66 percent of the fields existed near weedy sunflower (Burke et al., 2002). It is important that the cultivated and weedy sunflowers flowered simultaneously (52–96 percent), and evidence of hybridization ranged from 10 percent to 33 percent of the weedy sunflower (Burke et al., 2002). Evidence of genes coding for herbicide resistance in cultivated sunflower moving to weedy sunflower suggests that there is a substantial risk of the introgression of the trait into wild sunflower populations, which might result in increased management problems for growers if the wild plants are in cultivated fields (Marshall, 2001; Massinga and Al-Khatib, 2002; Massinga, 2003). These management problems may emerge in association with sunflower varieties with resistance to the herbicide imazamox that were developed using conventional breeding methods and not genetic engineering. Hybrids of imazamox-resistant sunflowers and two interbreeding relatives appear to be competitively equal to the HR domesticated sunflower, suggesting that the resistance gene will persist when gene flow occurs (Massinga et al., 2005).

GE glyphosate-resistant creeping bentgrass was field-tested in Oregon in 2003, and introgression of the transgene into weedy populations was detected at a considerable distance from the test sites (Mallory-Smith et al., 2005; Reichman et al., 2006). The inability to mitigate GE trait introgression into compatible weedy relatives of creeping bentgrass has delayed commercialization of the GE creeping bentgrass product (Charles, 2007). The transfer of this trait may be important if glyphosate is used to control weedy populations of the grass.

In the case of rice, GE glufosinate-resistant rice cultivars have been developed to improve weed management of red rice (*Oryza sativa* L.), a common and important weed in commercial

Copyright © National Academy of Sciences. All rights reserved.

Impact of Genetically Engineered Crops on Farm Sustainability in the United States
http://www.nap.edu/catalog/12804.html

rice production. However, these GE cultivars have never been commercially available (Gealy et al., 2007) though they were first deregulated in 1998. The commercialization of rice with resistance to the herbicide imazethapyr (produced by a chemical-induced seed mutagenesis, not genetic engineering) has resulted in the movement of this HR trait into red rice because total control of red rice is not always possible (Burgos et al., 2008). Stewardship recommendations to prevent and to control the spread of HR red rice exist and encourage crop diversity (BASF, 2009); data on the success of managing imazethapyr-resistant red rice may provide useful information for the regulation of GE cultivars. In addition to concerns about introgression with the weed red rice, GE rice has historically been unacceptable to consumers for the reasons discussed in Chapter 1 (Gealy and Dilday, 1997; Gealy et al., 2003; Gealy et al., 2007).

Wheat is a major grain crop in the United States, and there has been interest in commercializing genetically engineered HR cultivars. The potential for introgression of a GE trait into near-relative weed populations exists (Ellstrand et al., 1999; Morrison et al., 2002; Morrison et al., 2002; Stewart et al., 2003). Jointed goatgrass (*Aegilops cylindrica*) is reported to be an important weed of small grains in Colorado, Kansas, New Mexico, Oklahoma, Oregon, Utah, Washington, and Wyoming (NAPPO, 2003) and is a weed in the Great Plains (Stubbendieck et al., 1994). Specifically, it causes serious problems in winter wheat in the western United States due to its similarity to wheat in appearance, seed size, growth pattern, and genetics (Schmale et al., 2008; Schmale et al., 2009; Yenish et al., 2009). Studies have demonstrated hybridization with wheat varieties (Hanson et al., 2005; Rehman et al., 2006). It is predicted that hybridization between HR wheat cultivars and *Aegilops* spp. will result in the introgression of the HR trait and thus a more competitive weedy hybrid, complicating management issues in wheat production (Hanson et al., 2005; Loureiro et al., 2008). Glyphosate-resistant hard red spring wheat provided an opportunity for better weed management and resulted in a 10-percent higher grain yield than conventional wheat cultivars treated with conventional herbicides (Howatt et al., 2006). Despite the technical fit, the program to develop glyphosate-resistant cultivars was postponed in 2004 because of regulatory and marketing issues, concern for stewardship, and the inability to ensure the segregation of the GE wheat from non-GE wheat grain at the time (Dill, 2005) (see Chapter 4 for further details). An imazamox-resistant winter wheat, which was bred using conventional techniques, has been commercially available since 2002, and the identical concerns about the development of HR jointed goatgrass biotypes exist (Kniss et al., 2008).

The ecological and economic consequences of the introgression of GE traits into weedy or native relatives will vary among types of GE traits (Owen, 2008). For HR crops, the introgression of herbicide resistance from GE crops into weedy near-relatives is likely to have consequences for weed management *when* weeds with the resistance trait occur in fields or other ecosystems treated with the herbicide. Therefore, for future HR plants, understanding the extent to which a herbicide controls weedy relatives will provide valuable information on the consequences of gene flow for on-farm and off-farm weed management.

CONCLUSIONS

Environmental effects at the farm level have occurred as a result of the adoption of GE crops and the agricultural practices that accompany their cultivation. The introduction of GE crops has reduced pesticide use or the toxicity of pesticides used on fields where soybean, corn, and cotton are grown. Available evidence indicates that no-till practices and HR crops are complementary,

http://www.nap.edu/catalog/12804.html

and each has encouraged the other's adoption. Conservation tillage, especially no-till, reduces soil erosion and can improve soil quality. The pesticide shifts and increase in conservation tillage with GE crops have generally benefited farmers who adopted them so far. Conservation tillage practices can also improve water quality by reducing the volume of runoff from farms into surface water, thereby reducing sedimentation and contamination from farm chemicals. Given that agriculture is the largest cause of impaired quality of surface waters, that may constitute the largest benefit of GE crops, but the infrastructure for tracking and understanding this does not exist.

The effects of Bt crops on nontarget invertebrates, including predators, are favorable or neutral, depending on the degree to which Bt crops replace insecticide treatment and on whether additional insecticide treatments are applied to the Bt crop. Evidence indicates no effect of Bt toxins on the honey bee, a widespread pollinator in agricultural systems. For HR crops, the effects on the abundance of arthropods in the fields correlate with whether weeds are controlled more effectively. Shifts in the weed communities have occurred in response to weed-management tactics used for HR crops, in particular when weeds in glyphosate-resistant crops are treated only with glyphosate. Similarly, glyphosate-resistant weeds have evolved where the glyphosate application is repeated and constitutes the only weed-management tactic used. The evolution of resistance to glyphosate in particular kinds of weeds and shifts in the weed community may increase production costs for farmers, require more tillage for weed control, and lead to at least a partial return to the use of different and often more toxic herbicides. The development and establishment of more diversified control strategies for managing weeds in HR crops is needed.

The first generation of IR crops commercialized in the United States produced a single Bt toxin for the control of insect pests. Since the commercialization of those crops, EPA has mandated the refuge strategy to delay the evolution of resistance in major insect pests that are controlled by Bt corn and cotton. After 14 years of use of Bt crops, two insect pests have evolved resistance to Bt crops in the United States: cotton bollworm (*Helicoverpa zea*) evolved resistance to Cry1Ac and Cry2Ab in Bt cotton, and fall armyworm evolved resistance to Cry1F in Bt corn. The evolution in bollworm of resistance to Bt cotton did not have serious agronomic, economic, or environmental consequences. Information for assessing the consequence of the evolution of resistance to Cry1F in Bt corn in fall armyworm is lacking. The second generation of IR crops produces two or more Bt toxins for the control of individual insect pest species. The complete replacement of one-toxin with multitoxin Bt crops should help in delaying the evolution of insect-pest resistance to IR crops.

The changes in weed and insect population densities resulting from the adoption of HR and IR crops can affect farms beyond the boundaries of the operations that are using the GE crops. That is, farming practices may have landscape as well as local level effects on pest populations. For example, large-scale planting of IR crops has decreased populations of some insect pests targeted by Bt crops not just at a farm-field level but on a regional scale. It can also affect local and possibly landscape populations of non-target or beneficial organisms according to crop species planted and management of pests, nutrients, water, and soil (Björklund et al., 1999; Cattaneo et al., 2006; Dale and Polasky, 2007; Zhang et al., 2007; Carrière et al., 2009). Beneficial organisms with high mobility move among habitats and crop fields, so effects within a field that is planted to GE crops could influence beneficial organisms on other farms as well as noncultivated habitats in the region.

For corn and soybean, gene flow between GE varieties and wild relatives is not an issue in the United States because corn and soybean have no wild relatives here. Limited overlap occurs between cotton and wild relatives and between sugar beet and introduced, weedy relatives. Gene flow is unlikely for Bt cotton and wild relatives because of planting restrictions, but there are no planting restrictions for HR cotton. Other crops in which gene flow with wild or weedy relatives is possible include canola, alfalfa, sunflower, creeping bentgrass, wheat, and rice. Gene flow between GE and non-GE crops occurs via cross-pollination between GE and non-GE plants from different fields, co-mingling of seed before or during the production year, and germination of seeds that are left behind after the production year. Gene flow between GE and non-GE crops is almost impossible to prevent completely with current technology. The complex interactions among the multiple factors that influence gene flow between GE and non-GE crops and the resulting levels of adventitious presences of GE traits in non-GE crops deserve more attention.

3

Farm-Level Economic Impacts

As shown in Chapter 1, farmers growing soybean, cotton, and corn adopted genetically engineered (GE) varieties over the last decade on the majority of acres planted to these crops in the United States. Much smaller acreages were planted in 2009 to a few other GE crops, such as canola, sugar beet, squash, and papaya. The decision to plant GE crops has affected the economic circumstances not only of the adopting farmers but in some cases of farmers who chose not to adopt them. The economic effects on farmers who adopt GE crops span their production systems and marketing decisions. In this chapter, we discuss the potential yield effects, changes in overhead expenses and management requirements, and shifts in market access and value of sales. A wide array of studies conducted mostly during the first 5 years of adoption has provided evidence for assessing the overall economic implications for farmers (see Box 3-1). We also discuss here the economic effects of GE-crop use on livestock producers who use the crops for feed and on farmers who do not elect to use the technology. The chapter concludes by examining the economic implications of gene flow from GE crops to non-GE crops and weedy relatives.

ECONOMIC IMPACTS ON ADOPTERS OF GENETICALLY ENGINEERED CROPS

GE crops have affected the economic status of adopters in several ways. The use of GE crops has had an effect on yields and their risk-management decisions. Genetic-engineering technology has also changed farmers' production expenses and altered their decisions related to time management. Furthermore, because of the widespread adoption of GE crops and their subsequent impact on yields, genetic-engineering technology has influenced the prices received by U.S. farmers.

Yield Effects

The first generation of GE varieties contains traits that control or facilitate the control of pest damage. A starting point for analyzing the productivity effect of such control is the damage-control framework (Lichtenberg and Zilberman, 1986) that was developed to estimate the effectiveness of the use of chemical pesticides and other pest-control activities. The framework

Copyright © National Academy of Sciences. All rights reserved.

Impact of Genetically Engineered Crops on Farm Sustainability in the United States
http://www.nap.edu/catalog/12804.html

recognizes that damage-control agents, like pesticides and GE traits for pest management, have an indirect effect on yield by reducing or facilitating the reduction of crop losses, in contrast with such inputs as fertilizers, capital, and labor, which affect yields directly. In particular, the framework assumes that

$$\text{effective yield} = (\text{potential yield})(1 - \text{damage}).$$

Potential yield is defined as the yield that would be realized in the absence of damage caused by pests (i.e., weeds, insects).[1] It is a function of production inputs, such as water and fertilizer, and of agroecological conditions and seed varieties. The yield actually observed is called effective yield and is equal to potential yield minus damage. Damage is affected by the pervasiveness of pests, which may be controlled with pesticides, the adoption of GE varieties, or other control activities. With that framework, the yield effects of GE varieties can be analyzed, but spatial, temporal, and varietal factors must be taken into consideration.

BOX 3-1
Measuring Impacts

To evaluate the economic impacts of GE crops on adopters and nonadopters, the committee relied on the results of empirical analyses of farmer surveys and market data. Studies were peer reviewed, but the research approach and methods varied considerably with each study's purposes and data. Each study has its own strengths and limitations. For example, some studies may use a different guideline in judging the significance (i.e., confidence level) of factors affecting the adoption of GE crops compared to other studies. The committee could not make the various studies comparable and accepted each set of findings as valid evidence. Some of the general approaches used to estimate economic impacts are explained here.

Empirical data. A comparison of means or averages is sometimes used to analyze results from experiments in which factors other than the item of interest are "controlled" by making them as similar as possible. For example, means of yield or pesticide use can be compared for two groups of soybean plots that are similar in soil type, rainfall, sunlight, and all other respects. One of the two groups is considered to have a *treatment* (e.g., soybean with a genetically engineered trait), and the other does not (e.g., conventional soybean). As an alternative to controlled experiments, the subjects that receive treatment and those that do not can be selected randomly with data collected through mail, phone, internet, or personal surveys.

Survey data. Caution must be exercised in interpreting the results obtained by analyzing the differences in means from data from "uncontrolled experiments," such as farm surveys. Conditions other than the "treatment" are not equal across the farms surveyed. For example, differences between mean estimates for yield and pesticide use from survey results cannot necessarily be attributed to the use of GE seeds because the different results are influenced by many other factors which are not controlled, including irrigation, weather, soil, nutrient and pest-management practices, other cropping practices, operator characteristics, and pest pressures.

[1]Damage may also be caused by weather conditions, such as wind, rain, drought, and frost. For succinctness and convenience here, the definition of damage is restricted to pest problems.

Copyright © National Academy of Sciences. All rights reserved.

Impact of Genetically Engineered Crops on Farm Sustainability in the United States
http://www.nap.edu/catalog/12804.html

Moreover, farmers are not assigned randomly to the two groups (adopters and nonadopters) but make the adoption choices themselves. Therefore, adopters and nonadopters may be systematically different as groups, and these differences may manifest themselves in farm performance. They could be confounded with differences due to the adoption of GE crops (i.e., the treatment). This situation, called self-selection, would bias the statistical results unless it is recognized and corrected.

However, farmer surveys give a more accurate picture of the total farm-level economic effects of GE-crop adoption in terms of the secondary behavioral changes resulting from adoption (e.g., adoption of conservation tillage and changes in the timing of pesticide application). Moreover, it is rarely the case that a farmer would or could choose to adopt a GE cultivar to replace a non-GE cultivar that is an isoline or near-isoline, so relying on agronomic experimental data to measure the economic differences can be biased. Also, only farmer surveys can reveal the value of the changes in nonpecuniary characteristics that can occur with the adoption of GE cultivars.

Social scientists often are able to statistically control for certain influencing factors for which there are data (apart from the GE-crop treatment) by using multiple regression techniques in econometric models. That is, differences in economic conditions and crop or management practices that also influence yield or other outcomes are held constant so that the effect of adoption can be isolated. For example, in research on GE crops, economists control for many factors, including output and input prices, pest infestation levels, farm size, operator characteristics, and management practices such as crop rotation and tillage. In addition, economists control for self-selection and simultaneity (of GE adoption and pesticide use decisions) using particular types of econometric models. To account for simultaneity of decisions and self-selectivity, a two-stage model may be used. The first stage consists of the adoption-decision model for GE crops. The second stage then uses the findings from the first stage to examine the impact of using GE crops on yield, farm profit, and pesticide use.

The Counterfactual. Ideally, measuring the impact of a treatment requires the observation of the results that would emerge in the absence of the treatment: a *counterfactual*. Aside from controlled experiments, it is not possible to observe this counterfactual outcome. Rather, the counterfactual is inferred by methods such as those summarized above (e.g., controlling for all other influencing factors). Moreover, regarding environmental impacts, Ferraro (2009) argues that "elucidating casual relationships through counterfactual thinking and experimental or quasi-experimental designs is absolutely critical in environmental policy and that many opportunities for doing so exist." The use of the two-stage estimation procedure to correct for selection bias exemplifies such a quasi-experimental design. However, Ferraro also admits that "not all environmental programs are amenable to experimental or quasi-experimental design." In those cases, firm conclusions cannot be drawn about the causative factors inducing GE-crop adoption or other outcomes of interest.

Indirect Yield Effects

The indirect yield effects of the use of insect-resistant (IR) crops are most pronounced in locations and years in which insect-pest pressures are high. For example, it is generally recognized that the adoption of Bt corn for European corn borer (*Ostrinia nubilalis*) control resulted in annual average yield gains across the United States of 5-10 percent (Falck-Zepeda et al., 2000b; Carpenter et al., 2002; Fernandez-Cornejo and McBride, 2002; Naseem and Pray, 2004; Fernandez-Cornejo and Li, 2005). Empirical studies, however, have clearly indicated that the indirect yield effects of Bt corn hybrids for European corn borer control vary temporally and spatially. In years with high pressure—corn borer damage of more than one tunnel per plant that

Copyright © National Academy of Sciences. All rights reserved.

Impact of Genetically Engineered Crops on Farm Sustainability in the United States
http://www.nap.edu/catalog/12804.html

exceeds 2 inches in length (Baute et al., 2002; Dillehay et al., 2004)—the yield advantage for Bt hybrids relative to near-isolines[2] was 5.5 percent in Pennsylvania and Maryland (Dillehay et al., 2004), 6.6 percent in Wisconsin (Stanger and Lauer, 2006), 8 percent in New Jersey and Delaware (Singer et al., 2003), 9.4 percent in Iowa (Traore et al., 2000), and 9.5 percent in South Dakota (Catangui and Berg, 2002). The yield advantage for Bt corn was negligible in those regions during years with low pest pressure (Traore et al., 2000; Catangui and Berg, 2002; Singer et al., 2003; Dillehay et al., 2004; Stanger and Lauer, 2006). Likewise, in regions where European corn borer is an occasional pest, there was no indirect yield advantage from the use of Bt hybrids in comparison to near-isolines (Cox and Cherney, 2001; Baute et al., 2002; Ma and Subedi, 2005; Cox et al., 2009). Most of the early empirical studies, however, included some Bt events[3] that did not have season-long control of corn borer, and this may have muted the yield advantage of Bt hybrids (Traore et al., 2000; Catangui and Berg, 2002; Pilcher and Rice, 2003).

There have been fewer empirical studies of the yield effects of Bt corn for control of corn rootworm (*Diabrotica* spp.) than of the effects of Bt corn for control of European corn borer. Rice (2004) estimated potential annual benefits if 10 million acres of Bt corn for corn rootworm control were planted. They included

- Intangible benefits to farmers (safety because of reduced exposure to insecticides, ease and use of handling, and better pest control).
- Tangible economic benefits to farmers ($231 million from yield gains).
- Improved harvesting efficiency due to reduced stalk lodging.
- Increased yield protection (9 to 28 percent relative to that in the absence of insecticide use and 1.5 to 4.5 percent relative to that with insecticide use).
- Reduction in insecticide use (a decrease of about 5.5 million pounds of active ingredient per 10 million acres).
- Increased resource conservation (about 5.5 million gallons of water not used in insecticide application).
- Conservation of aviation fuel (about 70,000 gallons not used in insecticide application).
- Reduced farm waste (about 1 million fewer insecticide containers used).
- Increased planting efficiency.
- Improved safety of wildlife and other nontarget organisms.

A recent study by Ma et al. (2009) indicated spatial and temporal variability in indirect yield responses. Bt corn rootworm hybrids produced yields 11-66 percent larger than untreated near-isoline hybrids. Bt yields were also larger than yields of the non-Bt hybrid variety planted on clay soils and treated with insecticide in 1 of 3 years that had high infestations of western corn rootworm (*Diabrotica virgifera virgifera*). On sandy soils, where corn rootworm infestations are typically much lower than on clay soils, yield differences also occurred between Bt corn rootworm hybrids and their near-isolines with or without the standard soil-applied insecticide

[2]Near-isolines are cultivars that have the same or near genetic constitution (except for alleles at one or a few loci) as the original cultivar from which they were developed. Near-transgenic isolines that have similar genetic makeup except for the transgenic trait allow a comparison of the cultivar with or without the transgene for its agronomic, quality, or nutritional aspects.

[3]Each seed company has different events associated with different insertion places of the Bt gene and different promoter genes that allow a Bt toxin to be produced at different times of the season or in different plant parts.

Impact of Genetically Engineered Crops on Farm Sustainability in the United States
http://www.nap.edu/catalog/12804.html

treatment in 1 of 2 years. The study reported low levels of western corn rootworm on droughty sandy soil, however, and attributed yield increase to improved drought tolerance from the finer, longer fibrous roots of the Bt hybrid corn. Cox et al. (2009) found no yield advantage for corn hybrids with Bt rootworm control compared with near-isolines in a dry year when rootworm damage did not occur.[4]

Gray et al. (2007) expressed concern that one of the Bt corn rootworm events was somewhat susceptible to injury by a variant of western corn rootworm in Illinois. Another Bt corn rootworm event, however, had superior control of western corn rootworm larvae in Iowa, Illinois, and Indiana (Harrington, 2006); this suggests that distinct Bt events from different seed companies may differ somewhat in corn rootworm control as they did initially in corn borer control. Cox et al. (2009) evaluated both Bt rootworm events on second-year corn in field-scale studies on four farms in New York and found that neither rootworm event provided a yield advantage because rootworm occurrence was low in all fields. As with Bt corn for corn borer, Bt corn for rootworm control did not provide an indirect yield benefit in the absence of pest pressure.

Piggott and Marra (2007), relying on 1999–2005 university field-trial data from North Carolina, found that Bt cotton with two endotoxins out-yielded conventional cotton by 128 more lbs of lint per acre (14 percent of average yield in the region) and out-yielded Bt cotton with one endotoxin by 80 lb/acre (8 percent of average regional yield). A study of Bt cotton varieties with two endotoxins in 13 southern locations that had mostly moderate to high infestations of cotton bollworm (*Helicoverpa zea*), with or without foliar-applied insecticides, showed that indirect yield effects had spatial variability. The Bt cotton cultivars without insecticide use provided consistent control of the *Heliothines* (cotton bollworm and tobacco budworm, *Heliothis virescens*), regardless of the magnitude of infestation (Siebert et al., 2008). Furthermore, supplemental insecticide applications to the Bt cotton cultivars rarely improved control of budworm and bollworm. In the low-infestation environments, however, the use of Bt cultivars with or without insecticides provided no yield improvement relative to the control or the non-Bt cultivar without insecticide application. In the moderate- to high-infestation environments, the Bt cultivars provided the same 30-percent yield increase in lint yield with or without insecticides compared with the control (Siebert et al., 2008). In a large-scale study of 81 commercial cotton fields conducted in 2002 and 2003, average yield did not differ among Bt cotton, Bt cotton resistant to glyphosate, and non-GE cotton (Cattaneo et al., 2006). However, after statistical control for variation in two factors significantly associated with yield (number of applications of synthetic insecticide and seeding rate), the yield of Bt cotton and Bt cotton with herbicide resistance was significantly larger (by 8.6 percent) than the yield of non-GE cotton. A total of eight GE cotton cultivars and 14 non-GE cultivars were included in the study. For those

[4]As discussed in Chapter 1, all Bt rootworm corn hybrids are treated with a low level of insecticide and fungicide (typically a neonicotinoid). The low level (0.25 mg of active ingredient per seed) targets secondary pests but does not affect corn rootworm. In fields planted continuously with corn, the low level used with a soil-applied insecticide resulted in lower corn yields compared to a high level (1.25 mg of active ingredient per seed) with a soil-applied insecticide (Cox et al., 2007c). That is indirect evidence that the high level of seed-applied insecticide increases control of corn rootworm, but the low level does not. In addition, the low and high levels of seed-applied insecticides had no positive effects on corn grain (Cox et al., 2007b) or corn silage yields (Cox et al., 2007a) when following soybeans, which suggests there is no yield enhancement of these seed-applied insecticides in the absence of pests.

Impact of Genetically Engineered Crops on Farm Sustainability in the United States
http://www.nap.edu/catalog/12804.html

cultivars, it appears that Bt cotton (herbicide-resistant or not) would generally out-yield non-Bt cotton given similar production inputs and agronomic conditions.

The indirect yield effects of herbicide-resistant (HR) crops generally may have less spatial and temporal variability because weeds are ubiquitous and cause yield losses in most situations. For example, the use of HR soybean with timely glyphosate application almost always achieves yield gains relative to production without weed control (Tharp and Kells, 1999; Corrigan and Harvey, 2000; Mulugeta and Boerboom, 2000; Wiesbrook et al., 2001; Knežević et al., 2003a, b; Dalley et al., 2004; Scursoni et al., 2006; Bradley et al., 2007; Bradley and Sweets, 2008). Likewise, the use of HR corn and cotton varieties with timely glyphosate application almost always results in yield increases (Culpepper and York, 1999; Johnson et al., 2000; Gower et al., 2002; Dalley et al., 2004; Richardson et al., 2004; Sikkema et al., 2004; Thomas et al., 2004; Cox et al., 2005; Myers et al., 2005; Sikkema et al., 2005; Cox et al., 2006; Thomas et al., 2007).

Yield Lag and Yield Drag

Despite properties that result in indirect yield benefits, some farmers observed a yield reduction when they first adopted HR varieties (Raymer and Grey, 2003). Indeed, shortly after the adoption of glyphosate-resistant soybean, university soybean trials reported lower yields of HR varieties (Oplinger et al., 1998; Nielsen, 2000). In a study that compared five HR varieties with five non-HR varieties in four locations in Nebraska, evidence of "yield lag" and "yield drag" was found (Elmore et al., 2001a, b).[5] A 5-percent yield lag was due to the difference in productivity potential between the older germplasm used to develop the HR varieties and the newer, higher yielding germplasm of the non-HR varieties.[6] A 5-percent yield drag resulted from the reduced production capacity of the soybean plant following the presence or insertion process of the HR gene (Elmore et al., 2001b). Although not as pronounced as in the Nebraska study, Bertram and Petersen (2004) also presented data that indicated a potential yield lag at one location in Wisconsin with the early HR soybean varieties.

Fernandez-Cornejo et al. (2002b) reported that a national farm-level survey indicated that HR soybean showed a small advantage in yield over conventional soybean, probably because of better weed control. A national survey of soybean producers in 2002 found that there was no statistical difference in yield between conventional soybean and HR soybean (Marra et al., 2004). A mail survey of Delaware farmers in 2001 found that HR soybean had a 3-bushel/acre

[5]Yield lag is a reduction in yield resulting from the development time of cultivars with novel traits (in this case, glyphosate resistance and Bt). Because of the delay between the beginning of the development of a cultivar with a novel trait and its commercialization, the germplasm that is used has lower yield potential than the newer germplasm used in cultivars and hybrids developed in the interim. Consequently, the cultivars with novel traits have a tendency to initially yield lower than new elite cultivars without the novel traits. Over time, the yield lag usually disappears.

Yield drag is a reduction in yield potential owing to the insertion or positional effect of a gene (along with cluster genes or promoters). This has been a common occurrence throughout the history of plant breeding when inserting different traits (e.g., quality, pest resistance, and quality characteristics). Frequently, the yield drag is eliminated over time as further cultivar development with the trait occurs.

[6]During selection for a particular trait in a plant-breeding program, many other traits may also change. Such "correlated" changes may occur because a gene controls more than one trait (pleiotropy), because genes controlling two traits are in physical proximity on a chromosome (linkage), or because of random segregation (drift). The distinctions among the three causes are important because the solutions to them differ. Solutions may be necessary because some correlated changes are undesirable.

Impact of Genetically Engineered Crops on Farm Sustainability in the United States
http://www.nap.edu/catalog/12804.html

yield advantage (Bernard et al., 2004). The survey data and results of empirical studies in Wisconsin indicate that the use of more elite germplasm in variety development has probably eliminated the yield lag or yield drag associated with the use of HR varieties (Lauer, 2006).

Similarly, early empirical studies of Bt corn hybrids indicated a potential yield lag, as indicated by the lower yield of Bt hybrids than of new elite hybrids (Lauer and Wedberg, 1999; Cox and Cherney, 2001). However, Bt hybrids yielded as well as or better than near-isolines (Lauer and Wedberg, 1999; Traore et al., 2000; Cox and Cherney, 2001; Baute et al., 2002; Dillehay et al., 2004), and this suggests that there was no yield drag or loss of yield because of the insertion of the Bt gene with the early Bt corn hybrids.

Furthermore, whether a yield loss or a yield increase materializes for a GE crop depends on the particular farming situation. For example, in their comparison of HR corn hybrids with non-HR varieties, Thelan and Penner (2007) reported that in low-yield environments HR hybrids yielded 5 percent more than non-HR hybrids and in high-yield environments non-HR hybrids yielded about 2 percent more than HR hybrids. An early study of cotton (May and Murdock, 2002) that compared first-generation glyphosate-resistant cultivars with nonresistant cultivars showed no yield lag in glyphosate-resistant cultivars and a yield advantage of using glyphosate instead of the standard conventional soil-applied herbicides. The results of the study suggested that the use of soil-applied herbicides resulted in some type of injury to cotton, whereas glyphosate application before the fourth leaf stage did not. A study at nine locations across the United States (May et al., 2004) showed that one of Monsanto's later glyphosate-resistant cotton lines provided even greater yield than the first-generation glyphosate-resistant cotton when glyphosate was applied from the fourth to the 14th leaf stage; this resulted in an agronomic advantage of the later technology.

A 2002 U.S. Department of Agriculture (USDA) survey found that increases in cotton yields in the Southeast were associated with the adoption of HR cotton and Bt cotton in 1997: a 10-percent increase in HR-cotton acreage led to a 1.7-percent increase in yield and a 10-percent increase in Bt cotton acreage led to a 2.1-percent increase in yield if other productivity-influencing factors were constant (Fernandez-Cornejo and Caswell, 2006).

It was noted above that most of the yield studies of GE versus non-GE crops conducted in the United States used data from the late 1990s and early 2000s.[7] Any yield differences between GE and non-GE varieties found during the first 5 years of adoption could have diminished as seed companies developed new IR and HR events. One reason for the lack of recent studies on yields may be that it is increasingly difficult to find sufficient data on non-GE varieties owing to the predominance of GE varieties in major crops (see Chapter 4).

Improved Crop Quality and Risk Management

Bt corn has been found to decrease concentration of the toxic chemical aflatoxin (Wiatrak et al., 2005; Williams et al., 2005) and some other mycotoxins produced by fungi (fumonisins in particular) in the grain (Clements et al., 2003). In doing so, it decreases the risk of price dockage to farmers because of poor crop quality and increases food safety for consumers. Bt crops also have reduced stalk lodging at harvest (Rice, 2004; Wu et al., 2005; Stanger and Lauer, 2006;

[7]More recent data from field trials are available but have not been published in peer-reviewed literature.

Copyright © National Academy of Sciences. All rights reserved.

Impact of Genetically Engineered Crops on Farm Sustainability in the United States
http://www.nap.edu/catalog/12804.html

Wu, 2006);[8] this improves crop quality and increases harvest efficiency, thus reducing the farmers' fuel and labor costs. Another benefit of the use of HR soybean is that the presence of foreign matter (such as weed seeds) in the harvested crop has greatly decreased (from 5-25 percent to 1-2 percent in the southeastern states) (Shaw and Bray, 2003), reducing the need for handlers to blend soybean with high foreign matter with soybean with lower foreign matter to improve the overall quality of the crop.

The use of GE crops can also reduce agronomic risks for farmers. For example, in the case of HR crops, glyphosate breaks down quickly in the soil, removing the potential for the residual herbicide to injure a succeeding crop (Scursoni et al., 2006). Additionally, some Bt varieties may improve drought tolerance (Wilson et al., 2005). Empirical studies have not documented that the use of Bt corn for corn borer provides a yield benefit in the presence of drought (Traore et al., 2000; Dillehay et al., 2004; Ma et al., 2005), but Ma et al. (2009) found in an empirical study on Bt corn for corn rootworm that in a drought year on sandy soil, the Bt corn rootworm hybrid yielded 10 percent more than the near-isoline. The roots of the Bt corn rootworm hybrids were longer and more dense than those of the non-GE hybrid because the Bt trait kills the below-ground larvae that feed on the roots of the corn plant. Ma et al. (2009) speculated that Bt corn rootworm hybrids may have more drought tolerance than standard hybrids in drought years because the root system is more intact and therefore capable of taking up more water. Such risk reduction may explain in part farmers' motivation to adopt these GE crops. A related risk posed by adoption of Bt corn in northern latitudes, however, is the potential for higher grain moisture at harvest because of improved plant health, which increases drying costs or delays harvest (Pilcher and Rice, 2003; Dillehay et al., 2004; Ma and Subedi, 2005; Cox et al., 2009).

Because GE crops have the ability to reduce yield loss, adopting farmers also have different insurance options for managing risk. In 2007, Monsanto developed a submission to the USDA Federal Crop Insurance Corporation for a new crop-insurance endorsement for corn that contains three traits: a Bt toxin that controls corn borer, one that controls corn rootworm, and herbicide resistance.[9] The submission proposed a premium-rate discount for those hybrids based on several thousand on-farm field trials conducted over several years in the Corn Belt states of Illinois, Indiana, Iowa, and Minnesota. The trials demonstrated the yield and yield-risk reduction advantages of the hybrids compared with conventional or single-trait HR hybrids and showed that the current premium rates were no longer actuarially appropriate. A lower insurance premium became available in the 2008 crop year to farmers who adopted the triple-stacked hybrids. The rate discount was applied to the yield portion of the premium for actual production history of the field and based policies on crop-insurance units in which at least 75 percent of the acreage was planted to qualifying corn hybrids. The average premium-rate discount was 13 percent in 2008, or about $3.00/acre.

Comparable triple-stacked hybrids from seed companies Dupont/Pioneer and Syngenta were approved for inclusion in the program for the 2009 crop year, and the premium-rate discount applies to all three companies' and licensees' seed brands that contain at least the above-mentioned traits for dryland corn in at least a subset of 13 Midwest states and irrigated corn in

[8]Stalk lodging is the permanent displacement of the stems of crops from their upright position, resulting in a crop that either leans or can be prostrate. A mildly lodged crop results in only a slight slowdown of harvest, whereas a severely lodged crop greatly slows down harvest (in some instances the crop can only be harvested in one direction further reducing harvesting efficiency).

[9]These products are marketed by Monsanto as YieldGard® Plus, Roundup Ready 2®, and YieldGard ® VT Triple hybrids.

Impact of Genetically Engineered Crops on Farm Sustainability in the United States
http://www.nap.edu/catalog/12804.html

Kansas and Nebraska. This is the first approved crop-insurance innovation that has resulted in reduced premium rates, and it provides a saving for farmers and reduces the need for premium subsidies by the federal government. Cox et al. (2009), however, found no consistent yield or economic advantage for triple-stacked hybrids compared to double-stacked hybrids from both companies in second-year corn in New York, despite one of the years being dry and warm. In both years, corn rootworm damage was low, and corn borer damage was sporadic across locations.

Production Expenses

The use of GE crops triggers changes in several production expenses, particularly those related to seed technology, pesticide expenditures, labor and management requirements, and machinery operations.

Seed Prices

U.S. farmers pay for the GE traits in the seeds that they plant in the form of a technology fee because GE seeds are considered proprietary in the United States. The market price of seed, which includes the technology fee, incorporates the costs associated with development, production, marketing, and distribution (Fernandez-Cornejo and Gregory, 2004). The price must be responsive to farmers' willingness to purchase the technology while ensuring an attractive return on capital to the seed development firms (technology provider and licensee seed companies or distributors) and their investors. The price also depends on the competitiveness of the particular seed market and on the pricing behavior of firms that hold large shares of the market.

In recent decades, private-sector research and development costs have risen with the application of new technologies. Much of the increase in seed prices paid by U.S. farmers has been associated with that general trend (Krull et al., 1998). The seed-price index has exceeded the average index of prices paid by U.S. farmers by nearly 30 percent since the introduction of GE seeds in 1996 (Figure 3-1). The contrast is even starker for cotton and soybean. After adjustment for inflation, the real average cotton seed price almost tripled between 1996 and 2007 (Figure 3-2), while the soybean seed price grew by more than 60 percent.

SOURCE: Fernandez-Cornejo, 2004; USDA-NASS, 2000, 2005, 2009a.

The rise in real seed prices can be accounted for by improvements in germplasm, by the increasing price premiums paid for GE seed, and by the growing share of GE seed purchased by U.S. farmers (as the share of seed saved by farmers correspondingly decreased). The price premium, which includes the technology fee, doubled in real terms for GE cotton seed between

Impact of Genetically Engineered Crops on Farm Sustainability in the United States
http://www.nap.edu/catalog/12804.html

2001 and 2007 (adjusted for inflation) (Figure 3-3). U.S. farmers also experienced similar price-premium increases for corn and soybean seed (Figure 3-4 and Figure 3-5). Some of the increase reflects the larger number of services that the seed delivers to the buyers compared with conventional seed. For example, farmers who purchase Bt cotton receive the seed germplasm and an insecticide combined in one product, whereas for non-GE crops they must buy each separately and pay for costs related to applying the insecticide. The increase also reflects the additional value to the farmer provided by later GE cultivars with more than one type of trait or more than one mode of action for particular target pests. The rates of adoption noted in Chapter 1 indicate that the price premiums have not deterred many U.S. farmers from purchasing GE seeds and that non-GE seed options were less attractive or were not available.

http://www.nap.edu/catalog/12804.html

Other Input Costs

If U.S. farmers who have adopted GE crops pay higher prices for the seed, have they experienced compensatory cost reduction for other inputs? With insect-resistance technology, a plant contains its own insecticide, whereas most HR crops are engineered to be used with the herbicide glyphosate. Have those conditions changed adopters' farming practices and purchasing habits?

Economic reasoning suggests that the influence of genetic engineering on pesticide use depends on whether the GE cultivar and the pesticides are complementary or substitute inputs (Just and Hueth, 1993). Where IR or stacked GE cultivars substitute for other pesticides, chemical-pesticide use should decline. That is often the case with Bt crops (see Chapter 2, Figures 2-7 and 2-8). For HR crops, it often means reducing the use of less effective, more costly, and possibly more toxic herbicides although exceptions occur (Cattaneo et al., 2006). That substitution effect can produce cost savings as well as reductions in environmental and human health risks associated with chemical applications (Sydorovych and Marra, 2007). Several studies have attempted to establish whether the adoption of GE crops affects pesticide use. Some early investigations found evidence of a decline in pesticide use as adoption of GE crops increases (Heimlich et al., 2000; Hubbell et al., 2000; Carpenter et al., 2001; Marra et al., 2002). Some studies have found that most of the reduction in pesticide use resulting from adoption of an IR cultivar was in highly toxic chemicals, and average toxicity declined with adoption(Heimlich et al., 2000; Sydorovych and Marra, 2007). However, others have concluded that pesticide use increases in tandem with GE-crop production (Benbrook, 2004). Such contradictory findings have been attributed to the different approaches to measuring pesticide use, specifically

- How pesticide use is recorded (pesticide active-ingredient volume, formulated volume, relative toxicity, or number of applications) (Sydorovych and Marra, 2007).
- Which factors are controlled for (results would vary from region to region and from year to year depending on the extent of pest infestation, weather, cropping patterns, and so on).
- The method of aggregation (Frisvold and Marra, 2004).

A general overarching effect cannot be discerned because of the variability in specific conditions on different farms and in different regions.

The observed change in pesticide use with IR crops depends on the crop and the pest. Changes in insecticide use for treatment of European corn borer were minimal because many farmers accepted yield losses rather than incur the expense and uncertain results of chemical control. A survey of corn growers in Iowa and Minnesota determined that only 30 and 17 percent, respectively, had managed European corn borer with insecticides during any season in the early 1990s because chemical use was not always profitable and timely application was difficult owing to the unpredictability of pest outbreaks (Rice and Ostlie, 1997).

In the case of Bt cotton, however, GE control greatly reduced expenditures on pesticides to treat tobacco budworm, pink bollworm (*Pectinophora gossypiella*), and cotton bollworm (Jackson et al., 2003; Cattaneo et al., 2006). Survey data indicated that the number of insecticide sprays and insecticide costs generally decreased with the adoption of GE cotton across the United States (Table 3-1). Where measurable, farm-level profit was also shown to have increased with the adoption of Bt cotton in all states (Piggott and Marra, 2007). Although the studies

Impact of Genetically Engineered Crops on Farm Sustainability in the United States
http://www.nap.edu/catalog/12804.html

reported in Table 3-1 seem to suggest that insecticide costs increased after commercialization of Bt cotton in Arizona, detailed surveys of insecticide use and costs conducted since 1979 clearly show that use and costs were drastically reduced after 1996 (Ellsworth et al., 2009). One major factor in the reductions has been the efficient control of the pink bollworm by Bt cotton (Carrière et al., 2003; Carrière et al., 2004). However, other critical factors in reducing insecticide use and cost were the introduction of novel and highly efficient insecticides for the control of the whitefly (*Bemisia tabaci*) in cotton (Carrière et al., 2004) and the success of the boll weevil eradication program (Fernandez-Cornejo et al., 2009). That illustrates an important point (see Chapter 2): longitudinal data on pesticide use should not be taken at face value in assessing the effects of GE crops without controlling for other influences, as many factors can contribute to changes in patterns of insecticide use.

Impact of Genetically Engineered Crops on Farm Sustainability in the United States
http://www.nap.edu/catalog/12804.html

Bt corn is a preferred method for growers for controlling rootworm because of its simplicity and safety in applying it compared with soil-applied insecticides or with higher levels of active ingredient in seed treatments on non-Bt corn seed[10] (Al-Deeb and Wilde, 2005; Vaughn et al., 2005; Ahmad et al., 2006). The adoption of Bt corn for rootworm control has resulted in a substantial reduction in insecticide use, by an estimated 5.5 million pounds of active ingredient per 10 million acres (Rice, 2004).

In addition to the pesticide quantity effects, the adoption of HR and IR crops lowers the demand of competing pesticides used on conventional varieties and may therefore lower the prices of these pesticides. Huso and Wilson (2006) shows that this effect benefits farmers who adopt the GE variety and those who plant the conventional variety.

Indirect cost differences between GE crops and conventional crops originate in the adoption of practices that are linked to the adoption of some GE crops. For example, if a GE crop reduces the need for tillage to control weeds, reductions in machinery, fuel, and labor for the avoided cultivation practices amount to indirect cost savings. The indirect cost differences are particularly important for HR crops because of the complementary relationship between their adoption and conservation tillage. That is, GE-crop adoption increased the probability of adoption of conservation tillage, and conservation tillage increased the probability of higher adoption of GE crops (for a more detailed discussion of conservation tillage, see Chapter 2).

The increased use of conservation tillage has been facilitated by the commercialization of more effective postemergence herbicides, such as glyphosate, that can be applied topically to crops and weeds. Glyphosate can supplement or replace tillage as a tool for controlling most weeds and in so doing can reduce the use of machinery and fuel and lower labor requirements (Harman et al., 1985; Chase and Duffy, 1991; Baker et al., 1996; Downs and Hansen, 1998; Boyle, 2006; Baker et al., 2007). Mitchell et al. (2006) reported that a reduced-tillage system in the planting of California cotton reduced the number of tractors in operation by 41 to 53 percent, fuel use by 48 to 62 percent, and overall production costs by 14 to 18 percent. Sanders (2000) reviewed and summarized results of several studies and concluded that conservation tillage can reduce fuel costs by as much as 50 percent and labor cost by up to 40 percent. Those conclusions agree with USDA Natural Resources Conservation Service estimates that Iowa farmers would save 30-50 percent in fuel costs by adopting conservation-tillage practices (Table 3-2). Using Nebraska survey data for various row crops, Jasa (2000) showed that fuel use for no-till was 1.43 gal/acre compared with 5.28 gal/acre for moldboard-plow tillage and that labor requirements for no-till were 0.49 hours/acre, compared with 1.22 hours/acre for moldboard-plow use.

[10]As discussed in Chapter 1, Bt corn hybrid seed for corn rootworm control has 0.25 mg of active ingredient of insecticide and fungicide applied per seed compared to 1.25 mg of active ingredient applied to non-Bt corn hybrids.

Saving			32%	33%	52%

SOURCE: USDA-NRCS, 2008.

The financial returns to GE crops should vary directly with fuel prices if they save costly machinery passes over a field. HR crops do not necessarily save passes over a field, but they do substitute herbicide applications for more expensive and more fuel intensive methods of weed management, such as intensive tillage practices or the use of herbicides that require physical incorporation into the soil. Also, with potentially fewer passes over the field, tractor and spraying equipment lasts longer, and this results in savings in machinery and equipment costs over the long term.

Management Requirements and Nonpecuniary Benefits

Many of the commercially available GE products have consistently been shown to be profitable for U.S. farmers. For example, the profitability of Bt cotton in the Cotton Belt and Bt corn for controlling corn rootworm is well documented (Marra, 2001; Alston et al., 2002). However, the national evidence supporting the use of HR soybean is inconclusive (Bullock and Nitsi, 2001; Gardner and Nelson, 2007). Fernandez-Cornejo et al. (2002b) and Fernandez-Cornejo and McBride (2002) evaluated 1997 field-survey data and 1998 whole-farm survey data, respectively, and found that the differences in net returns between adopters and nonadopters of HR soybean were not significant. This lack of significance is consistent with findings from other producer surveys (Couvillion et al., 2000; Duffy, 2001). In light of high overall adoption rates, those findings suggest that other considerations have motivated farmers to use genetic-engineering technology. The wide adoption of HR soybean despite the associated technology fee stimulated research to identify possible nonpecuniary benefits to GE adopters that motivate such a shift in technology use.

In addition to the substantially superior control of a broad spectrum of weeds (Scursoni et al., 2006), simplicity, flexibility, and increased worker safety have been suggested as root causes of herbicide-resistance technology adoption, in that growers can use one herbicide instead of several to control a wide array of broadleaf and grass weeds (Gianessi and Carpenter, 1999; Bullock and Nitsi, 2001). The convenience of HR soybean use may mean that farmers can reduce the time that they spend scouting fields for weeds and mixing and spraying different

Impact of Genetically Engineered Crops on Farm Sustainability in the United States
http://www.nap.edu/catalog/12804.html

herbicides to address various weed problems (Bullock and Nitsi, 2001). Furthermore, the window of application for glyphosate is wider than that for other postemergence herbicides. That application flexibility can effectively control weeds but often the weeds have already caused a loss in potential crop yield by the time glyphosate is applied.

However, quantifying the simplicity, flexibility, and safety of pest-control programs has been difficult. The inability to include a measure of management time in the evaluation of benefits of new technologies in agriculture is not unique to HR soybean. As Fernandez-Cornejo and Mishra (2007) observed, assessments of technology adoption using traditional economic tools pioneered by Griliches (1957) have proved insufficient to explain differing rates of adoption of many recent agricultural innovations. The standard measures of farm profits, such as net returns to management, give an incomplete picture of economic returns because they usually exclude the value of management time itself (Smith, 2002). HR soybean was adopted rapidly despite showing no statistically significant advantage in net returns over conventional soybean in most studies, but adoption of such strategies as integrated pest management has been rather slow even though it has explicit economic and environmental advantages (Fernandez-Cornejo and McBride, 2002; Smith, 2002). That inconsistency led to the hypothesis that HR adoption is driven by unquantifiable advantages—such as presumed simplicity, flexibility, and safety—that translate into a reduction in managerial intensity, which frees time for other pursuits, and into increased worker safety.

An obvious use of managers' time is off-farm employment; alternatively, a farmer could farm more acreage to increase farm income. Fernandez-Cornejo and collaborators examined the interaction of off-farm income-earning activities and adoption of different agricultural technologies of varied managerial intensity, including HR crops (Fernandez-Cornejo and Hendricks, 2003; Fernandez-Cornejo et al., 2005) and Bt corn (Fernandez-Cornejo and Gregory, 2004). They also estimated empirically the relationship between the adoption of those innovations and farm household income from on-farm and off-farm sources. To do that, they expanded the agricultural household model to include the technology-adoption decision and off-farm work-participation decisions by the operator and spouse (Fernandez-Cornejo et al., 2005; Fernandez-Cornejo and Mishra, 2007).

Those studies hypothesized that adoption of management-saving technologies frees operators' time for use elsewhere, most notably in off-farm employment, and that leads to higher off-farm income. They found that the relationship between the adoption of HR soybean and off-farm household income is positive and statistically significant: after controlling for other factors, a 15.9-percent increase in off-farm household income is associated with a 10-percent increase in the probability of adopting HR soybean. The adoption of HR soybean is also positively and significantly associated with total household income from off-farm and on-farm sources. A 9.7-percent increase in total household income is associated with a 10-percent increase in the probability of adopting HR soybean. In contrast, and consistent with the lack of higher returns from this technology, adoption of HR soybean did not have a significant relationship with household income from farming. Those findings complement the findings of Gardner and Nelson (2007), who used national survey data from 2001–2003 and found that adopting HR soybean reduced household labor requirements by 23 percent.

Studies have also found that farmers value the convenience and reduced labor requirements of Bt cotton above and beyond the pecuniary benefits. Because conventional cotton faces heavy pest pressure, IR varieties decrease the time demands of spraying, and this leads to a 29-percent reduction in household labor requirements (Gardner and Nelson, 2007). Survey data of Marra

Impact of Genetically Engineered Crops on Farm Sustainability in the United States
http://www.nap.edu/catalog/12804.html

and Piggott (2006) support the finding that farmers place a monetary value on the convenience, flexibility, and relative safety of GE crops. In a stated-preference approach, participants in four surveys placed values on such characteristics as saved time, operator and worker safety, and total convenience. In each survey that evaluated the total-convenience attribute of genetic-engineering technology, it made up over 50 percent of the total value placed on nontraded aspects of the GE crop (Table 3-3). The median total value of convenience ranged from $3.33/acre per year for soybean to $5.00/acre per year for HR cotton. Survey respondents also placed a value on the improved operator and worker safety characteristics of GE crops. Farmers valued the reduction in handling and toxicity of the pesticides involved with those crops at $0.43–$2.36/acre per year. Although initially they increase the demand for GE seeds, the perceived management benefits may cause the demand for the seeds to become more inelastic (i.e., less responsive to price increases) over time. As farmers get accustomed to the characteristics and continue to place a value on them, increases in seed expenditures through either a price increase or an increase in user cost will not reduce the use of GE seeds by as large an amount as when the nonpecuniary attributes are not present (Piggott and Marra, 2008).

Management benefits do not appear to influence the adoption of GE corn. Fernandez-Cornejo and Gregory (2004) did not find a statistically significant relationship between adoption of Bt corn (to control corn borer) and off-farm household income, and Gardner and Nelson (2007) noted no effect of adoption of Bt or HR corn on household labor. The lack of a significant relationship supports the observation that most farmers accepted yield losses rather than incur the expense and uncertainty of chemical control for European corn borer before the introduction of Bt corn (Fernandez-Cornejo et al., 2002a). For those farmers, the use of Bt corn was reported to result in yield gains rather than pesticide-related savings, and savings in managerial time were small. However, one of the benefits of adoption of Bt corn for rootworm control is that it makes it unnecessary to handle toxic insecticides at planting or to deal with high rates of insecticide-treated seeds.

Thus, the econometric results are consistent with anecdotal statements that many GE crops save managerial time because of the associated simplicity and flexibility of pest control. In the case of some GE crops, such as HR soybean, these nonpecuniary benefits provide incentives for adoption that counteract the additional cost of GE seeds. Indeed, the benefits increase demand for the GE seeds, and that in turn supports a higher price. In the case of other GE crops, such as Bt cotton, nonpecuniary benefits are accrued above and beyond additional farm profits.

Lower management costs and increased yield and nonpecuniary benefits have figured in the economic value of the natural refuge for cotton with two endotoxins for control of the bollworm-budworm complex. As discussed in Chapter 2, the Environmental Protection Agency (EPA) changed the refuge requirement for these IR cotton varieties from a 20 percent refuge treated with insecticide (or a 5 percent refuge not treated with insecticides) to a natural refuge where wild host plants constitute the refuges. The benefits of the refuge change were estimated for North Carolina to be $26.90 per year per impacted acre when pecuniary and nonpecuniary impacts were considered (Piggott and Marra, 2007).

Impact of Genetically Engineered Crops on Farm Sustainability in the United States
http://www.nap.edu/catalog/12804.html

Value and Market-Access Effects

In addition to the input-cost effects, the use of GE crops can affect the revenue potential of farmers. Two such effects can occur: foreign yield effects on the prices of products sold and market access to sell the GE crops.

Increase in grain and oilseed supplies should result in downward pressure on the prices received by farmers, all else being equal. Genetic-engineering technology helped to boost yields that had already been growing over the last 70 years through improved plant-breeding techniques. As a result, supply exceeded demand; the real price of food (adjusted for inflation) had fallen until 2006. However, over the period 2006–2008, corn and soybean prices increased rapidly because of various factors, including the rise in world incomes and the demand for renewable fuels made from agricultural feedstock. The increase in the global supply of those crops due to the adoption of GE crops and improvements in germplasm and plant breeding likely moderated the upward pressures on prices during this time.

Assessing the impact of new agricultural technologies on commodity prices is difficult because the effect on price cannot be measured directly. As Price et al. (2003) explain, once a new technology is introduced and adopted, only the world price that results from increasing global supply (supply shift) can be observed. It is not possible to observe the counterfactual price—the price that would have existed, assuming the same supply and demand conditions, if the new technology had not been introduced (see Box 3-1). Therefore, the counterfactual world prices and demanded quantities of the commodities must be estimated from market equilibrium conditions by using econometric models, which generally are reliable in the short term and when systems are stable.

The approach to calculating the effect of genetic-engineering technology on commodity prices followed by most studies (Falck-Zepeda et al., 2000a; Falck-Zepeda et al., 2000b; Moschini et al., 2000; Price et al., 2003; Qaim and Traxler, 2005) is based on the theoretical framework developed by Moschini and Lapan (1997) to assess the impacts of an innovation on economic welfare when the innovator behaves as a monopolist under the protection of intellectual-property rights in an input market by pricing the new technology above marginal cost (the cost of producing one more unit of a good) (Price et al., 2003). Changes in the economic welfare of producers and consumers in a competitive output market can also be measured because some of the benefits generated by the innovation are passed on to them in the form of higher production efficiency and lower commodity prices.[11]

Table 3-4 shows the estimates of the effect of GE-crop adoption (corn, soybean, and cotton) on crop prices. The price effects are different for each crop and technology and depend on the market penetration (the extent of adoption) of the new technology and on the details of the

[11] As Price et al. (2003) described it, the estimated total market benefit of adopting each of the GE crops depends on the extent to which the global commodity supply curve shifts outward after the introduction of the technology. In each case, the shift in supply reflects potential yield increases and/or decreases in costs. The estimated market benefit also depends on the interaction of the supply and demand curves before and after the introduction of the new technology. The empirical models calculate the preinnovation and postinnovation prices and quantities in an international market setting by using information on adoption rates, crop yields, costs, technology fees, and seed premiums. The framework also takes into account the adoption of biotechnology outside the United States. The counterfactual world price, the equilibrium world price without the innovation, is the sum of the observed market price and the vertical supply shift resulting from the adoption of GE crops. The equilibrium world price occurs at the intersection of the excess-supply and excess-demand curves.

Impact of Genetically Engineered Crops on Farm Sustainability in the United States
http://www.nap.edu/catalog/12804.html

models used (particularly supply and demand parameters). For example, adoption of Bt cotton was associated with a decline in cotton prices of 0.65 percent for the first year of adoption in the United States only but with a price decline of 1.1 percent when adoption continued in the United States and took place in other countries. The effect of adoption of HR soybean varieties on soybean price ranged from a decline of 0.17 percent in 1997, when adoption had only occurred in the United States, to about 2-percent decline following further adoption in the United States and Argentina and a 2.6-percent decline for world adoption in 2001. Simultaneous adoption of Bt corn and HR soybean could lead to a decline in corn prices of 2.5 percent and a decline in oilseed prices of 3.9 percent, all other things being equal.

Table 3-5 presents the estimated distribution of the tangible benefits among consumers, farmers, technology providers (biotechnology firms), seed firms, and consumers and producers in the United States and the rest of the world. The distribution of benefits varies by crop and technology because the economic incentives to farmers (crop prices and production costs), the payments to technology providers and seed firms, and the effect of the technology on world crop prices are different for each crop and technology. For example, farmer adoption of HR cotton benefits mainly consumers, whereas adoption of Bt cotton benefits farmers and technology providers. Innovators (technology providers and seed firms) are often the largest beneficiaries in the case of HR soybean, but producers and consumers also gain (Moschini et al., 2000). The aggregate net benefits to crop farmers depend on the aggregate cost saving relative to the estimated price decreases and increased production (sales). The lower output prices may deter some farmers who have relatively lower yield gains or higher costs from adoption. But farmers with sufficient yield gains and cost saving will adopt GE crops even when an increase in supply puts downward pressure on prices. Livestock producers primarily receive benefits from lower prices of feedstocks than would have occurred without GE-crop adoption. Analyses of the benefits of GE crops and their distribution have many nuances.

The studies mentioned above analyzed the economic effects of GE varieties during the early period of their adoption of these technologies (the latest study used data from 2001).[12] Results of studies of adoption in agriculture (Feder et al., 1985) suggest that early adopters of new yield-increasing technologies gain early in the life of the technologies, but that their gains dissipate as prices go down. The United States was the dominant early adopter of GE varieties; James (2009) has since found a high rate of adoption of GE varieties more recently, mostly in developing countries. The agricultural products produced with genetic engineering are traded globally, and adoption of GE varieties worldwide affects prices that U.S. farmers receive.

[12]These studies were carried out before Brazil began producing large amounts of GE soybean. The entry of Brazil into the GE soybean market and the continued expansion of GE soybean in Argentina may have pushed considerable amounts of the benefits from producers to consumers.

Impact of Genetically Engineered Crops on Farm Sustainability in the United States
http://www.nap.edu/catalog/12804.html

According to (James, 2009), 331 million acres of land were planted to GE cultivars worldwide in 2009, of which nearly 95 percent was in six countries: the United States, Argentina, Brazil, Canada, India, and China. The total global acreage planted to GE crops in 2009 amounted to 8 percent of the world's tillable cropland. The GE cultivars were mostly of four crops: soybean (52 percent), corn (31 percent), cotton (12 percent), and canola (5 percent). In 2009, 77 percent of the soybean area, 49 percent of the cotton, 26 percent of the corn, and 21 percent of the canola lands were grown with GE cultivars. Much of the adoption of GE corn and cotton has been in the United States, Argentina, and Brazil, but China and India are major adopters of Bt cotton. The majority of acres planted to GE crops were HR varieties, at approximately 62 percent, followed by stacked traits at 21 percent and IR varieties at 15 percent. Stacked traits grew at a 23 percent rate from 2007 to 2008, the highest rate of the three trait categories (James, 2009).

According to Sexton et al. (2009), the high increases in yield that resulted from adoption of Bt cotton in developing countries have contributed to the increase in the world cotton supply and to the relatively low prices of cotton from 1998–2008. They suggest that the decline in the price of cotton relative to the price of other agricultural commodities has contributed to the transition from cotton to other crops in California. The same shift away from cotton is taking place in other cotton-producing regions. Total upland cotton-planted acreage in the United States has declined by 36.8 percent since 2002 (USDA-NASS, 2009).

Soybean acreage began to increase in the United States in 1997 and stayed relatively high until 2002, in part because the commodity support prices in the Federal Agricultural Improvement and Reform Act of 1996 favored soybean over other program crops. Even though Sexton et al. (2009) found that average yield of soybean—the crop with the highest rate of adoption of GE cultivars—grew more slowly than that of cotton after the introduction of GE varieties, the introduction of GE soybean contributed to the expansion of harvested soybean area worldwide, which grew by nearly 30 percent from 1997 to 2007 (FAO, 2008). In Argentina alone, GE soybean enabled adoption of no-till practices, which facilitated double cropping of wheat and soybean and contributed to a 9.9-million-acre increase in the soybean area from 1996 to 2003 (Trigo and Cap, 2003). The adoption of GE soybean in South America contributed to the increase in soybean supply, which also occurred because of the expansion of soybean acreage in Brazil. That supply shift caused downward pressure in soybean prices and had an adverse effect on growers in the United States, although the price effect was overwhelmed by the effect of increased global demand for soybean during the period 2006–2008.

Many of the analyses summarized in Table 3-4 and Table 3-5 are based on partial-equilibrium models (in which the price of one good is examined and all other prices are held constant), but several studies have examined the effect of adoption of GE cultivars on producers and consumers by using a computable general-equilibrium approach (the prices of good are examined in relationship to one another). Some of the studies also attempted to assess the costs of access barriers imposed on GE crops by the European Union (EU), which has had a moratorium on the production and import of GE crops since 1999. Qaim (2009) has surveyed those studies and found that they predict an annual global welfare gain to consumers and producers from adoption of GE cultivars without restrictions, ranging from $1.4 billion from the adoption of Bt cotton to $10 billion from the adoption of GE oilseed and corn. The results of the studies suggest that bans on imports of GE crops reduce the potential economic welfare of several parties, including U.S. farmers, but that European consumers suffer much of the loss.

Anderson and Jackson (2003) estimated that even under free trade—with global welfare gain from the introduction of GE cultivars of cotton, corn, and oilseed that will enhance supply—farmers in the exporting countries will actually lose 0.07 percent of their income because of lower prices, whereas low-income consumers in North America will stand to gain from the introduction of GE cultivars because of lower food prices, all other things being equal. A moratorium on the export of GE crops to the EU will quadruple the losses to U.S. farmers. Such asynchronous conditions, when GE crops are approved at different times or not at all by different countries, could influence farmers' planting decisions because of those losses. Yet at the same time that U.S. farmers suffer economically, U.S. consumers benefit. A more severe moratorium on GE exports by the EU and other developed economies, such as that of Japan, is estimated to reduce the income of North American farmers by 0.5 percent. Those bans will hurt European consumers but benefit European farmers. Nielsen and Anderson (2001) showed that the welfare

Impact of Genetically Engineered Crops on Farm Sustainability in the United States
http://www.nap.edu/catalog/12804.html

costs of less drastic barriers, such as labeling and segregation requirements, are important but smaller than the cost of bans.

Lence and collaborators (Lence and Hayes, 2005a, b; Lence and Hayes, 2006; Lence et al., 2005) show that, in addition to the cost saving and other benefits, the overall welfare impact of genetic-engineering technology depends on the level of consumer concern with the technology and the costs of identity preservation. In particular, they state that their results suggest "the United States may have maximized welfare by not requiring labeling" of GE corn and soybean, but they claim that their results also suggest that "recently approved EU legislation enforcing labeling of GE crops also makes sense because consumer concern in the EU appears to be greater than that in the United States."[13]

The literature suggests that adoption of GE cultivars puts downward pressure on crop prices and increases the earnings of adopting farmers in the early years of the adoption process and that barriers to access reduce grower income. But there is a paucity of studies of the welfare effects of genetic-engineering technology in recent years, when adoption has increased globally, and this is an important subject for future research.

ECONOMIC IMPACTS ON OTHER PRODUCERS

Livestock Producers

Much of the soybean and corn produced in the United States is fed to livestock (Figure 3-6 and 3-7), and byproducts are used in consumer products, so quality and nutritional characteristics of soybean and corn associated with GE crops have been closely examined. Most studies of soybean have reported no differences in animal performance (Hammond et al., 1996); in important nutritional qualities, such as isoflavones (Duke et al., 2003); or in other characteristics at the macroscopic level of HR soybeans (Magaña-Gómez and Calderón de la Barca, 2009). Researchers (Cox and Cherney, 2001; Jung and Sheaffer, 2004) have reported that glyphosate-resistant Bt corn does not affect feeding-quality characteristics of corn silage. Lutz et al. (2006) reported that the Bt protein Cry1Ab is degraded during the ensiling process. In feeding studies, there was no difference in milk production or milk composition between glyphosate-resistant corn, with or without the stacked Bt gene, and nontransgenic hybrids (Barrière et al., 2001; Phipps et al., 2005; Calsamiglla et al., 2007). There were no differences in body weight and feed use between rats fed grain from a Bt corn rootworm hybrid and rats fed grain from a nontransgenic hybrid (He et al., 2008). Likewise, no differences were observed in mortality, weight gain, feed efficiency, or carcass yield between broiler chickens fed grain from a Bt corn rootworm hybrid and chickens fed grain from a near-isoline (McNaughton et al., 2007). Thus, empirical studies have clearly indicated that there is no adverse effect on quality of livestock feed or on the output or quality of livestock products.

[13]The welfare implications of different regimes of protection of intellectual property rights in the seed industry have also been studied (Lence et al., 2005).

Furthermore, nutritional characteristics of GE and conventional corn hybrids—including fatty acid profiles, mineral and vitamin contents, lutein, and total phenol and antioxidant activity—were comparable (Venneria et al., 2008) although some slight differences in triglycerides and urinary phosphorus and sodium extractions were noted in male rats (Magaña-Gómez and Calderón de la Barca, 2009). Cotton seed is used as a byproduct in animal feed, and cottonseed oil is used for human consumption. Castillo et al. (2004) found that Bt cotton seeds were deemed nutritionally equivalent with no difference in feed intake, milk yield, or composition. Few studies have been conducted to assess the levels of the glyphosate metabolite aminomethylphosphonic acid (AMPA) in glyphosate-treated, glyphosate-resistant corn hybrids; however, one study by Reddy et al. (2008) reported no detection of AMPA. Duke et al. (2003) reported that AMPA was detected in glyphosate-treated, glyphosate-resistant soybean seeds; however EPA has not established a tolerance for AMPA. Given that AMPA is not considered significantly toxic (Giesy et al., 2000), the discovery of AMPA in glyphosate-treated, glyphosate-resistant soybean is not considered to be an issue of importance at this time.

Feed costs constitute nearly half the variable costs of livestock production, so even moderate price fluctuations can seriously affect the trajectory of the livestock market (USDA-NASS, 2008). As mentioned above, livestock operators are the buyers of feed, and they are the major beneficiaries of reductions in the prices of corn and soybean, to which the adoption of GE crops has contributed. They also benefit from increased feed safety from the reduction of mycotoxins (Wu, 2006). We are not aware of any quantitative estimation of savings to livestock operators and final consumers due to the adoption of GE crops or of the resulting effect on the profitability of livestock operations. This is another subject on which future research is desirable.

Impact of Genetically Engineered Crops on Farm Sustainability in the United States
http://www.nap.edu/catalog/12804.html

Producers of Non-Genetically Engineered Crops

The adoption of GE crops affects production costs for non-GE farmers in several key ways. GE crops alter the demand for inputs, and this affects the cost of inputs to GE and non-GE crops alike.[14] For example, Bt crop varieties that reduce insecticide use also lower the input costs for producers who use insecticides that substitute for Bt because the lower overall demand for them puts downward pressure on their prices. In other cases, GE crops increase the demand for other inputs. HR varieties increase demand for broad-spectrum herbicides, like glyphosate, which can have mixed effects on the price. On the one hand, the increase in demand puts upward pressure on the prices of those herbicides and, everything else being equal, increases the profits of the firms that manufacture GE seeds. On the other hand, the expanded market for broad-spectrum herbicides compatible with HR crops may allow firms to reduce the price of the herbicide but still increase profits through greater sales. HR varieties also affect the demand and prices for the herbicides that were used before HR crop varieties became available, usually by lowering prices because of reduced demand.

We have observed in Chapter 2 that GE crops can affect production of non-GE crops favorably or unfavorably through externalities associated with pest-control activities. To the extent that genetic-engineering technology successfully reduces pest pressure on a field, farmers of adjacent or nearby fields planted with non-GE crops may benefit from reductions in costs for pest control associated with reductions in regional pest populations (Sexton et al., 2007). Such favorable externalities may exist for Bt crops, which control pests that target GE and non-GE crops equally (Ando and Khanna, 2000). HR crops may provide some benefits to non-GE crops on adjacent fields by reducing rates of pollination of weeds, but more certain benefits will accrue to crops planted in rotation with GE crops. Specifically, because HR crops permit the postemergent use of broad-spectrum herbicides, such as glyphosate, weed species that affect GE and non-GE crops may be controlled more effectively. In particular, glyphosate has proved effective in controlling perennial weeds that appear late in the principal crop season, persist, and impose losses on subsequent crops (Padgette et al., 1996; Shaw and Arnold, 2002). The reduction in pest pressure from the late-season use of effective chemicals on HR crops may benefit the crop planted in the following season (Baylis, 2000; Tingle and Chandler, 2004) although empirical evidence of this effect is scarce. A massive field trial of crop rotation and herbicide application practices in Britain has provided evidence that the production systems used for HR canola can improve weed control in cereal crops planted in rotation (Sweet et al., 2004).

---

[14] As stated above, the introduction of GE crops will probably reduce pest damage and, in some cases, will reduce the commodity prices of corn, soybean, and cotton. In the damage-control framework, the demand for inputs other than the ones controlling pests (such as water and energy) is represented by (Lichtenberg and Zilberman, 1986)

$$\text{Quantity demanded} = (\text{crop price})(1 - \text{damage})(\text{marginal value of the input in producing potential output}).$$

This equation suggests that GE cultivars will contribute to increased demand for inputs—such as fertilizer, water, and capital—if adoption of GE cultivars increases the earning per unit of potential output, which is equal to (crop price)(1 – damage), assuming no acreage constraints. Thus, when the introduction of GE cultivars does not affect crop prices but reduces pest damage, adoption of GE crops increases the demand for other input use. That increases the demands for fertilizer, water, capital, and so on, and causes upward pressure on their market prices. When the introduction of GE cultivars reduces commodity prices substantially, it may lead to reduced demand for other inputs. We are not familiar with empirical studies that have tried to estimate the impact of GE crops on the demand for or prices of other inputs, and this is a subject for future work.

Impact of Genetically Engineered Crops on Farm Sustainability in the United States
http://www.nap.edu/catalog/12804.html

Farmers of non-GE crops may also experience adverse externalities associated with HR-crop weed control. Growers experience an adverse effect when an economically important amount of herbicide resistance builds up. As discussed in Chapter 2, resistance to broad-spectrum herbicides is a concern associated with adoption of HR varieties because use of other chemicals drastically declines in favor of the herbicide to which the crop is resistant (Shaner, 2000). When resistance in weeds evolves, farmers have resorted to managing those weeds with additional forms of control; they have either increased their use of the herbicide to which the HR crops are resistant, used additional and possibly more expensive forms of weed control (such as cultivation), or both. Such actions not only reduce or reverse the environmental benefits of HR crops reviewed in the previous chapter but also result in higher production costs for the grower compared to using glyphosate alone. To date, costs have not risen to the level of costs incurred in the conventional systems of weed control. If they had, a substantial reduction in the use of HR crops would have occurred. Resistance-management strategies, such as the use of refuges, can be expensive for individual farmers, though such strategies can provide long-run pest control benefits in the area that will offset the sum of individual costs if implemented correctly. Although Bt crops may be prone to resistance buildup because the toxins that target pests are always present in the field, the refuge requirements for Bt crops have thus far provided adequate protection from insect resistance buildup in the United States. The tradeoff is the requirement to plant some percentage of a crop to non-Bt cultivars, which may result in net economic costs to producers growing IR crops. Those costs, if they occur, are in the form of higher pesticide costs, foregone yield, or both. A benefit is the lower cost of seed for the refuge acres. A case in point is Bt cotton with the single trait for bollworm and budworm control, for which EPA requires a 20 percent insect-treated refuge or a 5 percent non–insect-treated refuge in the Southeast. Farmers who choose the 20 percent refuge can incur higher insecticide costs to treat insect infestations—more passes over the field and more labor to scout for insects—but have lower overall seed costs. Those who choose the 5 percent, untreated refuge can experience substantial yield loss on the refuge acres, though the cost of seed for those acres is lower. It is important to note that before the introduction of the Bt crops substantial insect resistance to other classes of insecticides, such as pyrethroids, had been observed.

SOCIOECONOMIC IMPACTS OF GENE FLOW

Inadvertent gene flow from GE to non-GE crops can also have a variety of social and economic effects. Both the Ecological Society of America and the National Research Council have recognized that some degree of gene flow between sexually compatible GE and non-GE crops occurs regularly (NRC, 2004; Snow et al., 2005). Indeed, the presence of adventitious GE traits in the intended non-GE seed supply of canola, cotton, corn, and soybean and in the seed supply of GE crops (e.g., a Bt trait in crop seed that is intended as HR only) is well documented (Beckie et al., 2003; Friesen et al., 2003; Mellon and Rissler, 2004; Heuberger et al., 2008; Heuberger and Carrière, 2009) The probability of gene flow is similar in both directions between GE and non-GE varieties of a crop (Mallory-Smith and Zapiola, 2008); however, for farmers, consumers, and food distributors, the actual and perceived consequences of gene flow from GE to non-GE crops are greater than the consequences of gene flow from non-GE to GE crops.

Gene flow between GE and non-GE crops occurs via three routes: cross-pollination between GE and non-GE plants from different fields (as discussed in "Gene Flow and Genetically Engineered Crops" in Chapter 2), co-mingling of seed before the production year (in the

Copyright © National Academy of Sciences. All rights reserved.

Impact of Genetically Engineered Crops on Farm Sustainability in the United States
http://www.nap.edu/catalog/12804.html

presence of GE traits in seed bags of non-GE crops) or during the production year (mixing of seed at planting, at harvest, or during storage), and germination of seeds left behind (i.e., volunteers) after the production year (Owen, 2005; McHughen, 2006). Generally, GE and non-GE crops can coexist. However, given that some domestic and foreign consumers are willing to pay a premium for non-GE products, there are strong market incentives as well as some sociocultural reasons for farmers, seed distributors, and food processors to minimize the adventitious presence of GE traits in non-GE crops and derived products (Lin et al., 2003; Belcher et al., 2005; Furtan et al., 2007; Devos et al., 2008).

Gene flow between HR and non-HR crops can increase production costs if gene flow promotes weediness. For example, when volunteer seeds survive and germinate to the following season, field management costs increase because the volunteers will not be eliminated by glyphosate applications. Similarly, if HR traits cross into weedy relatives, weed-control expenses will be higher for all fields on to which these weeds spread, whether the farmer grows GE crops or not (Smyth et al., 2002).

Gene flow of GE traits could jeopardize the economic value of the entire harvest of non-GE-crop farmers by rendering their output unsuitable for high-value markets (Bullock and Desquilbet, 2002). They could also have unfavorable effects on the levels of trust that exist between market participants. Two groups of farmers could be impacted by gene flow: those farming non-GE crops conventionally and organic farmers. The U.S. government does not have thresholds for what level of purity is required to characterize a product as non-GE; the thresholds are instead determined by the market. The U.S. National Organic Program excludes GE methods from the organic process (OFPA, 2009). Because of adventitious gene flow, the organic process does not necessarily result in a non-GE product when it goes to market; whether adventitious presence is discovered depends on if testing for GE material is conducted. Therefore, if GE traits are discovered in organic crops intended for a non-GE market, the organic or non-GE status of a crop may be forfeited depending on the potential legal or market tolerances for the presence of GE traits (Gealy et al., 2007). Other governments have set thresholds for organic and non-GE crops; for example, Japan has a 5 percent threshold for corn while the EU has zero tolerance for non-approved GE material but a 0.9 percent permissible level for GE material that has been approved by the EU (Bradford, 2006; Ronald and Fouche, 2006). Tests can be performed to assess the presence of GE traits in grain to preserve the identity of non-GE grain; whether a positive test results in rejection of a product depends on the individual policies of buyers. Additional research is needed to determine the extent to which screening is used and its relationship to variation in consumer desires for purity in the food supply. Although non-GE products can lose market value because of the adventitious presence of GE material, the price of GE products is not affected by the adventitious presence of non-GE material. Accordingly, gene flow between GE and non-GE crops imposes costs primarily on consumers and producers of GE-free crops (Smyth et al., 2002; Belcher et al., 2005; Devos et al., 2008). Such a need to protect the market value of non-GE products probably contributed to the creation of GE-free zones in some regions of the United States and in the EU (Jank et al., 2006; Furtan et al., 2007). Widespread use of GE crops in the United States may have forced some corporations that were producing GE-free products to move their operations to countries where GE crops were less prevalent (Mellon and Rissler, 2004). Nevertheless, a survey published in 2004 suggested that 92 percent of U.S. organic growers who responded to the survey had not incurred any direct costs or suffered losses attributable to the adventitious presence of GE crops (Brookes and Barfoot, 2004). However, it must be noted that there have been considerable increases in the adoption of

Copyright © National Academy of Sciences. All rights reserved.

Impact of Genetically Engineered Crops on Farm Sustainability in the United States
http://www.nap.edu/catalog/12804.html

GE crops in the United States as well as growth in U.S. organic-crop production and the market for non-GE products since this survey was conducted, that so far GE traits have been incorporated into a small number of crops that have few near-relatives in U.S. agriculture, and that few studies have analyzed trends in the socioeconomic impacts of gene flow.

A zero tolerance for the presence of GE traits in non-GE crops is generally impossible to manage and is not technically or economically feasible. Pollen transfer between sexually-compatible GE and non-GE crops is difficult, if not impossible, to prevent, and segregation between GE and non-GE products may be accomplished more easily and economically when nonzero thresholds for the adventitious presence of GE material in non-GE end-user products and seed are established. The goal of the thresholds is to set acceptable limits for the presence of GE traits that have been deemed safe and approved for human consumption. Accordingly, programs aimed at establishing such thresholds are analogous to seed-certification and food-labeling programs that have been used for decades to ensure the quality of seeds for agriculture and of food for consumers. The difficulty of maintaining the coexistence of GE and non-GE crops increases as the tolerance for the adventitious presence of GE traits in non-GE products becomes lower and the adventitious presence of GE traits in non-GE products becomes easier to detect even at very low levels due to technological advances.

The situation has a drastically greater impact when GE traits *not* approved for human consumption contaminate non-GE products. Such contamination can have strong adverse effects on market value, on the possibility of exporting crops, on the costs of remedial actions to remove contaminated supplies, and therefore on the profit margins of food producers and distributors (Lin et al., 2003; Vermij, 2006; Vogel, 2006). It can also undermine public confidence in the food system. The effects of the identification of a variety of Bt corn marketed under the name StarLink® in human food constitute an important example. StarLink® was approved only for use in animal feed but was discovered in products destined for human consumption. The resulting concerns about food safety led to the recall of more than 300 food products, and some major U.S. export markets, such as Japan and South Korea, imposed trade restrictions (Lin et al., 2003). The technology developer ultimately discontinued sale of StarLink® seed. Similarly, the accidental release of glufosinate-resistant rice in the United States in 2006 and the contamination of sulfonylurea-resistant flax in Canadian exports in 2009 imposed heavy costs on farmers, commodity traders, and processors.

Those examples of accidental releases, or any other low-level presence of unapproved GE material in the food supply, impose considerable costs on the food system that need to be accounted for in cost-benefit analyses of GE crops (Salazar et al., 2006). They also affect farmers' planting decisions because of the risk of lost revenues and other economic and social costs. As more exotic GE crops (e.g., pharmaceuticals) enter the commercialization phase, possible supply disruptions will multiply with greater potential for conflict between sectors in the food and non-food industries and substantial economic costs. Such potential market and political repercussions indicate that a very low tolerance threshold set by U.S. regulatory authorities is appropriate for the presence of unapproved GE traits in food intended for human consumption.

Certain groups of consumers prefer GE-free products, a preference that is likely to increase the demand for products made with ingredients from organically grown crops. The NOP regulations require the certified organic producers must produce and handle their organic agricultural products without the use of GE methods (NOP, 1990). However, the unintentional presence of GE material in organic products will not necessarily lead certifying agents to change the status of an organic product or operation (Federal Register, 2000). As explained above,

Copyright © National Academy of Sciences. All rights reserved.

Impact of Genetically Engineered Crops on Farm Sustainability in the United States
http://www.nap.edu/catalog/12804.html

because some level of gene flow between GE and non-GE crops is difficult to prevent, the adventitious presence of GE material has been detected in non-GE products, including certified organic products. Therefore, the process-based NOP standard that excludes GE methods in production and handling systems does not assure that organically grown crops with non-GE methods will be free of GE material for marketing.

The presence of GE material can affect the ability of growers to sell non-GE and organic crops in domestic and foreign markets with requirements beyond the process-based standard of the NOP. Accordingly, policies have been established to manage the potential for adventitious presence while enabling coexistence of GE, GE-free, and organic production systems. However, policy-established tolerance thresholds for the adventitious presences of traits from commercialized GE crops in non-GE or organic products vary considerably among countries. For example, in the United States, voluntary labeling of food as GE-free is allowed as long as a product contains less than 5 percent adventitious presence of GE material(Demont and Devos, 2008; OFPA, 2009). In contrast, the EU allows up to 0.9 percent adventitious GE material in non-GE food, animal feed, and products labeled as organic if the GE crop has been approved in the EU; otherwise, the threshold is zero (Demont and Devos, 2008). Certified non-GE seed sold to farmers in the United States is typically expected to contain less than 0.5-1 percent of seeds (depending on crop type) with GE traits (Mellon and Rissler, 2004; CCIA, 2007). Thresholds for commercial seed have been considered but have not yet been implemented uniformly in the EU (Kalaitzandonakes and Magnier, 2004; Devos et al., 2008).

GE-free or organic products lose their premium market value when the adventitious presence of GE material exceeds established government or market thresholds. Anecdotal stories suggest that the crops of U.S. organic growers are being screened in the marketing chain for the presence of GE material and are being rejected if levels exceed market-determined levels. We do not have evidence to judge how widespread such testing is in the United States. This issue deserves more investigation to determine the extent of such market-led behavior and the social and other factors driving it. We do know that given the threshold criteria in the EU for GE material in organic products, food produced in the United States and labeled as organic by U.S. certifiers could be rejected in the EU as not organic because of adventitious presence of GE material even though no GE seed or crops were used in production by U.S. producers. The coexistence of GE and non-GE products is possible as long as measures are taken to ensure that the adventitious presence of GE traits remains below the thresholds set in receiving markets, either by governments or buyers. In general, threshold differences among regions contribute to creating barriers to the use of GE crops and trade in non-GE products (Smyth et al., 2002; Demont and Devos, 2008; Devos et al., 2008).

Separating GE and non-GE products at every step of the production process is expensive, and costs increase as thresholds for the presence of GE traits in non-GE products decrease (Lin et al., 2003; Kalaitzandonakes and Magnier, 2004). Growers must attend to details and apply considerable effort to achieve effective segregation between GE and non-GE crops (CBI, 2007). Grain segregation in normal production settings is difficult but can be accomplished and could effectively minimize the co-mingling of GE and non-GE crops. Given that co-mingling of seeds can be costly for growers, particularly for growers who have specific contracts that restrict GE traits, tactics for isolating GE crops from non-GE crops must be established effectively (Owen, 2000). Controlling volunteer GE crops in non-GE crops may not be difficult, depending on crop rotation, but requires considerable diligence on the part of growers (Owen, 2005). When volunteer crops acquire a GE trait for herbicide resistance via unintended gene flow, weed-

Copyright © National Academy of Sciences. All rights reserved.

Impact of Genetically Engineered Crops on Farm Sustainability in the United States
http://www.nap.edu/catalog/12804.html

management costs for a grower may increase and potential crop yield may decline if the crop planted the following season is also resistant to glyphosate (Owen and Zelaya, 2005). Furthermore, the isolation distances required to maintain complete segregation for open-pollinated crops are often too large to be economically feasible (Matus-Cádiz et al., 2004).

An economic assessment based on data from major seed firms in the United States indicated that reducing the adventitious presence of GE traits in non-GE corn seed from 1 percent to 0.3 percent would raise seed production costs by about 35 percent (Kalaitzandonakes and Magnier, 2004).[15] The increased costs would involve changes in field operations and in processing and result from new expenses for extra purity testing, storage, and transportation, but most of the increase in production costs would result from measures taken at the field level to minimize gene flow. Thus, programs that set levels of tolerance for the adventitious presence of GE traits in non-GE products probably have substantial impacts on growers directly and would increase the cost of non-GE seed and the market value of GE-free and organic products (Smyth et al., 2002; Kalaitzandonakes and Magnier, 2004; Belcher et al., 2005).

Barring the risk of contamination, GE crops can contribute to the creation of market opportunities for non-GE farmers. The organic market is a primary example. By virtue of the ban on the use of GE traits in the official USDA definition of organic production, the organic movement can market itself to, and collect a price premium from, consumers who prefer not to purchase food or fiber produced with genetic-engineering technology. Consumer preference for non-GE foods may be related to other traits associated with organic production, but the stated price premium for non-GE crops is substantial in some segments of the population (Huffman et al., 2003).

CONCLUSIONS

The widespread adoption of GE crops has had agronomic and economic implications for adopters and non-GE producers in the United States. For GE farmers, the general increase in yield, reduction in some input costs, improvement in pest control, increase in personal safety, and time-management benefits have generally outweighed the additional costs of GE seed. The use of HR crops has not greatly increased yields, but it has generally improved weed control, especially on farms where substantial weed resistance to the specific herbicide to which the HR crop is resistant has not developed, and it has improved farmers' incomes by saving time thus facilitating more off-farm work or providing more management time on the farm. IR crops have increased yields in areas where economically damaging insect-pest pressures occur and have saved on expenditures for conventional pesticide. Thus, the use of HR and IR crops has mostly increased adopters' incomes compared with the use of non-GE varieties.

It should be noted that the economic benefits have changed over time and probably will continue to change. Yield lag and yield drag were not uncommon when HR crop varieties were first introduced, but GE traits have since been incorporated into high-yielding varieties, and improved GE events have replaced the initial events. Although research has identified those changes in farmers' experience with GE crops, there has been little investigation of the economic impact of GE crops more recently. More research would improve the information available to

[15]This study is a summary assessment over various GE crop technologies and therefore should not be applied to specific situations. It is likely that the impacts would vary considerably over different GE cultivars and their specific farming situations.

Impact of Genetically Engineered Crops on Farm Sustainability in the United States
http://www.nap.edu/catalog/12804.html

farmers, plant breeders, and policy-makers as market, environmental, and social conditions change.

The extent to which GE crops make it economical to expand production to lands not previously cultivated or to intensify production on existing cropland with double cropping has not been reported adequately in the literature. More research on the economic effects of GE-crop adoption on non–GE-crop producers would also be beneficial. Examples include the costs and benefits of shifts in pest management for non-GE producers due to the adoption of GE crops, the value of market opportunities afforded to organic farmers by defining their products as non-GE crops, the economic impacts of GE adoption on livestock producers, and the costs to farmers, marketers, and processors of adventitious presence or contamination from approved or unapproved GE traits and crops into restricted markets.

Farm-System Dynamics and Social Impacts of Genetic Engineering

The dissemination of genetically-engineered (GE) crops, like the adoption process associated with other farm-level technologies, is a dynamic process that both affects and is affected by the social networks that farmers have with each other, with other actors in the commodity chain, and with the broader community in which farm households reside. As noted in Chapter 1, farmer decisions to adopt a technology are influenced not only by human-capital factors, such as the educational level of the adopter, but by social-capital factors, such as access to information provided by other farmers through social networks (Kaup, 2008). That necessarily implies that farmers receive information from others—for example, on the risks and benefits of a particular technology—and that they share their own knowledge and experience through the same networks. Such findings confirm the relevance of social factors in influencing how genetic-engineering technology is adopted, what the impacts of its adoption are, and the significance of farmers' active participation in both formal and informal social networks with other actors in commodity chains and communities.

However, little research has been conducted on the social impacts of the adoption of genetic-engineering technology by farmers, even though there is substantial evidence that technological developments in agriculture affect social structures and relationships (Van Es et al., 1988; Buttel et al., 1990). Because further innovations through genetic engineering are anticipated, such research is needed to inform seed developers, policymakers, and farmers about potential favorable benefits for adopters and nonadopters and unwanted or potentially unforeseen social effects (Guehlstorf, 2008). With such information, the likelihood of maximizing social benefits while minimizing socials costs is increased. To demonstrate the necessity for increasing commitments to the conducts of research on the social effects of GE-crop adoption, this chapter synthesizes what is known in the scientific literature about the social impacts of farm-technology adoption and the interactions between farmers' social networks. The chapter also identifies future research needs.

SOCIAL IMPACTS OF ON-FARM TECHNOLOGY ADOPTION

The earliest academic research in the United States on the social impacts of technology adoption at the farm and community levels was focused on mechanical technologies. More than a century ago, the use of machines in U.S. agriculture not only displaced labor but widened

Copyright © National Academy of Sciences. All rights reserved.

Impact of Genetically Engineered Crops on Farm Sustainability in the United States
http://www.nap.edu/catalog/12804.html

socioeconomic discrepancies between skilled and unskilled laborers (Quaintance, 1984). Academic interest in the socioeconomic consequences of agricultural mechanization was particularly strong in the 1930s and 1940s in the southern United States (Buttel et al., 1990) and again in the 1970s throughout the country. Berardi (1981) summarized the findings of the literature and found that mechanization was associated with decreases in the agricultural labor force, particularly those among the least educated and least skilled workers and in minority groups; with better working conditions and less "drudgery" for the remaining work force; with a decrease in farm numbers and an increase in farm size; with increased capital costs for agricultural producers; and with a decline in the socioeconomic viability of agriculture-dependent rural communities. Data also suggested that the technological development of U.S. agriculture had contributed to declines in farm labor, in community dependence on agriculture, and in rural community viability although other on-farm and off-farm factors also contributed to these changes (Van Es et al., 1988).

In the 1980s, social scientists broadened their research on the impacts of technology adoption on farms and farm communities to include studies of the potential and actual impacts of biological (pre–genetic engineering) technologies in agriculture. Many observers assumed that, unlike the earlier wave of mechanical agricultural technologies, genetic-engineering technology would not be biased towards large-scale farming operations. Such an assumption was supported by analyses of the production capabilities of agricultural biotechnology. For example, it was noted that no interaction effect was observed between genetic predisposition to produce milk and the use of the growth hormone bovine somatotropin (BST) to increase milk production in dairy cows (Nytes et al., 1990). However, other studies that directly examined farm-level social change revealed that, despite the presumption of scale-neutrality, it was difficult to isolate the impacts of biological innovations from those of other technological innovations in agriculture because biological innovations were often developed and disseminated in conjunction with other technologies that may not have been scale-neutral (Kloppenburg, 1984).

Additional research conducted on the social impacts of biotechnology in animal agriculture, specifically on the use of BST, noted that rates of adoption of BST were moderate and that, although adoption did not require large herds, scale effects were observed because BST use was more effective in high-producing cows, which were more likely to be found in large herds with complementary feeding technologies (Barham et al., 2004). Beck and Gong (1994) also observed the existence of a scale effect with adoption of BST, with adopters more likely to have larger herds, as well as being younger and having more formal education. Additionally, it was suggested that the quality of farm management had an impact on the benefits accruing to the adoption of BST (Bauman, 1992). The use of BST also was thought to lead to lower prices and thus to result in increased economic pressure on smaller producers (Marion and Wills, 1990). In other words, the body of research on the socioeconomic consequences of the use of biotechnologies, including Green Revolution technologies, indicated that "scale neutrality is not inevitable, but a possibility that depends on institutional context" (DuPuis and Geisler, 1988: 410). To put it another way, the social context of the adoption process and the impacts on that context are interconnected, from which it follows that the social impacts of genetic-engineering technology on farms and communities differ among cultures, commodities, and historical periods.

Thus, though seed varieties are generally conceptualized as being scale-neutral, the adoption of any technology may be biased toward large firms that can spread the fixed costs of learning over greater quantities of production (Caswell et al., 1994). In developing countries, the

Impact of Genetically Engineered Crops on Farm Sustainability in the United States
http://www.nap.edu/catalog/12804.html

economics of genetic-engineering technology do not appear to vary with farm size (Thirtle et al., 2003). However, scale may affect accessibility to technology. Small farmers have less influence in input supply and marketing chains with which to secure access to desired technologies. Thus, there can be a scale bias in the development and dissemination processes associated with herbicide-resistance technology that puts small farmers at a disadvantage. In contrast, as noted in Chapter 3, insect-resistance technology can replace insecticide applications that require fixed capital investments, such as for tractors and sprayers. In this regard genetic-engineering technology has the potential to favor small farmers, who would benefit more from a technology that required less fixed capital investment. The scale effects of transgenic varieties may also depend on the pricing (such as quantity discounts) set by seed companies, which typically assess a technology-user fee.[1]

An early empirical study was carried out by Fernandez-Cornejo et al. (2001) using 1998 U.S. farm data. They found that, as expected, the adoption of HR soybean was invariant to size, but adoption of HR corn was positively related to size. They explained this disparity as due to the different adoption rates: 34 percent of the farms had adopted HR soybean at the time, implying that adoption of HR soybean had progressed passed innovator and early-adopter stages into the realm where adopting farmers are much like the majority of farmers. On the other hand, adoption of HR corn was quite low at the time (5 percent of farms), implying that adoption was largely confined to innovators and other early adopters who in general tend to control substantial resources and who are willing to take the risks associated with trying new ideas. Thus, they claimed that the impact of farm size on adoption is highest at the very early stages of the diffusion of an innovation (HR corn), and becomes less important as diffusion increases. This result confirms Rogers's (2003) observations that adoption is more responsive to farm size at the innovator stage, and the effect of farm size in adoption generally diminishes as diffusion progresses. Early adopters, by virtue of early adoption, also are able to capture a greater percentage of the economic benefits of the technology adoption process.

Clearly, one cannot extrapolate the social impacts of the adoption of GE crops based solely on an assumption that the productive capabilities of genetic-engineering technology, when isolated from the interaction with other factors, should be scale-neutral. In other works, previous research on the social impacts of agricultural technologies suggests the possibility that the early dissemination of genetic-engineering technology would be associated with farm size, and that the use of GE crops could have differential impacts across farm types, farm size, and region, despite the fact that GE crops are presumed to be scale-neutral.

In an article that attempted to predict some of the environmental, economic, and social effects of genetic engineering of crops, it was argued that the use of GE crops was "clearly capable of causing major ecological, economic, and social changes" (Pimentel et al., 1989 p. 611). Nonetheless, over the last decade, there has been virtually no empirical research conducted on the social impacts of the use of GE crops on farms and rural communities. The lack of research may have to do in part with the scarcity of funds available for such research as well as a relative lack of interest in social issues on the part of environmental groups (Chen and Buttel, 2000), and other groups and organizations that might be expected to support such research. Nonetheless, the results of research referred to above on the social repercussions of agricultural technologies, including non–genetic-engineering biotechnology in crops and biotechnology in

[1]Examples of empirical studies on the effect of farm size on GE adoption are given in "An Early Portrait of Farmers who Adopt Genetically Engineered Crops" in Chapter 1.

Impact of Genetically Engineered Crops on Farm Sustainability in the United States
http://www.nap.edu/catalog/12804.html

animal agriculture, would suggest that there are impacts, that these impacts could be favorable or adverse, and that adverse impacts could be alleviated through the adoption of appropriate policies. For example, based on earlier research on the introduction of new technologies in agriculture, it might be hypothesized that certain categories of farmers (those with less access to credit, those with fewer social connections to university and private sector researchers, etc.) might be less able to access or benefit from existing GE crops. There is also the possibility that the types of genetic advances being marketed do not meet the needs of certain classes of farmers, and that the full spectrum of the potential of genetic-engineering technology is not being achieved. Furthermore, the possibility exists that communities where farmers play an important social, political, and economic role could be impacted as well. However, for the purpose of this report, no conclusion on the social impacts of the adoption of GE crops can be drawn on the basis of empirical evidence. Research on such impacts clearly should be accorded a high priority as genetic-engineering technology evolves. Without such research, the potential for genetic-engineering technology to contribute to the sustainable development of U.S. agriculture and rural communities cannot be adequately assessed. Thus, we recommend that such research be sponsored and pursued actively and immediately.

SOCIAL NETWORKS AND ADOPTION DECISIONS

The adoption of genetic-engineering technology and its performance on the farm are functions of the knowledge of agricultural decision-makers, who include farmers, input suppliers, commodity traders, farm-management consultants, and extension agents. In making technology-adoption decisions, farmers rely principally on information about the relative performance of competing technologies and on information about best practices for optimizing yields and controlling costs, given the technologies that they use. The performances of firms and technology, therefore, depend upon the information used by various commodity-system actors. Just et al. (2002) have shown that the internal competences of decision-makers affect the degree to which they rely on different types and sources of information.

Farmers rely on a variety of intermediaries—such as extension agents, commodity groups, commercial vendors, agricultural media, and other farmers—for information. For example, farmers often turn to commodity associations for information about regulations and regulatory changes. Many of the intermediaries that farmers communicate with use public information, especially data and research results provided by the U.S. Department of Agriculture (USDA) Economic Research Service and the National Agricultural Statistics Service and by state extension services, particularly for information about the economic outlook of agriculture and specific industries. Intermediaries use formal channels of information more than farmers (Just et al., 2002) and then make that information available to farmers.

Farmers obtain about half their information from informal sources (i.e., sources whose professional duties do not include provision of information) (Just et al., 2002), including people in the end-users' civic, community, professional, and commercial networks, like neighbors, colleagues, customers, and suppliers. Farmers' reliance on informal sources may reflect low availability of or access to information from formal channels, issues of affordability of private information, and credibility (Just et al., 2002).

Those findings suggest that farmers' attitudes toward GE crops are likely to be affected by a number of information providers. USDA's Cooperative Extension Service, commodity groups, and agricultural media are particularly influential in informing farmers' views on the technical

Copyright © National Academy of Sciences. All rights reserved.

Impact of Genetically Engineered Crops on Farm Sustainability in the United States
http://www.nap.edu/catalog/12804.html

aspects of genetic-engineering technology, its economic implications, and its prospects. Although the influence of those sources has not been widely appreciated, they have played a key role in the adoption of the technology. As Wolf et al. (2001) and Just et al. (2002) demonstrated, informal sources of information are just as likely as formal sources to accelerate or to slow the rate of GE-crop adoption. It would also be reasonable to hypothesize that patterns of information use would be linked to the ability of farmers to use the technology effectively and maximize its potential.

INTERACTION OF THE STRUCTURE OF THE SEED INDUSTRY AND FARMER DECISIONS

The U.S. seed industry has experienced extensive structural change in the last few decades. The changes have affected decisions at the farm level by shaping the choices available to corn, soybean, and cotton farmers.

As Fernandez-Cornejo and Just (2007) have summarized, plant-breeding research until the 1930s was conducted primarily by the public sector (for example, USDA and state agricultural experiment stations), and most commercial seed suppliers were small, family-owned businesses that multiplied seed varieties that had been developed in the public domain. Seeds embody the scientific knowledge needed to produce a new plant variety with desirable attributes—such as higher yield, disease or pesticide resistance, or improved quality—so seed innovators face both the risk of imitation by competing seed firms and the risk of seed reproduction by farmers themselves (Fernandez-Cornejo, 2004). The development of hybrid corn in the first half of the 20th century provided breeders with greater protection of intellectual-property rights (IPR) because seeds saved post-harvests produced substantially smaller yields than the hybrid plants from which they were gathered. With that incentive, the number of private firms engaged in corn breeding grew rapidly.

The proliferation of firms was followed by consolidation in part because U.S. law evolved to provide incentives to innovators for research and development by giving them exclusive control of their innovations through patent laws and other forms of enforceable legal protection (Fernandez-Cornejo, 2004). Two principal forms of legal protection for seed innovators are plant variety protection (PVP) certificates issued by the Plant Variety Protection Office of USDA and patents issued by the Patent and Trademark Office (PTO) of the U.S. Department of Commerce. Both grant private crop breeders exclusive rights to multiply and market their newly developed varieties. Patents provide more control because PVP certificates have a research exemption that allows others to borrow a new variety for research purposes (Fernandez-Cornejo and Schimmelpfennig, 2004). IPRs for seed innovators were strengthened by the U.S. Supreme Court's 1980 *Diamond* v *Chakrabarty* decision, which extended patent rights to GE microorganisms, important tools and products of biotechnology. A series of rulings by PTO's Board of Appeals and Interferences widened the scope of patent protection for GE organisms by including plants and nonhuman animals. Those rulings extended IPRs to a wide array of new biotechnology products in the form of utility patents (also referred to as patents for invention). Products protected under the rulings include seeds, plants, plant parts, genes, traits, and biotechnology processes (Fuglie et al., 1996; Fernandez-Cornejo, 2004).

Enhanced IPR protection has brought rapid increases in private research and development (R&D), and indirectly assisted technology developers in setting prices above marginal costs (Goldsmith, 2001). Private spending on R&D in crop varieties increased by a factor of 14 in real

Copyright © National Academy of Sciences. All rights reserved.

Impact of Genetically Engineered Crops on Farm Sustainability in the United States
http://www.nap.edu/catalog/12804.html

terms from 1960 to 1996 (Fernandez-Cornejo, 2004), whereas public (federal and state) spending changed little (Figure 4-1); (Fernandez-Cornejo and Schimmelpfennig, 2004). At the same time, IPR protection may have spurred market concentration in the seed industry. The potential profits of seed firms made possible through IPR protection may strengthen the incentive to invest and thus provide greater opportunities to large firms (Lesser, 1998). Many seed firms have been acquired by corporations that have the resources needed to achieve large economies of scale in R&D (Fernandez-Cornejo, 2004). For example, Lesser (1998) stated that more than 50 seed firms were acquired by pharmaceutical, petrochemical, and food firms after the passage of the Plant Variety Protection Act.[2] In contrast, Lesser (1998) also noted that weakness of IPR protection may lead to mergers and acquisitions. In any case, by 1997, the share of U.S. seed sales controlled by the four largest firms reached 69 percent for corn (up from 60 percent 1973), 47 percent for soybean (up from 7 percent in 1980), and 92 percent for cotton (up from 74 percent in 1970) (Table 4-1; Fernandez-Cornejo, 2004). Though it is difficult to obtain recent detailed published market share information, it appears from company reports and other sources that the trend of increased concentration in the structure of the seed industry continued in recent years.[3] Farm survey data for corn and soybean indicated that by 2007 the share of the four largest firms reached 72 percent for corn and 55 percent for soybean (Figure 4-2; Shi and Chavas, 2009).

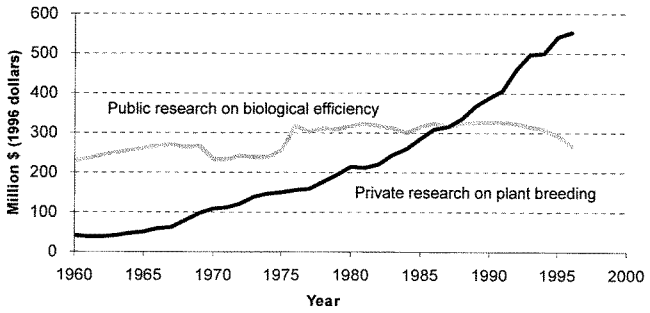

FIGURE 4-1 Public and private research expenditures on plant breeding. Biological efficiency includes breeding and selection of improved plant varieties.
SOURCE: Fernandez-Cornejo, 2004.

[2]The Plant Variety Protection Act (PVPA) of 1970 granted plant breeders a certificate of protection that gave them exclusive rights to market a new plant variety for 18 years from the date of issuance. Amendment of the PVPA in 1994 brought it into conformity with international standards. Protection provided by certificates of protection was extended from 18 to 20 years for most crops (Fernandez-Cornejo, 2004).

[3]In the case of corn, Pioneer has lost its dominant position in the corn seed market from about 40 percent to 30 percent while Monsanto's share of the corn seed market increased to about 30 percent as a result of the Landec acquisition (Leonard, 2006).

Concentration of R&D output can also be used to measure the concentration in innovation activity in the seed industry (Fulton and Giannakas, 2001). In genetic-engineering technology, a measure of R&D output is the number of GE cultivars approved by USDA for release into the environment for field testing. In particular, Fernandez-Cornejo (2004) adapted the four-firm concentration-ratio measure, commonly used to quantify industry concentration in terms of sales, to examine R&D concentration on the basis of regulatory approvals of GE crop varieties. Table 4-2 shows the percentage of field releases obtained by the leading four firms in 1990–2000. The top four firms controlled well over 50 percent of the approvals; this suggests consolidation in R&D and potential barriers to entry for competitors. As Fulton and Giannakas (2001) noted, expenditures on R&D and expenditures made to obtain regulatory approvals are sunk costs—costs that cannot be recouped. If such sunk costs are present, markets are not contestable, so there are potential barriers to entry.[4]

[4]A contestable market behaves in a competitive manner despite having few companies because of the threat of new entrants.

SOURCE: Fernandez-Cornejo, 2004.

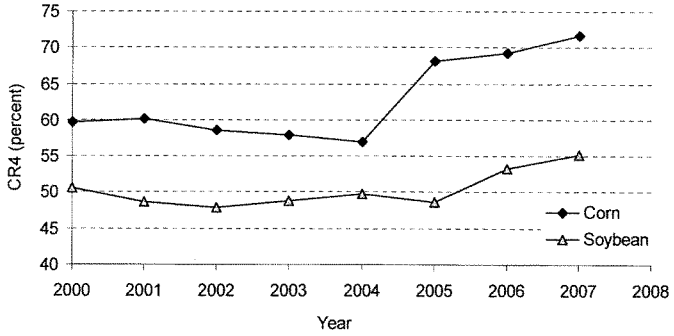

FIGURE 4-2 Share of planted acres of corn and soybean seeds by largest four firms (CR4). SOURCE: Stiegert et al., 2009.

As Fernandez-Cornejo (2004) observed, on the basis of the four-firm concentration ratio of approvals, the extent of corn-seed R&D concentration has been relatively constant at around 72 percent, which is fairly consistent with the four-firm concentration ratio in corn in terms of sales. Cotton-seed R&D is the most centralized, and this is also consistent with market-concentration measures.

Patent ownership shows a pattern of concentration similar to that evident in other R&D measures (Fernandez-Cornejo, 2004). Most of the biotechnology patents awarded to private firms are held by a small number of large companies. As of 1996–1997, Pioneer (soon after DuPont/Pioneer) held the largest number of patents for corn and soybean, followed by Monsanto (Brennan et al., 2000). The leading firms in the sector have received IPR protection not only by virtue of their respective R&D investments but through mergers and acquisitions. For example, Pioneer was one of the first four companies active in the emerging corn-seed market in the early 1930s. As shown in Figure 4-3, Pioneer (Pioneer Hi-Bred International, Inc.) made a series of

Copyright © National Academy of Sciences. All rights reserved.

Impact of Genetically Engineered Crops on Farm Sustainability in the United States
http://www.nap.edu/catalog/12804.html

acquisitions in 1973–1980 that strengthened its overall position in the seed market. The chemical firm DuPont bought 20 percent of Pioneer in August 1997 and bought the remaining 80 percent in 1999 for $7.7 billion. As a DuPont company, Pioneer continues to operate under the Pioneer name and remains headquartered in Iowa (Fernandez-Cornejo, 2004).

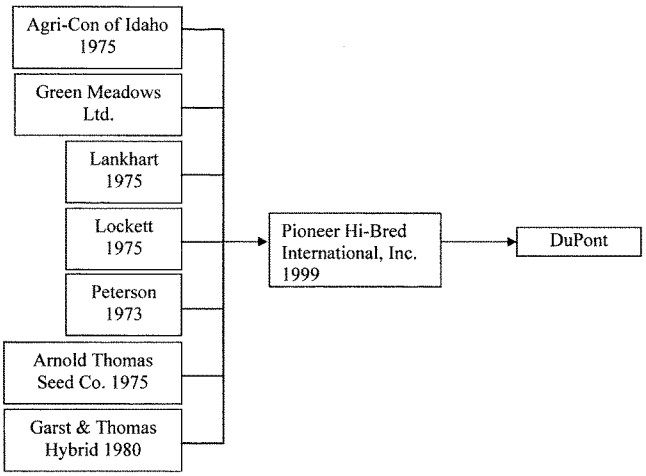

FIGURE 4-3 Evolution of Pioneer Hi-Bred International, Inc. / E. I. du Pont de Nemours and Company.

SOURCE: Fernandez-Cornejo, 2004.

Although the increase in seed-industry concentration has raised concerns about its potential impact on market power, and ultimately on the sustainability of farms, empirical results for U.S. cotton and corn seed industries over the period covering 1970–1998 (which includes only 2 years of GE-crop adoption) suggest that increased concentration during that time period resulted in a cost-reducing effect that prevailed over the effect of enhanced market power (Fernandez-Cornejo, 2004). Goldsmith (2001) argued that even though GE-seed prices were above the competitive price, the actions of biotechnology supply firms apparently were not adversely affecting the welfare of U.S. farmers.

However, concerns have been raised that, in time, such market power could lead to decreased variability in the types of seeds being produced for the market, as well as increased prices, which could limit the ability of farmers to purchase those seeds most suited for local environmental conditions. In addition, it is conceivable that the continued market power of biotechnology supply firms could lead to increased input costs for farmers, which in turn could have an unfavorable effect on the socioeconomic sustainability of farms. A recent study by Shi and

Copyright © National Academy of Sciences. All rights reserved.

Impact of Genetically Engineered Crops on Farm Sustainability in the United States
http://www.nap.edu/catalog/12804.html

Chavas (2009) has found that vertical integration (ownership of control of different stages of production) in the U.S. soybean seed industry had a substantial effect on soybean prices. Shi et al. (2008) analyzed the pricing of corn seed with stacked traits for the years 2000–2007 and found "significant departures from component pricing (where seeds are priced as the sum of their component values). The evidence supports sub-additive pricing. It shows that the marginal contribution of each component to the seed price declines with the number of components." The authors also have indicated that "such a finding is consistent with the presence of economies of scope in seed production. Indeed, synergies in R&D investment (treated as fixed cost) across seed types can contribute to reducing total cost."

In response to these concerns and others, USDA and the U.S. Department of Justice launched a series of workshops in 2010 to examine competition and regulatory issues in the agriculture industry (USDA, 2010). This is a first step towards updating and continuing research on how market structure in the seed industry may be impacting seed prices and availability to variability in genetic resources. In addition, studies of how seed-industry concentration, as well as the practice of cross-licensing, could interact with farmers' planting options and decisions, overall yield benefits, crop genetic diversity, and economic returns would be very valuable.

Although the private sector owns the majority of agricultural-biotechnology patents, the public sector still owns a substantial share. In a study of assignment of U.S. plant-biotechnology patents granted from 1982 to 2001, Graff et al. (2003) found that 41 percent of the patents were owned by large biotechnology companies, 35 percent by startups, and 24 percent by the public sector. The public-sector ownership is weaker in some categories, such as Bt and other insect-resistant traits (10 percent) and plant enzymes (8 percent), but stronger in other categories (42 percent in flowering and 56 percent in pathogen resistance). The capacity of the public sector to obtain freedom to operate in transgenic crops is often also constrained by the fragmentation of technology ownership among numerous institutions. Improved access to information about IPRs and reduced transaction costs to obtain rights to use patents could increase the public sector's contribution to the development of transgenic varieties. Concerns have also been raised that technology use and stewardship agreements prevent scientists in the public sector from conducting independent assessments of GE varieties marketed by the private sector. In February 2009, in response to a notice in the *Federal Register* on a meeting of the Federal Insecticide, Fungicide, and Rodenticide Act Scientific Advisory Panel, 26 entomologists submitted a general comment that, because of those restrictions, the data that the Environmental Protection Agency received regarding GE crops were inherently limited (*Federal Register*, 2009). If such restrictions exist, farmer welfare could be adversely affected by the lack of complete information regarding GE traits or crops. However, the degree to which technology use agreements may hamper public research is unclear and strongly disputed by private-sector seed companies (Monsanto, 2010). This issue merits careful investigation by neutral researchers to understand what, if any, effects such agreements have on public research.

SOCIAL AND INFORMATION NETWORKS BETWEEN FARMERS AND INDUSTRY

Agriculture is unique among American industries in that federal law allows farmers to cooperate in some collective activities while competing in the output market. That has enabled farmers to act collectively as a counterweight to the large firms on which they rely to sell their output (Cochrane, 1993). Farmers have developed cooperatives to coordinate research and marketing efforts to benefit from economies of scale in these activities (Sexton, 1986). That

Copyright © National Academy of Sciences. All rights reserved.

Impact of Genetically Engineered Crops on Farm Sustainability in the United States
http://www.nap.edu/catalog/12804.html

collective-action capacity is important for adoption of genetic-engineering technology in that it gives farmers the ability to influence crop traits that are introduced.

Farmers may attempt to block seed technologies if they anticipate that those new technologies will not enhance, or perhaps even endanger, farm profit. Innovation in any crop can increase farm revenue if the elasticity of demand for the crop is sufficiently high that increases in output compensate for decreases in prices. But if the elasticity of demand is low, increased output may lead to a fall in revenue and a decrease in profit unless the technology delivers cost savings. In the latter case, farmers may attempt to block the introduction of a technology. Farmers may also block a technology if its introduction would result in lower prices in national or international markets.

A large body of literature on the political economy of research argues that farmers use political pressure to shape public research funding. Ruttan (1982) argued that farmer pressure may have led to underinvestment in public research in the United States, and deGorter and Zilberman (1990) linked overall spending on research to the political power of such groups as consumers and producers. Graff and Zilberman (2007) argued that farmers' interests partly motivated Europe's effective ban on GE crops, which in turn affected the access of U.S. farmers who were growing GE crops to European markets.

Another example of farmers' collective action is how farmers' concerns influenced Monsanto's decision to halt its efforts to introduce and market herbicide-resistant (HR) wheat. Some farmer coalitions in the United States and in Canada played a role in that decision because they feared losing access to European and Asian markets that would not accept HR wheat. It was thought that the introduction of that GE crop might have closed markets to U.S. and Canadian farmers who planted non-GE wheat because of the difficulty in segregating wheat on fields and in grain elevators and trucks (e.g., Chin, 2004; Pollack, 2004). Many international buyers, including millers and bakers in important Asian and European markets, had made it clear that they wanted to purchase identity preserved (IP), non-GE commodities (Vandenberg et al., 2000). In the case of white wheat, Japan and South Korea, two countries that have GE-food labeling laws, were importing more than one-fourth of U.S. white wheat exports (Squires, 2004). Japanese millers and bakers were well aware that a large percentage of Japanese consumers were expressing negative attitudes toward the use of genetic-engineering technology in foods and believed that their government's regulation of GE food was too lax (Toyama et al., 2001). Indeed, Japan was the United States's largest market for non-GE corn and soybean: nearly 90 percent of the IP, non-GE corn and soybean produced in the United States was being exported to Japan (Wilson et al., 2003). Faced with such demands from the marketplace and with farmer concern about how those demands might influence sales in those markets, Monsanto decided to defer the introduction of HR wheat in 2004.

However, farm organizations are not monolithic; indeed, the issue of HR wheat divided the farming community (Graham and Martin, 2004). Even after Monsanto chose to suspend its HR-wheat program, wheat producers and support groups, such as the National Association of Wheat Growers, exhibited a strong interest in glyphosate-resistant wheat (Jussaume et al., 2004). Monsanto's HR trait had been inserted into only one variety of wheat grown in a subset of U.S. and Canadian regions. It was opposed primarily by farmers who did not plant the potential HR variety and by some farmers who could have planted it but were afraid of losing access to European and Asian markets. Furthermore, during its deliberations, the present committee heard that North Dakota wheat farmers who were against the introduction of HR wheat because of concern about losing market access in Europe may now believe that they are disadvantaged by

Impact of Genetically Engineered Crops on Farm Sustainability in the United States
http://www.nap.edu/catalog/12804.html

not having HR varieties and would like to see government and industry action that would lead to its development (Wilson, personal communication). Pest pressure is heterogeneous among growing regions, so support for or opposition to damage control through GE traits will vary according to farmers' abilities to benefit from them. Thus, the potential for collective action to restrain the power of the seed industry is a function of farmers' common interests, which are often variable.

Farmer cooperatives may also undertake efforts to bring about the introduction of seed traits that the private sector, for economic or other reasons, is not motivated to introduce. They may pool resources to undertake their own research or to defer the regulatory and development costs that private firms face when they introduce new seed technologies. Farmers have worked with universities to introduce new technologies (Bradford et al., 2006), and similar collaborations could be effective in the development of genetic-engineering technology. In California, grape growers have suffered considerable losses from Pierce's Disease, so they have contributed funds to the Public Intellectual Property Resource for Agriculture to support research for a genetic-engineering solution to the problem (PIPRA, 2006). More generally, pooled funds from farmers can lead to the introduction of desired traits for specialty crops when private seed companies lack the incentives to develop the traits alone (for more discussion of seed-access issues, see Chapter 3). As the price of wheat goes up, for instance, farmers in some regions may approach companies or universities to develop seed varieties to address specific constraints on productivity (Wilson, personal communication). They may also work with initiatives like the Specialty Crop Regulatory Assistance program, a fledgling collaboration of the federal government, scientists in public universities and the private sector, and farmers designed to assist technology developers in negotiating GE specialty crops through the requirements and expense of the regulatory process.

Despite the ability of farmers to organize collectively to counterbalance seed companies and processors, some farmers are concerned about the evolution of seed-technology innovation from a public good to a private good that is controlled by firms that have market power derived from patents on specific products. Innovation in most agricultural inputs is embodied in the technology, as in tractors and fertilizers. The technology is developed and sold by the private sector. But because it had historically been difficult to capture benefits from research efforts in seed technology before the advent of hybrid corn seed, the private sector underprovided seed-technology innovation, and the public sector took the lead in providing improved seed varieties in many crops (especially wheat, soybean, cotton, barley, and oat). Consequently, farmers who grew those crops—particularly wheat, barley, and oat—became accustomed to free or low-cost access to seed, and some farmers may consider open access to seeds a right.

In the case of GE seed, however, companies can make use of patent protection to enforce contracts that disallow reuse of the seed grown in farmers' fields. Farmers must instead purchase seed from firms to reward their research investment and effort. The patents enable the private sector to set prices for the protected technology and to restrict the flow of knowledge. The private sector had already begun to invest more in seed technology for major crops such as corn in the 1930s and soybean in the 1970s. Because of the difficulty and expense of removing lint from the seed, cotton farmers had traditionally purchased their seed from ginners and seed distributors. Consequently, the introduction of GE seeds by the private sector and the patented nature of the technology in the case of commercially available corn, soybean, and cotton may not have appeared to be strikingly different from the established relationship between seed companies and farmers of those commodities.

Impact of Genetically Engineered Crops on Farm Sustainability in the United States
http://www.nap.edu/catalog/12804.html

However, the developmental trajectory of GE-seed technology is leading to concern that access to seeds without GE traits or to seeds that have only the specific GE traits of particular interest to farmers may become increasingly limited. Additional concerns are being raised about the lack of farmer input and knowledge regarding which seed traits might be developed. The push to develop seed varieties with a series of stacked traits, some of which may not be of use to some farmers with respect to short-term productivity (leaving aside the issue of improved resistance management discussed in Chapter 2), raises the issue of access to seeds that have equivalent yield potential but only the desired GE traits or no GE traits at all. Although the committee was not able to find published research that documents the degree of U.S. farmers' access to and the quality of non-GE seed, testimony provided to the committee suggested that access to non-GE or nonstacked seed could become limited for some farmers and that available non-GE or nonstacked seed may not have the same yield characteristics as GE cultivars (Hill, personal communication). Research is needed to investigate the extent to which U.S. farmers are having difficulty purchasing high-yielding, non-GE seed. Public-sector institutions could address this concern by improving the design of licensing contracts with seed companies so that property rights of privately developed traits or cultivars will revert to university research programs if private companies do not use the technologies.

Boejlje (1999) has suggested that U.S. agriculture is going through a structural change in which activities that will enhance product differentiation and added value to farming are being emphasized. As part of that evolution, many agricultural sectors (poultry, swine, and some fruits and vegetables) have come to be dominated by contracting arrangements between major agribusiness companies and farmers or by large vertically integrated agribusiness firms. Those large companies have the resources and scale to finance research in the development of GE traits. The emergence of alliances between biotechnology companies and large agribusiness firms, and even large farmers' cooperatives to produce proprietary GE varieties, appears possible, but future research is needed to determine whether such relationships can lead to the development of differentiated products (Boehlje, 1999)—including those with traits that enhance direct value to consumers, such as improving health or convenience, or that respond to the environmental and management needs of specific groups of farmers—and whether such relationships will limit farmers' access to the types of GE traits they value.

INTERACTIONS OF LEGAL AND SOCIAL ISSUES SURROUNDING GENETIC ENGINEERING

Legal issues constitute an important sociopolitical dimension that influences the adoption of genetic-engineering technology and its impacts on farmers and communities. The legal issues are complex, and a complete treatment of them is beyond the expertise of any of the authors of this report. We briefly touch here on the issues of seed saving, gene flow, and organic standards.

Seed Biotechnology

Courts in the United States and Canada have consistently upheld the rights of companies that sell patented seeds and genes through technology-use agreements to prohibit seed-saving practices that involve seed sold through those contracts (Kershen, 2004; Anonymous, 2008). Although that property right has been established, some continue to express concern about the

Impact of Genetically Engineered Crops on Farm Sustainability in the United States
http://www.nap.edu/catalog/12804.html

ethical issues surrounding the patenting of life forms and over the effects of technology-use agreements on seed-saving practices. Research on whether those concerns are warranted and what the impacts are on farm sustainability are needed. Concerns are also being raised about the lack of farmer involvement in GE-trait development for traits that could address production problems identified by farmers and over the implications of current patenting procedures on power relationships between biotechnology firms and farmers (Phillipson, 2001). However, the social and economic effects of the exercise of such property rights, especially actual or potential litigation on both adopters and nonadopters of GE crops, have not been thoroughly investigated by social scientists. The lack of academic analyses of those issues may be due in part to the fact that companies, in any sector, that use the courts to enforce their property rights view legal actions and any out-of-court settlements as proprietary information. One interesting response by those who are concerned about the possible effects of the private control of genetic resources has been the open-source breeding movement.[5]

Gene Flow

A second set of legal issues related to genetic-engineering technology has to do with gene flow, particularly from fields of GE crops to those managed by people not using GE crops (for more on the potential for gene flow between GE and non-GE crops and on the challenges of coexistence of GE and non-GE crops, see Chapter 2). As in cases that involve restrictions on farmers against seed saving, these issues can be viewed as property-rights issues. Does gene flow impinge on the rights of producers and consumers who wish to grow and eat foods that do not include GE material (Conner, 2003)? That is of particular concern to some farmers who wish to produce organic or non-GE crops. Even though organic certification by the U.S. government is determined by the process used to grow the crop some farmers are concerned that their products may not be accepted by markets in other countries or by food distributors and consumers who establish their own standards, irrespective of process.

Several lawsuits have been filed by farmers against agricultural-biotechnology companies in part because of damage alleged to have occurred as a result of drift of genetic material to the fields of farmers who do not wish to grow crops with GE traits (Kershen, 2004). Consumer groups have also brought legal action against the federal government for approving the commercialization of GE crops that have the potential to cross with non-GE crops in the same vicinity. As was discussed in previous chapters, GE alfalfa was pulled from the market after a U.S. federal judge sided with arguments brought forward by numerous plaintiffs and found that USDA should have prepared an environmental impact statement before it deregulated the crop that facilitates commercialization (*Geertson Farms Inc.*, 2009). In another case filed by the Center for Food Safety and other plaintiffs, a federal judge decided in September 2009 that similar steps should have been taken before GE sugar beet was commercialized (Pollack, 2009).

Issues raised by the possibility of gene flow are not only legal in nature. As noted in Chapters 2 and 3, the adventitious presence of GE material in non-GE crops raises complex environmental and economic challenges. Similarly, social problems could arise as a consequence of gene flow,

[5]This movement, which has been inspired in part by open-source project movements in computer software and elsewhere, is in essence an attempt to develop publicly available genetic resources. As in the case of "shareware," researchers working on open-source biotechnology can access and improve on publicly available genetic resources and technologies but must agree to make the improved materials available for others to use (Delmer, 2005; Lerner and Tirole, 2005).

http://www.nap.edu/catalog/12804.html

particularly if GE and non-GE producers of the same commodity live in the same community. Gene-flow disputes could move beyond the merely legal and affect the overall functioning of communities where such disputes exist. This might include conflicts between farmers as well as stress related to the economic and social costs associated with lawsuits and the potential threat of lawsuits. Studies of the social effects of such disputes are needed to gauge the full impact on community well-being. The ability of GE production and non-GE production to coexist in society may depend on the health of communities. Proposals for establishing "landscape clubs" (Furtan et al., 2007) and voluntary "GMO-free zones"[6] (Jank et al., 2006) clearly depend on the existence of high levels of community cooperation, which could be undermined by disputes related to gene flow.

Organic Laws and Resistance to Genetic Engineering

One of the intriguing public debates that has emerged around genetic engineering in agriculture has been that regarding whether GE crops should be allowable in legal standards for organic agriculture. As discussed in Chapter 1, many organic growers have vehemently resisted the notion that GE crops should be allowable in organic agricultural production systems. However, scientific arguments can be made for the use of genetic-engineering technology for making organic agricultural production more sustainable. Ronald and Adamchak (2008) note that what is or is not an appropriate use of genetic-engineering technology for "organic" producers is problematic given that genetic-engineering techniques can be used to transfer genes within plant species as easily as between them. Genetic-engineering techniques also include the use of marker-assisted breeding wherein the genetic "fingerprint" of plants can be used to aid conventional plant breeding. These authors also note the potential for genetic-engineering technology to develop new varieties of crops that could be grown under conditions that reduce some of the adverse environmental impacts of growing food and that contribute to local food production. The rationale parallels the arguments used in discussing the potential of genetic-engineering technology for improving the productive capability of orphan crops in developing countries (Naylor et al., 2004).

The ideological divisions between those who favor and those who oppose the use of GE plants in organic production systems are complex, and in many cases concerns about safety and naturalness are connected to and mask socioeconomic concerns. An example of the complexity was the successful vote in Mendocino County, California, in 2004 to ban the local use of GE organisms in agriculture. The legal focus of the vote was on GE organisms, but it was clear, because of how genetic-engineering technology was linked to issues related to corporate versus local control of agriculture, that the technology was viewed by many of those supporting the measure as a social problem (Walsh-Dilley, 2009). Similarly, some genetic-engineering proponents argue for including GE products in organic standards and labels at the same time that they argue against the labeling of foods with GE content because they consider GE and non-GE foods to be substantially equivalent products (Klintman, 2002). That position can be understood, in part, as a desire to obtain the economic benefit of some labels while avoiding the cost of being associated with other labels. Those examples underscore the important socioeconomic and

[6]A group of growers concerned about the organic purity of an open-pollinated field crop may come together to form a "landscape club", a fee-based organization designed to increase their economic welfare by providing protection against contamination through gene flow from related GE crops. A zone free from genetically modified organism (GMO-free) would provide similar protection (Jank et al., 2006)

Impact of Genetically Engineered Crops on Farm Sustainability in the United States
http://www.nap.edu/catalog/12804.html

sociopolitical dimensions in public debates about genetic-engineering technology. To reconcile those debates over the potential use of genetic engineering in sustainable and developing-country agriculture, it may be wise to heed the suggestion of Ronald and Adamchak (2008) and use various social, environmental, and economic criteria in making decisions on when to use and not to use genetic-engineering technology in agriculture.

CONCLUSIONS

Social dynamics and networks between farmers and within local communities play a substantial role in the decisions that farmers make with respect to the use of GE crops and likely are impacted by the use of and conflicts over those crops. Research on the adoption of other agricultural technologies has demonstrated substantial social impacts on a farm level and a community level. Those impacts include, but are not limited to: decreases to and change of composition in the agricultural labor force; better on-farm working conditions; changes in farm and agricultural-industry structure; increases in capital requirements for farmers; and a decline in the socioeconomic viability of some rural communities. Comparable research on the effects of GE crops is lacking, and although it is reasonable to hypothesize that the social impacts of the spread of GE crops have been low due to the assumed scale neutrality of this technology, it is equally reasonable to assume that the social impacts have been numerous and profound. Those questions cannot be answered without short- and long-term empirical research on the social processes surrounding, and the social impacts associated with, the adoption of genetic-engineering technologies at the farm level. Such research must take into account the various contextual factors that are influencing social changes on U.S. farms and rural communities.

Research has demonstrated that farmers' interest in genetic-engineering technology and patterns of adoption are influenced by farmers' social networks and by farmers' associations, private firms, and public actors, including universities. Research also has identified the continuing consolidation of the seed industry and its integration with the chemical industry. The market power of firms that supply seed has not adversely affected farmers' economic welfare so far, but research is needed on how market structure may affect ongoing access to non-GE or single-trait seeds and future seed prices. Furthermore, there has been comparatively little research on how changes in farmer social networks and seed-industry concentration might be affecting farmers' planting decisions and options, overall yield benefits, crop genetic diversity, and economic returns.

A final set of social issues has to do with complex legal issues, including the adoption of and the use of genetic-engineering technology. U.S. and Canadian courts have also upheld the legal rights of seed companies to prohibit seed-saving practices through the use of contracts. The issue of gene flow is complicated. One important question being raised is whether adventitious presence of genetic material from GE crops into non-GE crops impinges on the rights of producers, including organic producers, who do not wish to use specific GE traits. The legal debates may mask deeper social and ideological divisions over the use of GE plants and how to define and implement sustainable agricultural practices.

5

Key Findings, Remaining Challenges, and Future Opportunities

The first generation of genetically engineered (GE) crops has mostly delivered effective pest control for a few major crops because farmers producing these crops spend a lot of time and money on the task, because the firms developing the new seed technologies saw considerable profit potential in doing so, and because adding the traits was relatively straightforward, requiring transformation of a genome at only a single location. The first generation of GE crops continues a reliance on pesticide technology—in-plant toxins or resistance to herbicides—to mitigate pest problems primarily in corn, cotton, and soybean. Thus, the application of genetic-engineering technology to crops has not developed novel means of pest control, such as developing plant mechanisms to resist pest damage, nor has it reached most minor crops.

The next set of challenges for the application of GE-crop technology is to expand to additional crops and to address additional desirable traits, such as drought tolerance, enhanced fertilizer utilization to reduce nutrient runoff, nutritional benefits, renewable energy production, and carbon sequestration. A number of those applications are under development by the private sector, some by the public sector. Clearly, the future agenda for genetic-engineering technology is extensive and of great importance for improvements in agricultural productivity and sustainability in a rapidly-changing world.

This chapter opens by summarizing the major findings of our assessment of the farm-level environmental, economic, and social impacts of GE crops. We then identify key remaining challenges that will frame future development and commercialization of genetic-engineering technology in crops. The discussion turns next to the future agenda of GE-crop applications, including general patterns of crop-trait development, implications for future weed-resistance management, and the potential role of GE crops for biofuels. The penultimate section highlights two subjects of research that the committee believes deserve more resources and effort: water quality and social impacts of GE crops. In closing, we discuss options for strengthening public and private research and development to exploit the potential of genetic-engineering technology to contribute more fully to environmental, economic, and social objectives.

KEY FINDINGS

The evidence shows that the planting of GE crops has largely resulted in less adverse or equivalent effects on the farm environment compared with the conventional non-GE systems that

Copyright © National Academy of Sciences. All rights reserved.

Impact of Genetically Engineered Crops on Farm Sustainability in the United States
http://www.nap.edu/catalog/12804.html

GE crops replaced. A key improvement has been the change to pesticide regimens that apply less pesticide or that use pesticides with lower toxicity to the environment but that have more consistent efficacy than conventional pesticide regimens used on non-GE versions of the crops. In the first phase of use, herbicide-resistant (HR) crops have been associated with an increased use of conservation tillage, in particular no-till methods, that can improve water quality and enhance some soil-quality characteristics. That farmers who practice conservation tillage are more likely to adopt GE crops suggests the two technologies are complementary.

At least one potential environmental risk associated with the first phase of GE crops has surfaced: some adopters of GE crops rely heavily on a single pesticide to control targeted pests, and this leads to a buildup of pest resistance regardless of whether GE crops or non-GE crops are involved. The governmental regulation of GE Bt crops through refuge requirements seems to have proved effective in delaying buildup of insect resistance with two reported exceptions, which have not had major consequences in the United States. Grower decisions to use repeated applications of particular herbicides to some HR crops have led, in some documented cases, to evolved herbicide-resistance problems and shifts in the weed community. In contrast with Bt-crop refuge requirements, no public or private mechanisms for delaying weed resistance have been extensively implemented. If the herbicide-resistance problem is not addressed soon, farmers may increasingly return to herbicides that were used before the adoption of HR crops. Tillage could increase as a pest-management tactic as well. Such actions could limit some of the environmental and personal safety gains associated with the use of HR crops. The newest HR varieties likely will have tolerance to more than one herbicide, and this would allow easier herbicide rotation or mixing, and, in theory, help to improve the durability of herbicide effectiveness. These new stacked varieties will be one more tool to help manage the evolution of weed as well as insect resistance.

The potential for gene flow via cross-pollination between current major GE crops and wild or weedy relatives is limited to cotton in small spatial scales in the United States because the other major GE crops have no native relatives. How this changes in the future will depend on what GE crops are commercialized, whether related species with which they are capable of interbreeding are present, and the consequences of such interbreeding for weed management. Gene flow (i.e., the adventitious presence) of legal GE traits in non-GE crops and derived products remains a serious concern for farmers whose market access depends on adhering to strict non-GE standards. It would appear that the resolution of the issue may require the establishment of enforceable thresholds for the presence of GE material in non-GE crops that do not impose excessive costs on growers and the marketing system.

The literature reviewed in this report indicates that a majority of U.S. farmers who grow soybean, corn, or cotton have generally found GE varieties with herbicide-resistance and insect-resistance traits advantageous because of their superior efficacy in pest control; their concomitant economic, environmental, and presumed personal health advantages; or their convenience. The extent of the benefits varies among locations, crops, and specific genetic-engineering technologies.

After some early evidence of yield disadvantages for some GE varieties in the United States, studies have now shown either a moderate boost in yields of some crops or a neutral yield effect. Some emerging evidence suggests that the attractiveness of the genetic-engineering technology for soybean, cotton, and corn has increased the global acreage planted to these crops over what would have been planted otherwise and thereby increased global commodity supplies (World Bank, 2007; Brookes and Barfoot, 2009). Consequently, the adoption of some of the GE crops

Copyright © National Academy of Sciences. All rights reserved.

Impact of Genetically Engineered Crops on Farm Sustainability in the United States
http://www.nap.edu/catalog/12804.html

around the world has put downward pressure on the prices received by U.S. farmers who are growing these crops, holding other factors constant. At the same time, livestock producers and consumers who purchase GE feed and food products may have benefited from the downward price pressure. However, the U.S. and world agricultural economies have been influenced by other factors that tend to increase commodity prices, making empirical verification of the effects difficult.

The economic effects of GE-crop adoption on nonadopters are mixed. To the extent that the use of genetic-engineering technology changes the types and amounts of inputs used, adopters of GE crops can influence the pesticide market. Changes in the price and availability of pesticides affect nonadopters as well. Farmers of non-GE crops in the vicinity of GE-crop farms may experience landscape-level effects from reduced pressure from pests targeted by GE traits. Marketing of non-GE crops may also be affected by GE crops, favorably or unfavorably. For example, products derived GE and non-GE crops can mix through gene flow or supply contamination. On the other hand, GE crops may create a market premium for non-GE products.

The historic social repercussions of introducing new technologies in agriculture, such as mechanization and the widespread planting of hybrid corn, have been studied extensively, and the results of the studies provide a basis for understanding the general effects of introducing GE varieties of crops. Despite the salience of those effects, however, there has been little investigation of farm-level and community-level social impacts of GE crops. The new seed technologies raise important potential social issues about farm structure, the input and seed choices available to farmers, and the genetic diversity of seeds. Among the known social facts associated with the dissemination of GE crops are the continued consolidation of the seed industry and its integration with the chemical industry. Another is the change in relationships between farmers and their seed suppliers. Testimony to the committee suggested that farmers of major crops have fewer opportunities to purchase non-GE seed of the best-yielding cultivars even when a GE trait is not perceived to be required in a particular cropping situation. As genetic-engineering technology matures and moves into its next phase, it is imperative that the full array of social issues involved be identified and investigated in depth.

REMAINING CHALLENGES FACING GENETICALLY ENGINEERED CROPS

Potential crop-biotechnology developments stir discussion around five issues. The treatment and resolution of those issues hold implications for long-term sustainability for farmers, including both adopters and nonadopters of GE crops.

First, the success of genetic-engineering technology in the United States has altered the seed industry by spurring consolidation of firms and integration with the chemical industry. Those developments continue to alter seed and pest-control options in the market, expanding pest-control options for some farmers and possibly limiting them for others, including those who do not grow GE crops. The resulting concentrated and legally enforceable private control of plant genetic material contrasts sharply with public plant-breeding programs that traditionally have fostered public access to discoveries, especially if GE varieties are developed for crops from which farmers have traditionally saved seed for the next year's crop (such as wheat, barley, and oat). Although corporate consolidation may offer greater economies of scale, it also is accompanied by the possibility of less competition and higher seed expenses, which may lower farmer returns, reduce pest-control options, and limit the benefits of commercialization of genetic-engineering technology to a few widely grown crops. There is not yet clear evidence of a

Impact of Genetically Engineered Crops on Farm Sustainability in the United States
http://www.nap.edu/catalog/12804.html

these trends should be monitored, and their effects ameliorated to remedy social losses that result.

Second, how the intensive use of current and prospective GE organisms will directly affect the natural environment differently from other agricultural production systems is incompletely understood (Ervin et al., 2003). Relatively few studies have provided integrated assessments of the indirect effects of GE crops on pest damage to non-GE crops and on the full suite of ecosystem services on the landscape scale. For example, the concurrent effects on regional water quality of shifting tillage and pesticide regimens with the introduction of GE crops on regional water quality conditions remain poorly documented and understood. Knowledge of the spatial and temporal effects on ecological health—favorable or unfavorable—assumes greater importance as the evolution of herbicide resistance in weeds alters patterns of herbicide use to make up for the loss of glyphosate's efficacy on some species, and as novel GE plants, such as those for energy and nonfood uses, approach commercialization. Evaluation and monitoring of the ecological health of soils, water quality and quantity, and air quality will provide the information needed for developing the most productive yet sustainable agricultural systems for the future (Ervin et al., 2003).

Third, progress in developing GE varieties for most "minor" crops (e.g., fruits and vegetables) and for other "public goods" purposes not served well by private markets has been slow. Minor crops play important roles in the agricultural sectors of many states. Some minor crops, such as sunflowers and grain sorghum, have been considered to be poor candidates for the HR traits because of the existence of near-relative weeds (grain sorghum) or native ancestral populations (sunflowers). However, that risk does not explain the relative dearth of research and development (R&D) on GE varieties of minor crops as a whole, especially fruits and vegetables. The high fixed investment, patent protection involving GE traits, and the regulatory expense of commercializing GE seeds have lessened the ability of small companies and public-sector crop-breeding programs to develop commercially viable GE varieties of most minor crops. It seems clear that more effort should be devoted to the enhancement of minor crops with the best available genetic-engineering techniques even though the commercial rewards per crop may be small. Private and public R&D programs for GE crops have not yet led to the commercialization of many additional plant traits, such as improved tolerance to drought and increased fertilizer-use efficiency that decreases nutrient runoff, a contributor to nonpoint-source water pollution. This is not to suggest that GE seeds represent a "silver bullet" technology to solve all of these problems. Such GE trait developments may or may not turn out to be the most cost-effective approach to solving these issues, but exploration is necessary to evaluate their relative efficacy. Even though the basic technology is over 20 years old, agricultural biotechnology in some regards is still in its infancy. The rate of progress of genetic-engineering technology for some purposes suggests that more time and resources and new institutional relationships, such as public–private R&D collaborations, are desirable for the technology to reach its potential. Traits that have not yet received much attention, such as improved nutrient absorption and enhanced food value of crops, should be emphasized in the future so that we can gain the knowledge needed for weighing how the advances of genetic-engineering technology could present options for addressing all aspects of food supply, energy security, and environmental challenges.

Fourth, the presence of transgenic material in non-GE products should be addressed. The current definition of organic food in the United States excludes the use of GE materials in production and handling processes, so organic farmers must take steps to ensure that their production methods do not expose their crops to GE traits. To avail themselves of market

Copyright © National Academy of Sciences. All rights reserved.

Impact of Genetically Engineered Crops on Farm Sustainability in the United States
http://www.nap.edu/catalog/12804.html

premiums for certified organic crops, they must incur costs for keeping their products separate from GE crops. Food producers who market products as non-GE face similar challenges to prevent co-mingling of GE and non-GE crops during storage and distribution. In those ways, the introduction of GE crops influences the decisions and operations of farmers and food producers who do not use the technology.

Fifth, U.S. farmers who grow GE crops may face market restrictions from some countries or retail firms on the importation or sale of the crops or products made from the crops. Under some international agreements, some countries impose these restrictions because of perceived food safety or environmental risks or for other reasons. Assuming that those actions satisfy international treaty rules, such market-access restrictions to some extent slow the development of a global market for GE crops. One effect of the trade restrictions has been to limit the market demand for GE crops.

The potential of GE crop varieties to address the world's emerging food-supply, energy, and environmental problems hinges on how those challenges are resolved. Success in resolving them may allow genetic-engineering technology to become even more transformational in fostering sustainable agricultural systems for farmers. This important agenda frames the discussion of future GE-crop applications.

FUTURE APPLICATIONS OF GENETICALLY ENGINEERED CROPS

In addition to expanding existing GE traits into other crops, the reach of genetic-engineering technology could be extended through the development and commercialization of new traits. Traits beyond those designed to control pests could have substantial benefits in fields other than agriculture, such as food and energy security. This section summarizes the present pattern of R&D of novel GE traits in the private and public sectors and highlights areas in which new traits could be especially useful to improving agricultural sustainability.

Patterns of Genetically Engineered Products in Development

The GE crops now being planted by U.S. farmers were developed over long gestation periods. Given that fact, the current portfolio of GE crops does not wholly capture the range of new crops being readied for commercialization that could cover the U.S. farm and global landscape in the future. For instance, companies are developing crops with more intricate pest control mechanisms (see Box 5-1), but they are also engineering traits that improve crop tolerance to stress or that provide benefits directly to consumers. Recent research also indicates that novel forms of pest control may be part of the next generation of GE crops. As an example, Baum et al. (2007) report positive laboratory findings that ribonucleic-acid (RNA) interference technology, a plant-based method for pest management, results in larval stunting and mortality in several coleopteran species controlled by Bt crops. Predicting future crop biotechnologies is somewhat difficult because companies, for reasons of competitiveness and patent protection, may not fully share the specifics of planned releases. However, three recent global surveys of product-quality innovations in the development phase of genetic-engineering technology help in discerning general trends in GE-crop development and, in particular, why quality-improving innovations from genetic-engineering technology have not yet been more numerous (Graff et al., 2009).

Impact of Genetically Engineered Crops on Farm Sustainability in the United States
http://www.nap.edu/catalog/12804.html

BOX 5-1
New Traits Reduce Refuge Requirement and Introduce Second Mode of Herbicide Resistance

On July 20, 2009, the Environmental Protection Agency (EPA) announced final approval for commercialization of SmartStax™ corn hybrids. These hybrids produce multiple proteins for the control of lepidopteran pests and for the control of corn rootworm (two of these proteins must be used together to induce significant rootworm mortality). The hybrids also have transgenes conferring resistance to glyphosate and glufosinate. Because of the multiple toxins affecting single pests, this group of hybrids was approved by EPA with a refuge requirement of 5 percent in the Corn Belt and 20 percent in the Cotton Belt (US-EPA, 2009). Those refuge requirements are reduced from the original requirements of 20 percent in the Corn Belt and 50 percent in the Cotton Belt for previous transgenic Bt corn hybrids. Resistance to the different broad-spectrum herbicides may help in delaying the evolution of resistance in weeds in areas where glyphosate-resistant populations have not been identified. However, growers must assume appropriate stewardship for these herbicides in order to manage the future evolution of herbicide-resistant weed populations.

The combined findings of the surveys show that less than 5 percent of the innovations reach the regulatory and commercialization phases. As might be expected, R&D activity has been uneven among different trait categories because of variation in the difficulty of achieving selected transformations and in the economic value of the traits. For example, traits governing content and composition of macronutrients—proteins, oils, and carbohydrates—and traits that control fruit ripening have more readily reached later stages of R&D, and few products with enhanced micronutrients, functional food components, or novel esthetics have approached commercialization (Graff et al., 2009). The analysts concluded that product-quality innovation appears more responsive to demand in intermediate markets for processing and feed attributes than to demand in retail markets for improved or novel products. They also noted that many of the observed traits offer potential efficiency gains in agriculture and improvements in natural-resource systems and a potential to reduce environmental impacts both because they will decrease input requirements and because they will reduce adverse externalities of crop production, processing, or consumption. For example, new traits may increase the efficiency of livestock-feed digestibility and by so doing increase the value of the feed to farmers. Traits that improve nitrogen-use efficiency that are on the horizon will bring value to farmers and could contribute to reducing agriculture's effects on water quality. The potential for environmental improvement from such traits depends on the degree to which they improve input-use efficiency and the extent to which farmers expand production because of lower unit costs.

The rate of product-quality innovations in genetic-engineering technology identified in the surveys decreased considerably after 1998. The authors noted that the cause of the decline remains conjectural. It coincided with the decrease in the number of transgenic field trials conducted in the United States and Europe, with the exit from the market of a number of small biotechnology companies that were not deeply involved in the first generation of GE pest-control crops, and with changes in the regulatory environment in Europe that restricted the introduction of GE varieties there.

Impact of Genetically Engineered Crops on Farm Sustainability in the United States
http://www.nap.edu/catalog/12804.html

Data on field tests of crop-biotechnology innovations corroborate the slowdown. A critical part of new variety development is field testing to ensure that the desired traits will perform under commercial production conditions and that no important environmental risks are associated with release of a GE organism. The release of new GE varieties or organisms into the environment is regulated, in part, through field-release permits monitored by the U.S. Department of Agriculture (USDA) Animal and Plant Health Inspection Service (APHIS) (Fernandez-Cornejo and Caswell, 2006).[1] The overall number of field releases of plant varieties for testing purposes is a useful indicator of R&D efforts in GE crops. By the end of 2008, about 15,000 applications had been received by APHIS since 1987, and nearly 14,000 (93 percent) had been approved (ISB and USDA-APHIS, 2009). Annual applications peaked in 1998 with 1,206, and annual approvals peaked in 2002 with 1,141 (Figure 5-1). Most applications approved for field testing in 1987–2008 involved major crops, particularly corn with 6,648 applications approved, followed by soybeans (1,554), cotton (912), potato (817), tomato (637), wheat (413), alfalfa (385), and tobacco (363). Applications approved during this time included GE varieties with herbicide resistance (25.1 percent), insect resistance (20.1 percent), improved product quality (flavor, appearance, or nutrition) (18.2 percent), and agronomic properties, such as drought resistance (13.4 percent) (Figure 5-2).

After sufficient field testing, an applicant may petition APHIS for a determination of "nonregulated" status to facilitate commercialization of a product. If, after extensive review, APHIS determines that unconfined release does not pose a substantial risk to agriculture or the environment, the organism is "deregulated" and can be moved and planted without APHIS authorization (Fernandez-Cornejo and Caswell, 2006). Petitions for deregulated varieties peaked in 1995–1997 with 14-15 petitions per year and have been below 10 petitions every year thereafter (ISB and USDA-APHIS, 2009). As of June 5, 2009, APHIS had received 119 petitions for deregulation and had approved 76. The deregulated varieties had HR traits (38 percent), IR traits (28 percent), product-quality traits (15 percent), virus-resistance traits (11 percent), and agronomic traits (6 percent) (ISB and USDA-APHIS, 2009).

[1] If a plant is engineered to produce a substance that "prevents, destroys, repels, or mitigates a pest", it is considered to be a pesticide and is subject to regulation by the Environmental Protection Agency (Fernandez-Cornejo and Caswell, 2006). Thus, all Bt crops are included.

Impact of Genetically Engineered Crops on Farm Sustainability in the United States
http://www.nap.edu/catalog/12804.html

Another study of the APHIS GE-crop release data investigated the private or commercial and public-goods aspects of traits being tested (Welsh and Glenna, 2006). The authors analyzed releases in 1993–2002 to answer two research questions (p. 936):

- "To what extent have universities mimicked the for-profit sector in agricultural biotechnology by focusing their transgenic research on a relatively few proven genotypes (traits)?"
- "To what extent have universities mimicked the for-profit sector in agricultural biotechnology by focusing their transgenic research on the relatively few major (commercially dominant) agronomic crops?" (Welsh and Glenna, 2006, p. 936)

They categorized the crop releases into major traits—herbicide resistance, insect resistance, and product quality—and "other" GE traits. Product quality includes the alteration of a particular crop's characteristics to make it more valuable to food, feed, or energy manufacturing firms, such as a higher lysine concentration in corn that would be useful to livestock producers. Other GE traits were nematode resistance, fungus resistance, bacterium resistance, virus resistance, and agronomic properties (such as yield). They also categorized the releases by whether they were major crops (soybean, corn, wheat, alfalfa, and cotton) or minor crops (such as other field crops, vegetables, and fruits planted on smaller acreages).

The results indicated that the research profiles of universities in 1993–2002 were less dominated by the major traits than were the profiles of for-profit firms. A similar pattern emerged for major crops: about 71 percent of notices filed with APHIS by for-profit firms entailed research on major crops compared with 32.6 percent filed by universities. Moreover, work on minor crops differed among universities depending on their region (for example, apples in the Northeast and citrus in the Southeast). The authors examined whether the relationships changed during three periods: 1993–1995, 1996–1998, and 1999–2002. The research profiles of the for-profit firms remained fairly uniform, but universities looked more like for-profit firms in the later periods. That trend was especially pronounced for major traits: almost 73 percent of notices filed by universities entailed at least one major trait in 1999–2002 compared with around 35 percent in earlier periods. The proportion of research on major crops by universities also increased.

To probe those relationships in more depth, Welsh and Glenna constructed a commercial index for each release. The index was computed by assigning scores of 1 for research on a major crop and 1 for research on a major trait. Research on a minor crop was scored as -1 and research on a minor trait was scored as -1. Possible index values were therefore 2, 1, 0, -1, and -2. A higher index value indicated greater research emphasis on more commercially relevant crops and traits, and a lower value indicated more emphasis on crops and traits with smaller markets. Plotting the value of the index for universities and private-sector firms over time revealed that universities and private-sector firms showed increasingly similar research trajectories, which emphasized major crops and major traits in genetic-engineering technology. The time-series relationship was also found to be statistically significant (Welsh and Glenna, 2006).

Results of those three studies of GE-trait developments indicated that some GE products in various phases of development serve purposes other than pest-control traits dominant today, but they have not been commercialized. The reasons for this vary with the crop and the trait, but include a small anticipated market, lack of access to technology, uncertainty about consumer acceptance, potential spillover to weedy relatives or gene transfer to non-GE cultivars, and high regulatory costs. During the process of innovation, commercialization, and adoption, all

Copyright © National Academy of Sciences. All rights reserved.

Impact of Genetically Engineered Crops on Farm Sustainability in the United States
http://www.nap.edu/catalog/12804.html

organizations weigh the costs and benefits of their decisions (Bradford et al., 2006). It is not surprising that the GE crops that were commercialized first provided substantial net benefits to the innovators, the seed companies, and adopting farmers.

Implications of Genetically Engineered Crops for Weed Management

An unmet challenge for GE crops documented in Chapter 2 revolves around sustaining the efficacy of particular herbicides. Maintaining their efficacy holds important implications for future farm economics and environmental sustainability. A key concept in understanding herbicide-resistance effects in weeds is the open, unregulated access of all farmers to the common pool of pest susceptibility. The presence of this condition leads to individual decisions that may impose user costs on the whole population of farmers, to suboptimal overall management, and to increasing total social costs (Hardin, 1968).

The data show that GE-crop cultivars resistant to glyphosate dominate in the corn, soybean, and cotton production regions across the United States. Results of a six-state survey to assess crop rotations by growers of GE crops showed that rotation of a GE crop with a non-GE crop was most commonly followed by rotation of a GE crop with a GE crop (Shaw et al., 2009). Rotation of a GE with a non-GE crop was more common in the Midwest than in the South. With the high acreage of glyphosate-resistant crops being planted, substantial changes in herbicide use occurred; notably, fewer herbicides were used (Young, 2006); the most common current herbicide tactic reported is one to three applications of glyphosate (Givens et al., 2009). A related change in production practice attributable to the adoption of HR crops that has implications for weed management was the increased adoption of conservation tillage (Givens et al., 2009). The overall grower assessment of the effect of HR crops on weed population densities was that there were fewer weeds because of the use of glyphosate on HR crops (Kruger et al., 2009). Few growers felt that weed populations would shift to species that had evolved resistance to glyphosate, understood the importance of alternative tactics to control weeds, or perceived the role of selection pressure caused by the use of glyphosate on HR crops (Johnson et al., 2009). Given that changes in weed communities in response to production practices have been a consistent problem in agriculture, future weed challenges are likely to increase quickly (Baker, 1991; Owen, 2001; Heard et al., 2003b; Heard et al., 2003a). To summarize, growers valued the immediate benefits of weed control without appreciating the long-term risks attributable to the tactics they used. That behavioral response might be expected given many farmers' desire to meet short-run financial needs and the fact that other growers may not take similar control actions.

Recent survey data show that growers emphasize the convenience and simplicity of the glyphosate-based cropping systems while discounting the importance of diversification of weed-management practices (Owen, 2008b). That prevailing attitude has several likely results: given growers' apparent unfamiliarity with or lack of concern about the implications of selection pressure for weed communities, weed shifts are inevitable; and growers' short-term interest in killing weeds rather than managing them will result in the loss of crop yield and farm profits in the long run unless innovation in weed-control technology occurs. The efficacy of glyphosate on a broad spectrum of weeds, its ability to kill larger weeds, and the fact that glyphosate can be applied to HR crops almost regardless of crop stage of growth all reinforce growers' perception of the simplicity and convenience of glyphosate-based programs.

Copyright © National Academy of Sciences. All rights reserved.

Impact of Genetically Engineered Crops on Farm Sustainability in the United States
http://www.nap.edu/catalog/12804.html

Weed management implies that there is a critical period of weed control (CPWC) when weed interference must be eliminated to protect crop-yield potential (Nieto et al., 1968; Kasasian and Seeyave, 1969; Swanton and Weise, 1991; Knežević et al., 2002; Knežević et al., 2003). The CPWC is the same whether the crop is GE or non-GE. There is considerable information about the proper timing of glyphosate applications that will provide protection of yield potential and the related economic loss of crop yield in response to untimely glyphosate application (Gower et al., 2003; Dalley et al., 2004; Cox et al., 2005; Cox et al., 2006; Stahl, 2007). Many growers may recognize the relationship between early weed interference with HR crops and the resulting economic loss to profitability or may face high individual cost or risk in changing their behavior. The perception of success with glyphosate results in the repeated use of this herbicide without consideration of alternative strategies. Recurrent application of any herbicide will cause shifts in the weed community that support the evolving dominance of weeds that are not susceptible. Growers must use diversified weed-management practices, recognize the importance of understanding the biology of the cropping system, and give appropriate consideration to more sustainable weed-management programs (Knežević et al., 2003; Owen and Zelaya, 2005; Owen, 2008a). Furthermore, unless growers collectively adopt more diverse weed-management practices, individual farmer's actions will fail to delay herbicide resistance to glyphosate because the resistant genes in weeds easily cross farm boundaries. Some form of private or public collective action may avert this classic management of the commons problem in which individual actions to apply glyphosate have adverse spillover effects on the entire community of farmers (Hardin, 1968). Further research that results in new HR traits and other efficient means of weed control likely will lessen this problem.

Potential for Biofuels

Amid diminishing reserves of fossil fuels, heightened concern about climate change, and growing demand for domestic energy production, biofuels have emerged as an important supplementary fuel that may have considerable potential in supplying future energy needs. First-generation biofuels are serving as fuel extenders, displacing only a small percentage of gasoline consumption in the United States (Energy Information Administration, 2007). Nevertheless, because some existing biofuel crops can be produced in a manner that reduces greenhouse-gas emissions relative to fossil fuels and because they reduce dependence on volatile oil import markets, governments around the world have supported production of biofuel crops with subsidies and mandates (Koplow, 2007). However, although, as noted, some biofuel technologies can reduce greenhouse-gas emissions (Farrell et al., 2006), that might not always be the case, depending on production practices (Fargione et al., 2008; Searchinger et al., 2008). Furthermore, when they increase the demand for food crops, biofuel production can contribute to higher prices and shortages of food like those witnessed in 2008 (Tyner and Taheripour, 2008; Sexton et al., 2009).

In the United States, ethanol is produced principally from corn, approximately 80 percent of which is grown with GE varieties. Similarly, biodiesel in the United States is produced almost entirely from soybean; about 92 percent U.S. acres in soybean produce GE varieties. If those GE crops have increased yields, they may reduce biofuel costs.

If developed appropriately, new GE-crop technologies could play an important role in ameliorating further the adverse economic and environmental impacts of biofuels (Sexton et al., 2009). Indeed, some governments, like that of the United States, have tailored their biofuels

Impact of Genetically Engineered Crops on Farm Sustainability in the United States
http://www.nap.edu/catalog/12804.html

policy to include, among other instruments, some support for next-generation technologies to overcome existing limitations (e.g., Rajagopal et al., 2007; Rajagopal and D.Zilberman, 2008). For example, genetic-engineering technology may help to improve the agronomic characteristics of plants used for cellulosic ethanol, which are not yet widely commercialized. Whereas ethanol is produced today only from the starch in plants, developments in microbiology allow the cellulosic material to be converted to biofuel. Genetic-engineering technology holds the potential to generate higher yields of these crops and to improve the amount of liquid fuel obtainable per plant by altering plants' genetic code in beneficial ways. It may provide these benefits without environmental damage. Because many of the plants that may provide fuel in the future have not been commercially farmed, it may be possible to improve plant genetics to maximize their energy-yield potential, minimize the costs of converting cellulosic plant material to liquid fuel, and devise best-management practices or mitigation for the environment.

RESEARCH PRIORITIES RELATED TO GENETICALLY ENGINEERED CROPS

Water-Quality Monitoring and Evaluation

Nonpoint pollution is the leading cause of water-quality impairments across the United States, extending into ocean estuaries, bays, and gulfs (US-EPA, 2007). Agriculture remains the largest source of these nonpoint pollution flows by volume, and much of the pollution stems from cropland operations. The predominant contaminants include sediment from land erosion and nutrient and pesticide residues not used or retained for growing crops. For example, a recent analysis estimated that agriculture contributes 70 percent of the nitrogen and phosphorus that enters the Gulf of Mexico and that corn production accounts for the majority of the nitrogen and corn and soybean production account for one-fourth of the phosphorus (Alexander et al., 2008). Particularly in view of the huge dead zone that has formed in the Gulf of Mexico, lessening such pollution has high national priority.

As explained in Chapter 2, evidence has begun to emerge that GE crops are often associated with changes in cropping practices that should lead to an improvement in the nation's water quality. The changes include shifts to conservation tillage or no-till techniques that leave more residues on the cropland surface and thereby reduce water runoff that contains sediment, nutrient, and pesticide contaminants. They also include the use of pesticides, such as glyphosate, that are less toxic and more quickly degrading than conventional crop herbicides and insecticides. The latter effects could also reduce contamination of groundwater and wells on farms from spills and mixing operations.

Because monitoring and research resources have been inadequate, those potential water-quality impacts of GE crops have not been documented. The committee received testimony from the U.S. Geological Survey that explained the lack of comprehensive data and analysis that could identify and estimate the magnitude of the potential improvements in water quality (Gilliom and Meyer, personal communication). Those effects are among the largest environmental effects of agriculture, and we recommend that more resources be devoted to the important tasks of spatial and temporal monitoring of how agricultural practices influence water quality. Monitoring changes associated with the adoption of GE cultivars is important given that the rapid, widespread adoption of those cultivars may have large impacts on water quality by changing agricultural practices. The resulting information could influence the design of future

Impact of Genetically Engineered Crops on Farm Sustainability in the United States
http://www.nap.edu/catalog/12804.html

environmental policies and agriculture programs. Such critical intelligence would help to improve the efficacy and cost-effectiveness of achieving regional and national water-quality standards, and thereby improve farm sustainability.

Social Issues in the Use of Genetically Engineered Crops

Accumulated research in the social sciences has verified that the processes of technological development and diffusion do not take place in a social vacuum. Choices made by those who create new technologies and decisions made by others regarding whether to use the technologies are influenced by political, economic, and sociocultural factors. The social impacts of the use of the technologies are influenced by the same factors. A particular technology can have dissimilar social impacts depending on the context within which it is adopted. It is reasonable to hypothesize, on the basis of the existing body of knowledge, that the adoption of particular genetic-engineering technologies has a variety of social, economic, and political impacts, and that these impacts would not be the same at all times and in all regions and cultures.

As noted in Chapter 4, the amount of research on the social processes and effects associated with the development and use of GE crops has been inadequate and has not matched what took place previously in the cases of agricultural mechanization or even the use of bovine somatotropin in dairy production. Thus, there is little empirical evidence to which the present committee can point to that delineates the full array of social impacts of the adoption of GE-crop technology. That includes a lack of research on the social impact on farmers of companies legally enforcing their intellectual property rights in GE seeds. Research that has been conducted on the role of industry–farmer social networks in influencing the development of new seed technologies, legal issues related to GE-crop technology, resistance to the use of the technology in organic production systems, and the development of the open-source breeding movement does suggest, however, that genetic-engineering technology is socially contested by some groups. Those findings and trends reinforce the need for research on the social processes associated with genetic-engineering technology, including its social impacts, to inform the decision-making processes of technology developers, farmers, and policymakers. The committee recommends the development of this research agenda, which should lead to findings important for addressing the sociocultural issues that will arise in connection with broader adoption of GE crops in the future.

ADVANCING POTENTIAL BENEFITS OF GENETICALLY ENGINEERING CROPS BY STRENGTHENING COOPERATION BETWEEN PUBLIC AND PRIVATE RESEARCH AND DEVELOPMENT

The rapid adoption by U.S. farmers of the first generation of GE soybean, cotton, and corn varieties illustrates the speed and scope with which agricultural systems can be improved if appropriate products and systems are available. This report documents how GE varieties contribute to the sustainability of agriculture related to the production of those major crops. Expanding the effects to additional crops and further improving the technology will require an expansive program of R&D. Private companies are already working to develop additional traits that will improve the productivity and sustainability of agriculture in the United States and worldwide. However, both the private and public sectors must play vigorous, if often times

Impact of Genetically Engineered Crops on Farm Sustainability in the United States
http://www.nap.edu/catalog/12804.html

different, roles if the full potential of genetic-engineering technology to foster a more sustainable agriculture is to be realized. In developing analogous traits for other crops, such as GE varieties of "minor" crops and additional GE traits to meet broader public environmental and social objectives (e.g., improved water quality and carbon sequestration), the active involvement of universities and nongovernment institutions will be crucial given the flexibility of such institutions in selecting research objectives when funding is available. Developing the most appropriate agenda for such research will require extensive stakeholder involvement, including input from adopters and nonadopters of GE crops, environmental and social interest groups, and industry representatives.

Public investment and innovation in genetic-engineering technology includes several phases, such as discovery, scaling-up of innovations, regulatory research, commercialization, production, and marketing. Life-science innovations increasingly take place within the educational–industrial complex, where research universities and public research institutions are engaged mainly in the early stages of innovation, and startup and major corporations are engaged more in product development (Graff et al., 2009). Much of the academic research addresses basic problems with uncertain outcomes that may result in new commercial innovations or in knowledge that has either pure public-good properties in the economic sense, such as basic-research discoveries that are nonrival and nonexclusive (Just et al., 2008), or properties that are not easy to appropriate, so revenues cannot be collected. Thus, such academic research will receive underinvestment by the private sector and warrants public-sector support (Dasgupta and David, 1994; Dasgupta, 1999).

Not all discoveries from academic research in genetic-engineering technology result in nonrival and nonexcludable products. For example, some scientists patent their innovations; these are then excludable products that can be licensed to other scientists, nonprofit organizations, or industry. A national survey in 2004 revealed that about 25 percent of responding scientists had filed for a patent since 2000. About 15 percent of the scientists had been issued a patent, and just under 8 percent had licensed their invention for use by private or public parties (Buccola et al., 2009). The responding scientists expressed slight support for patenting compared to the belief that publicly supported scientists should focus on knowledge with nonexcludable benefits (a mean of 2 versus a mean of 5 on a 6-point scale) (Buccola et al., 2009). Some scientists may be inclined to patent their discoveries in case they contribute to future, commercially developed technology.

In those cases where university discoveries and innovations are basic proofs of concepts, the private sector often undertakes the development effort, upscaling manufacturing capacity and commercializing the technology. Companies that invest in development of university innovations frequently buy rights to university patents to secure intellectual property protection and monopoly power once the products are developed. Without that protection, the firms may be unwilling to invest the capital necessary to move the technology to the commercialization stage.

There is likely to be underinvestment in commercialization of biotechnology innovation by the private sector because companies with implicit monopoly rights associated with patents aim to maximize their own profit without taking full account of consumers' welfare gains that result from the lower prices associated with an innovation. Firms cannot capture the potential benefits external to farmers and consumers, such as reduction in downstream pollution. The underinvestment in research makes a case for public-sector development of GE varieties as long as social benefits exceed social costs or social-equity objectives defined by elected representatives are achieved (de Gorter and Zilberman, 1990; Just et al., 2008). The situation suggests that public-sector research should emphasize the development of genetic-engineering

Copyright © National Academy of Sciences. All rights reserved.

Impact of Genetically Engineered Crops on Farm Sustainability in the United States
http://www.nap.edu/catalog/12804.html

technologies in specialty crops and innovation of other kinds, such as traits that may lead to a reduction in greenhouse-gas emissions from crop or livestock production or novel varieties that conserve water resources. The ability of the public and private sectors to develop new gene technologies depends on the costs of innovation, which may include access to intellectual-property rights and regulatory requirements. A tailored and targeted regulatory approach to GE-crop trait development and commercialization that meets human and environmental safety standards while minimizing unnecessary expenses could enhance progress on this front (Ervin and Welsh, 2006).

In reinforcement of those conceptual points, recent studies of genetic-engineering R&D have concluded that publicly funded research programs can complement private-sector R&D efforts in developing the full potential of agricultural biotechnology (Graff and Zilberman, 2001; Glenna et al., 2007; Buccola et al., 2009). There are several reasons for that conclusion. First, federal and state support encourages more basic research, whereas industry and foundations support more applied research in U.S. universities (Buccola et al., 2009). Downstream (i.e., more applied) research tends to be legally and economically more excludable than upstream (i.e., more basic) research. Publicly funded research offers the highest potential for achieving public goods, such as the basic science of genetic mechanisms, broadly accessible platform technologies, and nonmarket environmental services (Buccola et al., 2009). Second, industry collaborations with academic scientists have affirmed the necessity of a strong independent university research sector in helping to provide credible evaluations of new technology (Glenna et al., 2007). Third, both publicly and privately supported research assist in the transfer of basic discoveries in genetic-engineering technology, such as plant-genome characterizations, into useful crop-plant applications (Graff and Zilberman, 2001). For example, publicly supported basic research on *Arabidopsis thaliana* has provided an enormous store of information on basic plant biology, which in turn has enhanced our ability to produce commercially important advances in crops of all kinds. New institutional mechanisms are needed to provide an uninterrupted "pipeline" from basic research to field application (Graff et al., 2003). Fourth, commercialization of orphan and minor crops requires a special role for public R&D because the improvement of such crops often will not lead to sufficient profit to attract private-sector investment, even though the crops are important to many farmers and consumers. Fifth, public funding of academic research and government research fosters investigation that is too risky, or not sufficiently profitable, to be attractive to the private sector.

The evidence assembled in this report makes clear that the first generation of GE soybean, cotton, and corn varieties has generally been economically and environmentally advantageous for U.S. farmers who have adopted the technologies. The next generation of genetic-engineering technologies being reported by industry suggests that it is intent on enhancing those benefits and going beyond to new traits, such as drought and heat tolerance and enhanced fertilizer utilization that may indirectly reduce nutrient runoff, and new applicability to minor crops, renewable energy, climate change, and nutritional qualities. The public sector must complement industry by developing genetic-engineering technologies for crops that have insufficient markets to justify R&D and regulatory expense and to develop socially valuable public-goods applications. We envision the research and technology agenda to include individual private and public activities as well as private–public collaborations and to encompass work on the three essential components of sustainable development: environmental, social, and economic. Furthermore, we recommend that this agenda be undertaken in a program of research, technology development, and education that maximizes the potential synergies between the two sectors and their strengths and that limits

Impact of Genetically Engineered Crops on Farm Sustainability in the United States
http://www.nap.edu/catalog/12804.html

redundancies and tradeoffs. Such an integrated approach would have universities, government, and nonprofit organizations leading in the development of traits that deliver public goods, including basic discoveries and such environmental issues as improved regional water quality. The private sector would continue to lead in the commercialization of GE crops for which there are adequate market incentives.

Appendix A

Herbicide Selection

Herbicide[a]	Classification[b]	Mode of Action[c]	Relative Toxicity
Haloxyfop (Aryloxyphenoxypropionates) Clethodim (Cyclohexanediones) Pinoxaden (Phenylpyrazolines)	ACCase inhibitors ($A^{(1)}$)	Inhibitor of acetyl coenzyme-A carboxylase, a pivotal enzyme in plant fatty acid biosynthesis.	Varies based on specific chemical compound; likely to be carcinogenic to humans according to EPA *Proposed EPA Weight-of-the-Evidence Categories* (US-EPA, 2009a).
Alachlor (chloroacetanilides) Diphenamid (acetamides) Flufenacet (oxyacetamides) Fentrazamide (tetrazolinones)	Mitosis inhibitors ($K_3^{(15)}$)	Inhibition of cell division (long-chain fatty acid inhibitor).	Slightly toxic; oral RfD of 1×10^{-2} mg/kg-day. Critical effects: hemosiderosis, hemolytic anemia (US-EPA, 2009b).
Bensulfuron-methyl (Sulfonylureas) Imazethapyr (Imidazolinones) Cloransulam-methyl (Triazolopyrimidines)	ALS inhibitors ($B^{(2)}$)	Inhibition of the acetolactate synthase (ALS) enzyme resulting in cessation of the biosynthesis of essential branched chain amino acids (leucine, valine and isoleucine).	Varied; generally low acute and chronic toxicity to humans and not likely to be carcinogenic.
Atrazine (Symmetrical triazines)	Photosynthesis II inhibitors ($C_1^{(5)}$)	Inhibit photosynthesis by binding with a specific protein in the photosystem II complex.	Slightly to moderately toxic; oral RfD of 3.5×10^{-2} mg/kg-day. Critical effects: decreased body weight gain (other effect: cardiac toxicity and moderate-to-severe dilation of the right atrium (EXTOXNET, 2009a; US-EPA, 2009c).
Dicamba (benzoic acids)	Synthetic auxins ($O^{(4)}$)	The specific mode of action is not well defined, however these herbicide mimic endogenous auxin (IAA) and appear to negatively affect cell wall plasticity and nucleic acid metabolism.	Relatively non-toxic. Acute oral LD_{50} in rats ia 1707 mg/kg, dermal LC_{50} in rabbits is >2000 mg/kg. However, eye irritation in rabbit is extreme.

Impact of Genetically Engineered Crops on Farm Sustainability in the United States
http://www.nap.edu/catalog/12804.html

Herbicide[a]	Classification[b]	Mode of Action[c]	Relative Toxicity
Glufosinate (organophosphorus)	glutamine synthetase inhibitor ($H^{(10)}$)	Inhibits the activity of glutamine synthetase which causes ammonia build-up in the cell. The ammonia destroys cell membranes.	Practically nontoxic by ingestion; some increase in absolute and relative kidney weights in males. No observed carcinogenesis. Oral RfD of 4×10^{-4} mg/kg-day (NPIC, 2009; US-EPA, 2009d).
Glyphosate (organophosphorus)	Enolpyruvyl shikimate-3-phosphate (EPSP) synthase inhibitor ($G^{(9)}$)	Inhibits the EPSP synthase which leads to depletion of essential aromatic amino acids (tryptophan, tyrosine, and phenylalanine).	Generally nontoxic. Increased incidence of renal tubular dilation in third generation weanlings. Oral RfD of 1×10^{-3} mg/kg-day (US-EPA, 2009e).
Amides, pyridiazinones, pyridines, isoxazoles, pyrazoles, triazoles, triketones and others	Carotenoid biosynthesis inhibitors	Inhibit the catabolic degradation of tyrosine to plastoquinones (important for photosynthesis and carotenoid biosynthesis) and tocopherol (vitamin E, which protects biological membranes against oxidative stress and the photosynthetic apparatus against photo-inactivation)	Varied; developmental toxicity, probable human carcinogen, phytotoxic (US-EPA, 2004, 2006, 2009f, g).
Fluridone (unclassified)	($F_1^{(12)}$)	Inhibition of phytoene desaturase, an enzyme essential for carotenoid biosynthesis	
Mesotrione (triketones)	($F_2^{(28)}$)	Inhibition of hydroxyphenylpyruvate dioxygenase (HPPD), an enzyme involved in the synthesis of plastoquinone (PQ) and tocopherol (vitamin E).	
Amitrole (triazoles)	($F_3^{(11)}$)	Target site is generally considered unknown with the exception of amitrole which inhibits lypopene cyclase and clomazone that is reported to inhibit an early step in the non-mevalonic acid isoprenoid pathway ultimately leading to carotenoid synthesis.	
Metribuzin (triazinones, asymmetrical triazines)	Photosynthesis II inhibitors ($C_1^{(5)}$)	Inhibit photosynthesis by binding with a specific protein in the photosystem II complex.	A slightly toxic compound in EPA toxicity class III. Liver and kidney effects, decreased body weight, mortality; no indications of carcinogenic effects. RfD of 2.5×10^{-2} mg/kg-day (EXTOXNET (Extension Toxicology Network), 2009b; US-EPA, 2009h).

Herbicide[a]	Classification[b]	Mode of Action[c]	Relative Toxicity
dicarboximide herbicides, triazolone herbicides, diphenylethers, N-phenylphthalimides, oxadiazoles, thiadiazoles, triazolinones, and others	Protoporphyrinogen Oxidase (PPO) inhibitors ($E^{(14)}$)	Inhibits the protoporphyrinogen oxidase which is in the chlorophyll synthesis pathway. The PPO inhibition starts a reaction in the cell that ultimately causes the destruction of cell membranes. The leaking cell membranes rapidly dry and disintegrate	Varied; including compounds having: slight toxicity (EPA category III); classified as a "not likely" human carcinogen, to: "likely to be a human carcinogen" (US-EPA, 2001).
2,4-D (phenoxyacetic herbicide)	Synthetic auxins ($O^{(4)}$)	Mimics a plant growth regulator. The specific mode of action is not well defined, however these herbicide mimic endogenous auxin (IAA) and appear to negatively affect cell wall plasticity and nucleic acid metabolism.	Critical effects include: hematologic, hepatic and renal toxicity. RfD of 1×10^{-2} mg/kg-day.

[a]Herbicide listed is one example of the herbicide family.
[b]Herbicide mode of action code according to the Herbicide Resistance Action Committee (HRAC, 2010) and the Weed Science Society of America (WSSA) classification (Senseman and Armbrust, 2007). The capitalized letter is the HRAC classification and the superscript number is the WSSA classification.
[c]The indicated herbicide mode of action is from the HRAC and WSSA descriptions as well as other citations.

Appendix B

Tillage Systems

Below is an outline of general tillage and weed management practices for corn, soybean, and cotton. Tillage and weed control practices, however, vary greatly across regions of the United States and within a region based upon grower preference, soil texture, structure, and erosion potential for each individual farm.

Conventional or Conservation Tillage

Pre-tillage – may include shredding of cornstalks, usually in the fall, shortly after harvest.

Primary Tillage – types of equipment include moldboard plow, chisel plow, field cultivator, and tandem disk depending upon preference by the grower and soil erosion potential. For example, moldboard plow would be avoided if the fields are designated as Highly Erodible Land. Consequently, the chisel plow, field cultivator, or tandem disk are primary tillage implements in conservation tillage systems. Primary tillage can occur in the fall or the spring, depending on soil conditions and erosion potential of the soil. Furthermore, primary tillage may be done as a zone over the row where crops will ultimately be planted (strip tillage).

Secondary Tillage – types of equipment include tandem disk, field cultivator, chisel disk, disk harrow, harrow, and other implements. The type of equipment used depends on grower preferences, machinery complement, the region of the country, soil structure and texture, soil erosion potential, and environmental conditions during the season. Secondary tillage operations typically occur in the spring. Secondary tillage can involve multiple passes but quite often a series of implements are pulled in tandem, making it a one-pass operation. If growers are practicing conservation tillage, more than 30 percent of residue is present on the soil surface after planting.

Weed management – may or may not include a half rate or full rate of soil-applied herbicides with residual activity before or after planting (pre-emergence or early postemergence to the crop). Modern sprayers are typically 90 feet in width or more, and this step requires very little time and fuel use. Some growers, however, have tanks mounted on their planters and spray the residual herbicides at planting, thus saving an operation.

Impact of Genetically Engineered Crops on Farm Sustainability in the United States
http://www.nap.edu/catalog/12804.html

Herbicide-resistant crops are typically treated with glyphosate postemergence to the crop and weeds and may include other herbicides with different mechanisms of action. A second (and possibly a third) application of glyphosate is typically applied, especially in cotton and soybean where additional applications may be made. If one or more weeds have become resistant to glyphosate or the farmer's herbicide of choice, then the grower may apply a substitute herbicide or use a tillage operation to control the weed.

Organic growers substitute tillage (cultivation) operations, typically three or more, for herbicides for weed control. The first operation is usually performed just after corn or soybean has emerged, using a rotary hoe. This step is usually followed by two cultivations, the first occurring when corn or soybean is quite small.

No Tillage

Pre-tillage – some growers may shred cornstalks.

Weed management – some growers will use a non-selective "burn-down" herbicide, such as glyphosate, to kill existing weeds if they are present before planting. Farmers may also wait until after planting for the initial herbicide application. This treatment may include a combination of herbicides that provide residual control of weeds that emerge later in the season. Postemergence applications of herbicides may be used later in the season depending on the weed infestation.

Planting – involves more sophisticated versions of the planters used for conventional tillage. Typically, the planters have heavy coulters and other attachments to clear the residue from the previous crop in the planting row. Not all soils are suitable for no-till, especially wet and heavy soils in northern latitudes, and no-till may lead to increased pest occurrence because conventional tillage may reduce insect, pathogen, and weed occurrence. On the other hand, no-till is well adapted to well-drained soils in warm regions because no-till improves soil-water infiltration and reduces soil evaporation, thereby providing more soil water to the crop.

Appendix C

Biographical Sketches of Committee Members

David E. Ervin (*Chair*) is professor of environmental management, professor of economics, and fellow at the Center for Sustainable Processes and Practices at Portland State University. Dr. Ervin also serves on the board of the United States Society for Ecological Economics. He teaches economics of sustainability, business environmental management, and global environmental issues. His research and writing work includes university–industry research relationships in agricultural biotechnology, risk management of transgenic crops, voluntary business environmental management, and green technology. He recently directed a multi–university and multidisciplinary research project on public goods and university–industry relationships in agricultural biotechnology funded by the U.S. Department of Agriculture (USDA). He holds a B.S. and an M.S. from the Ohio State University and a Ph.D. in agricultural and resource economics from Oregon State University.

Yves Carrière is a professor of insect ecology in the Department of Entomology at the University of Arizona. He is an expert on the interactions between insects and transgenic plants, environmental impacts of transgenic crops, and integrated pest management. He is an associate editor of the *Journal of Insect Science.* Dr. Carrière received a B.Sc. and an M. Sc. in biology from Laval University and holds a Ph.D. in entomology and behavioral ecology from Simon Fraser University.

William J. Cox is a professor of crop science, joined the Cornell University faculty on an extension–research appointment in 1984. He has served in several capacities, including department associate chairman and extension leader. He recently evaluated the effects of transgenic seed on the yield and economics of corn production. His research also focuses on the environmental, biotic, and management interactions that influence the growth, development, yield, and quality of corn, soybeans, and wheat. He collaborates closely with soil scientists, animal scientists, plant pathologists, entomologists, and plant breeders in an effort to quantify whole-plant physiological responses of the crop to the environmental, biotic, and crop management interactions. He is a senior associate editor of the *Agronomy Journal* and the electronic publication *Crop Management*. Dr. Cox holds a Ph.D. in crop science from Oregon State University. He received an M.S. in agronomy from California State University-Fresno and a B.S. in history from the College of the Holy Cross.

Impact of Genetically Engineered Crops on Farm Sustainability in the United States
http://www.nap.edu/catalog/12804.html

Jorge Fernandez-Cornejo is an agricultural economist in the Resource and Rural Economics Division of U.S. Department of Agriculture Economic Research Service (ERS). He currently works on the adoption and diffusion of agricultural technologies, agricultural biotechnology, and economics of biofuel production. Since joining ERS in 1990, Dr. Fernandez-Cornejo has researched U.S. farmers' experience with biotechnology in the first decade of its adoption and the effects of the technology on farmers' decision-making process. He has also studied the seed industry. He has a Ph.D. in operations research and agricultural economics and a master's in chemical engineering from the University of Delaware, an M.A. in energy and resources from the University of California, Berkeley, and a B.S. in industrial engineering. Dr. Fernandez-Cornejo has expertise in agricultural economics, farm management, integrated pest management, and farm-level impacts of transgenic seed.

Raymond A. Jussaume, Jr., is professor and chair of the Department of Community and Rural Sociology at Washington State University. His academic appointment includes teaching, extension–outreach and research. The main thrust of his research has been to contribute to a growing international research agenda on the globalization of agri-food systems and various strategies for improving agricultural sustainability. Most recently, much of his research has been focused on how agricultural sustainability can be enhanced by increasing the extent to which agri-food systems are "localized". He recently published several journal articles evaluating Washington State farmers' attitudes toward biotechnology. Dr. Jussaume was a participant at the National Research Council's Conference on Incorporating Science, Economics and Sociology in Developing Sanitary and Phytosanitary Standards in International Trade. He received his Ph.D. in development sociology from Cornell University.

Michele Marra is a professor of agricultural economics at North Carolina State University and an extension specialist. A production economist, she has concentrated on economic issues surrounding integrated pest management and the characteristics of agricultural innovations that affect farmer choice. She works on the farm-level impacts of crop biotechnologies and the economics of precision farming. Her recent publications have analyzed the benefits of and risks posed by adopting new agricultural technologies and the effects of agricultural biotechnology on farmer welfare. Dr. Marra is a member of the American Agricultural Economics Association and served as the associate editor of the *American Journal of Agricultural Economics* from 2004 to 2007. She has a Ph.D. in economics and an M.S. and a B.S. in agricultural economics from North Carolina State University.

Micheal Owen has a Ph.D. in agronomy and weed science from the University of Illinois. He is associate chair in the Department of Agronomy of Iowa State University. He has extensive expertise in weed dynamics, integrated pest management, and crop risk management. His objective in extension programming is to develop information about weed biology, ecology, and herbicides that can be used by growers to manage weeds with cost efficiency and environmental sensitivity. His work is focused on supporting management systems that emphasize a combination of alternative strategies and conventional technology. Dr. Owen has published extensively on farm-level attitudes toward transgenic crops and their impacts; selection pressure, herbicide resistance, and other weed life-history traits; and tillage practices.

Peter H. Raven is the president of the Missouri Botanical Garden; a George Engelmann Professor of Botany, Washington University, St. Louis; adjunct professor of biology, University

Impact of Genetically Engineered Crops on Farm Sustainability in the United States
http://www.nap.edu/catalog/12804.html

of Missouri, St. Louis and St. Louis University; and a member of NAS. He earned his Ph.D. at the University of California, Los Angeles. Dr. Raven was a member of President Clinton's Council of Advisors on Science and Technology. He served for 12 years as home secretary of NAS and is a member of the academies of science of Argentina, Brazil, China, Denmark, India, Italy, Mexico, Russia, Sweden, and the U.K. Dr. Raven's primary research interests are in the systematics, evolution, and biogeography of the plant family Onagraceae; plant biogeography, particularly in the tropics and Southern Hemisphere; and tropical floristics and conservation. The author of numerous books and reports, both popular and scientific, Dr. Raven was a coauthor of *Biology of Plants* and *Environment*.

L. LaReesa Wolfenbarger conducts research on ecological effects of transgenic crops and agricultural practices, and on land management for grassland bird conservation at the University of Nebraska, Omaha. Other research interests include: the effects of agriculture on grassland ecosystems and the ecology of grassland ecosystems in agricultural landscapes. She has published several articles on the relationship between genetically engineered organisms and the environment and on the ecological risks and benefits related to genetically engineered plants. Her research also seeks to understand the responses of avian communities and reproduction to habitat variation and to management practices on restored grasslands, remnant prairies, and marginal agricultural habitats. Her other work includes synthesizing science on agricultural biotechnology, chairing a committee for a departmental graduate student program, organizing public symposia on environmental issues, and managing a 160-acre prairie preserve. Dr. Wolfenbarger earned her Ph.D. in ecology from Cornell University.

David Zilberman has been a professor in the Department of Agricultural and Resource Economics of the University of California, Berkeley, since 1979. His research interests are in agricultural and nutritional policy, economics of technological change, economics of natural resources, and microeconomic theory. He is a fellow of the American Agricultural Economics Association and the Association of Environmental and Resource Economists, which have recognized many of his publications on the adoption and regulation of agricultural biotechnology for their quality and value to the field. He received his B.A. in economics and statistics from Tel Aviv University in Israel and his Ph.D. in agricultural and resource economics from the University of California, Berkeley. Dr. Zilberman has expertise in the intersection of biotechnology and politics and economics and agricultural marketing. He has recently published on biofuels and biotechnology marketing.

Simultaneous Adoption of Herbicide-Resistant and Conservation-Tillage Cotton Technologies

Roland K. Roberts, Burton C. English, Qi Gao, and James A. Larson

If adoption of herbicide-resistant seed and adoption of conservation-tillage practices are determined simultaneously, adoption of herbicide-resistant seed could indirectly reduce soil erosion and adoption of conservation-tillage practices could indirectly reduce residual herbicide use and increase farm profits. Our objective was to evaluate the relationship between these two technologies for Tennessee cotton production. Evidence from Bayes' theorem and a two-equation logit model suggested a simultaneous relationship. Mean elasticities for acres in herbicide-resistant seed with respect to the probability of adopting conservation-tillage practices and acres in conservation-tillage practices with respect to the probability of adopting herbicide-resistant seed were 1.74 and 0.24, respectively.

Key Words: Bayes' theorem, conservation tillage, cotton, genetically modified crops, herbicide-resistant crops, simultaneous logit model, technology adoption

JEL Classifications: Q12, Q16, Q24, O33

Herbicide-resistant BXN (Buctril-resistant) cotton seed was first introduced in 1995 by the Stoneville Pedigreed Seed Company (Ward et al. 1995) and Roundup-Ready cotton seed became commercially available in 1996 (Johnson 1996). The adoption of herbicide-resistant seed by farmers has dramatically changed cotton production practices with potential consequences for the environment. Monsanto claims that adoption of herbicide-resistant seed facilitates adoption of conservation tillage, which "sustains the environment." Soule, Tegene, and Wiebe used data from the 1996 USDA Agricultural Resource Management Survey (ARMS) and with logit analysis evaluated the effects of land tenure on adoption of conservation-tillage practices. Although data from the 1996 ARMS were available for adoption of herbicide-resistant crops (Fernandez-Cornejo and McBride 2002), adoption was low, and Soule, Tegene, and Wiebe were not intent on evaluating the synergy between adoption of herbide-resistant seed and conservation-tillage practices. Fernandez-Cornejo and McBride (2002) used 1997 ARMS data and a two-equation simultaneous probit model to evaluate this potential synergistic relationship. Contrary to Monsanto's claim, they found no evidence that soybean farmers who

Roland K. Roberts and Burton C. English are professors, James A. Larson is associate professor, and Qi Gao is former graduate research assistant, Department of Agricultural Economics, University of Tennessee, Knoxville, TN.

The authors thank Bruno Alesii of Monsanto and John Bradley of Beltwide Cotton Genetics for their useful suggestions, Donald Tyler and Delton Gerloff for their insights into the research issues, and the anonymous reviewers for their helpful comments. Funding was provided by the Tennessee Agricultural Experiment Station.

had adopted herbicide-resistant seed had a higher probability of adopting no-tillage practices than farmers who had not adopted herbicide-resistant seed. They found evidence supporting the converse, however; farmers who had adopted no-tillage practices had a higher probability of adopting herbicide-resistant soybean seed than farmers who had not adopted no-tillage practices. Lack of simultaneity most likely resulted from using cross-sectional data for the year after herbicide-resistant soybean seed was first introduced, leaving little time for adjustment in tillage practices. Using data from a 1999 survey of cotton farmers conducted in South Georgia, Ward et al. (2002) found evidence based on efficiency measures that farmers may have incentive to simultaneously adopt herbicide-resistant seed and conservation-tillage practices. Marra, Piggott, and Sydorovych found that 76% of North Carolina corn, soybean, and cotton acreage in herbicide-resistant seed was produced with conservation-tillage practices in 2001, while only 64% of corn, soybean, and cotton acreage in conventional seed was produced with conservation-tillage practices. Their specific results for cotton were different, with these two percentages being about the same at close to 73%.

Findings from the aforementioned cross-sectional analyses suggest a simultaneous relationship may exist between adoption of herbicide-resistant seed and adoption of conservation-tillage practices, but the evidence is inconclusive, especially for cotton. Sufficient annual time-series data are now available to investigate the relationship of the adoption of these two technologies over time. The Conservation Tillage Information Center (Fawcett and Towery) used a limited time-series sample of percentages of acres in glyphosate-resistant crops by tillage method for 1998 through 2000 and a 2001 survey by the American Soybean Association to suggest a simultaneous relationship between adoption of glyphosate-resistant crops and conservation-tillage practices in the United States. The information for Tennessee cotton acreage in Figure 1 (Doane Marketing Research, Inc.; Monsanto; Tennessee Department of Agriculture, 1996–2003, 2004) also suggests a relationship between adoption of herbicide-resistant seed and conservation-tillage practices. From 1992 through 1998, the share of Tennessee cotton acreage in conservation-tillage practices averaged 38% with no discernable trend. In 1999 when adoption of herbicide-resistant cotton seed started in earnest, the share of conservation-tillage acreage began a slight upturn to 40% with a dramatic increase thereafter, averaging 76% between 2000 and 2004 and reaching almost 100% in 2003 and 2004. During the 1992 through 2004 period, cotton acreage in Tennessee showed no perceptible trend, except during the mid-to-late 1990s when the Boll Weevil Eradication Program was active in middle and southwestern Tennessee (Suarez, Larson, and English 2000). Because of eradication program costs, farmers had an incentive to switch to other crops during the active phase of the program. Cotton acreage was relatively stable after 1998, when herbicide-resistant seed and conservation-tillage practices were being rapidly adopted.

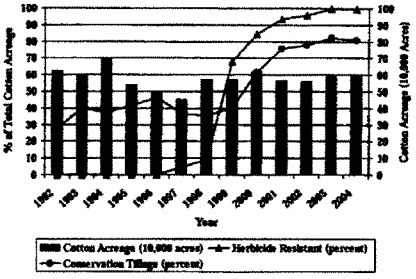

Figure 1. Total Tennessee cotton acreage with percentages in herbicide-resistant seed and conservation-tillage practices

In our research, annual time-series data along with Bayes' theorem and simultaneous estimation of two binomial logit models were used to examine the relationship between adoption of herbicide-resistant seed and adoption of conservation-tillage practices in Tennessee cotton production. If adoption of herbicide-resistant seed influenced adoption of conservation-tillage practices, adoption of herbicide-resistant seed may have indirectly led

to greater soil conservation and, if adoption of conservation-tillage practices influenced adoption of herbicide-resistant seed, adoption of conservation-tillage practices may have indirectly led to reduced residual herbicide use and increased farm profits as adoption of herbicide-resistant seed increased (Marra, Pardy, and Alston).

The choice of tillage method is a major decision for farmers because of its potential impacts on soil erosion and farm profit. Erosion of agricultural topsoils has been recognized as a problem for decades. Federal mandates have encouraged production practices to curb erosion. Anderson and Magleby and Heimlich provide a comprehensive overview of U.S. government policies designed to encourage conservation of our nation's topsoils. For example, Conservation Compliance, established in the 1985 Farm Bill, resulted in farms with highly erodible lands being required to alter cropping patterns and tillage practices to reduce erosion as a requirement for receiving government payments; in 1991, the Crop Residue Management Action Plan was developed to assist producers in implementing conservation systems. Tennessee has the most erodible cultivated cropland in the United States (Denton), with cotton being produced on some of those erodible soils. Adoption of conservation-tillage practices in cotton production has lagged behind adoption in other row crops (Tennessee Department of Agriculture 2004). Exploring the relationship between adoption of herbicide-resistant seed and adoption of conservation-tillage practices in Tennessee cotton production could lead to improved policies for reducing soil erosion.

Farmers who adopt conservation-tillage practices may benefit if adopting herbicide-resistant cotton seed allows them to use more effective herbicide treatment systems (Shoemaker et al.). Weed control is a vital component of conservation tillage. Failure to control weeds with conservation tillage can result in decreased quantity and quality of output. Besides preventing yield loss from weed competition, weed control is particularly important in cotton production because weeds can stain lint during harvest and processing, resulting in price discounts (Moore). Herbicide-resistant seed provides farmers with effective weed control programs that eliminate some problems associated with conservation programs (Fawcett and Towery). Investigating the relationship between adoption of conservation-tillage practices and herbicide-resistant seed could increase our understanding of ways to increase farm profit and reduce residual herbicide use (Marra, Pardey, and Alston) while conserving soil.

The objectives of this research were: (1) to evaluate the relationship between adoption of herbicide-resistant cotton seed and conservation-tillage cotton production practices over time and (2) to quantify the effects of economic phenomena on the adoption of herbicide-resistant seed and conservation-tillage practices for cotton production in Tennessee.

Methods and Data

The problem at hand is one of simultaneous adoption of synergistic technologies and management practices. Wu and Babcock used a polychotomous-choice selectivity model to evaluate choices among crop management plans, including tillage, rotation, and fertility management alternatives. Dorfman used a multinomial probit model, estimated in a Bayesian framework using Gibbs sampling (Geman and Geman), to evaluate adoption of improved irrigation methods and integrated pest management practices in apple production. Fernandez-Cornejo, Hendricks, and Mishra estimated a trivariate-choice selectivity model to evaluate the relationships among off-farm operator employment, off-farm spouse employment, and adoption of herbicide-resistant soybean seed. In an analysis more related to this article, Fernandez-Cornejo and McBride simultaneously estimated two binomial probit models for adoption of herbicide-resistant seed and no-tillage practices in soybean production.

Two methods were used to evaluate the relationship between adoption of herbicide-resistant cotton seed and conservation-tillage cotton production practices in Tennessee. The first method was a comparison of conditional

probabilities using Bayes' theorem (Render, Stair, and Hanna). The second was the simultaneous estimation of two binomial logit models, where the two equations represent the choices between adopting herbicide-resistant versus conventional seed and adopting conservation-tillage versus conventional tillage practices. Both methods assume the probability that a farmer will choose to produce an acre of cotton using a particular technology is equal to the share of cotton acreage produced with that technology.

Bayes' Theorem

Consider two events: (1) Event H occurs when an acre of Tennessee cotton is produced with herbicide-resistant seed and (2) Event C occurs when an acre of Tennessee cotton is produced with conservation-tillage practices. The complement of event H ($\bar{H}$) occurs when an acre is produced with conventional cotton seed and the complement of C ($\bar{C}$) occurs when an acre is produced with conventional tillage practices. Let the probability of an event occurring be represented by the share of total Tennessee cotton acreage in that event. When events H and C are not independent, Bayes' theorem states that the conditional probability of event H occurring given that event C has occurred, $P(H|C)$, is equal to the joint probability of events H and C occurring, $P(HC)$, divided by the marginal probability of event C occurring, $P(C)$, or mathematically (Render, Stair, and Hanna):

$$(1) \quad P(H|C) = \frac{P(HC)}{P(C)}.$$

If events H and C are independent, $P(H|C) = P(H)$ (Render, Stair, and Hanna). Bayes' theorem can be stated conversely as

$$(2) \quad P(C|H) = \frac{P(HC)}{P(H)},$$

where $P(C|H)$ is the conditional probability of event C occurring given that event H has occurred. If events H and C are independent, $P(C|H) = P(C)$.

Two other probabilities of interest are the conditional probability of one event occurring given that the complement of the other event has occurred

$$(3) \quad P(H|\bar{C}) = \frac{P(H\bar{C})}{P(\bar{C})} = \frac{P(H) - P(HC)}{1 - P(C)}, \text{ and}$$
$$P(C|\bar{H}) = \frac{P(\bar{H}C)}{P(\bar{H})} = \frac{P(C) - P(HC)}{1 - P(H)}.$$

When events H and C are independent, $P(H|\bar{C}) = P(H)$ and $P(C|\bar{H}) = P(C)$. Independence implies that the conditional probabilities in Equations (1) and (3) are equal, the conditional probabilities in Equations (2) and (4) are equal, and these conditional probabilities equal their respective marginal probabilities. Alternatively, if $P(H|C) > P(H|\bar{C})$, the adoption of conservation-tillage practices has increased the probability of adopting herbicide-resistant cotton seed, and if $P(C|H) > P(C|\bar{H})$, the adoption of herbicide-resistant seed has increased the probability of adopting conservation-tillage practices.

We calculated and compared the conditional probabilities in Equations (1) through (4) using data for 1998 through 2004 (Doane Marketing Research, Inc.) on the percentages of Tennessee cotton acres in herbicide-resistant seed, conservation-tillage practices, and in both technologies. This data set contained the only consistent time-series data found that included $P(C)$, $P(H)$, and $P(HC)$. Data were not available from Doane Marketing Research, Inc. for 1995 through 1997 and were excluded from the conditional probability analysis.

Logit Analysis

Following Garrod and Roberts, assume cotton production can be accomplished during a particular year using herbicide-resistant or conventional seed technologies and cotton acreage is constrained to a fixed level by exogenous or predetermined events (e.g., naïve price expectations and lagged cotton acreage). Let p_H and p_R represent average profit functions for herbicide-resistant and conventional seed technologies, respectively, where p_i is conditional upon the number of acres in technology i (q_i;

$i = H$ and $\bar{H}$), prices of outputs, and prices of inputs. Thus, we assume the farmer's problem is to allocate cotton acreage between herbicide-resistant and conventional seed technologies to achieve maximum profit. Our hypothesis is that adoption of herbicide-resistant seed is not independent of adoption of conservation-tillage practices. If they are not independent, p_i also includes conservation-tillage cotton acreage as an argument.

Assuming q_H and $q_{\bar{H}}$ are dependent on the conditional profits of both technologies, their quantities and shares can be defined as

$$(5) \quad q_i = f_i(p_H, p_{\bar{H}}, Q) \qquad i = H \text{ and } \bar{H}, \text{ and}$$
$$k_i = f_i \Big/ \sum_i f_i, \qquad i = H \text{ and } \bar{H},$$

where $k_H = q_H/Q$ and $k_H = q_H/Q$ are acreage shares of the respective technologies, which sum to one and are interpreted as probabilities of adopting the respective technologies. If we further assume

$$(6) \quad f_i = \exp[g_i(p_H, p_{\bar{H}}, Q)], \qquad i = H \text{ and } \bar{H},$$

then k_i is defined as a universal logit function (Amemiya). A convenient expression is then derived by taking the natural logarithm of the probability ratio, or odds ratio:

$$(7) \quad \ln(k_H/k_{\bar{H}}) = \ln(q_H/q_{\bar{H}}) = z_H = g_H - g_{\bar{H}}.$$

Equation (7) can be estimated using standard econometric methods if it is stochastic and linear in its arguments, and an estimate of the probability of adopting herbicide-resistant cotton seed can be obtained.

Conditional elasticities for q_H and $q_{\bar{H}}$ with respect to an explanatory variable can be calculated as in Roberts and Garrod. These elasticities, for variables other than Q, approach zero as k_i ($i = H$ or $\bar{H}$) approaches unity, suggesting that as the choice becomes limited to one alternative, that alternative cannot change in the short run because $q_i = Q$ is fixed. Also, the weighted sum of these two elasticities equals zero, where the weights are the acreage shares in each seed technology; thus, in the short run, cotton acreage in herbicide-tolerant seed cannot increase (or decrease) without decreasing (or increasing) acreage in conventional seed. For Q, the weighted sum of the elasticities is unity. If acreage in conservation-tillage practices is an argument of z_H, the influence of conservation-tillage adoption on the adoption of herbicide-tolerant seed, and its complement can be evaluated through their respective elasticities.

A similar model can be hypothesized for the choice between the use of conservation-tillage (C) and conventional tillage ($\bar{C}$) practices:

$$(8) \quad \ln(k_C/k_{\bar{C}}) = \ln(q_C/q_{\bar{C}}) = z_C = g_C - g_{\bar{C}},$$

where $k_j = q_j/Q$ ($j = C$ and $\bar{C}$); q_j is acreage in technology j ($j = C$ and $\bar{C}$); and $Q = q_c + q_{\bar{C}}$. We hypothesize that adoption of conservation-tillage practices is not independent of herbicide-resistant cotton seed adoption, suggesting that acreage in herbicide-resistant seed is an argument of z_C. If indeed acreage in conservation-tillage practices is an argument in Equation (7) and acreage in herbicide-resistant seed is an argument in Equation (8), these two equations form a system of simultaneous equations that must be estimated with appropriate econometric methods that account for simultaneity.

For empirical estimation, Equations (7) and (8) were specified as

$$(9) \quad \ln\left(\frac{HAC}{100 - HAC}\right) = \beta_0 + \beta_1 CAC + \beta_2 RUPR/COPR + \beta_3 RSPR/CSPR + \beta_4 D + \beta_5 CTAC + e_H,$$

and

$$(10) \quad \ln\left(\frac{CAC}{100 - CAC}\right) = \gamma_0 + \gamma_1 HAC + \gamma_2 RUPR/FUPR + \gamma_3 RAIN + \gamma_4 DRAIN + \gamma_5 NRAIN + \gamma_6 CTAC + e_C,$$

where variable definitions and means are given in Table 1 the βs and γs are parameters to be estimated; and e_H and e_C are random errors.

Table 1. Logit Model Variables, Definitions, and Means

Variable	Definition	Mean[a]
$\ln\left(\frac{HAC}{100 - HAC}\right)$	Natural logarithm of the ratio of the percentage of Tennessee cotton acres in herbicide-resistant seed (Roundup Ready, BXN, and Liberty Link, including stacked genes) to the percentage in conventional seed	1.80 (1.11)
$\ln\left(\frac{CAC}{100 - CAC}\right)$	Natural logarithm of the ratio of the percentage of Tennessee cotton acres in conservation tillage (no-till, ridge-till, strip-till, and mulch-till) to the percentage in conventional tillage	0.61 (0.20)
HAC	Percentage of Tennessee cotton acres in herbicide-resistant seed	69.31 (42.65)
CAC	Percentage of Tennessee cotton acres in conservation tillage	61.31 (52.58)
RUPR	Roundup price ($/pint)	5.83 (6.08)
COPR	Cotoran price ($/pint)	4.57 (4.93)
RUPR/COPR	Ratio of *RUPR* to *COPR*	1.28 (1.28)
RSPR	Roundup-Ready cotton seed price ($/lb)	1.88 (1.16)
CSPR	Conventional cotton seed price ($/lb)	1.01 (0.90)
RSPR/CSPR	Ratio of *RSPR* to *CSPR*	1.87 (1.15)
D	Dummy equals 1 for 1999 through 2004; 0 otherwise	0.75 (0.46)
CTAC	Total Tennessee cotton acres (100,000s)	5.52 (5.77)
FUPR	U.S. index of prices paid by farmers for fuel, 2002 = 1.00	1.07 (0.98)
RUPR/FUPR	Ratio of *RUPR* to *FUPR* lagged one period	6.35 (6.88)
RAIN	County average cumulative rainfall for April and May for the five highest cotton-producing counties in Tennessee (inches)	10.62 (9.96)
DRAIN	Dummy equals *RAIN* if *RAIN* is greater than one-half standard deviation above its mean (>11.16 inches); 0 otherwise	5.00 (3.08)
NRAIN	Dummy equals 1 if November rainfall in the previous year was greater than one-half standard deviation from its mean (>4.97 inches); 0 otherwise	0.38 (0.5)

[a] Means of annual data for 1997 through 2004, with means for 1992 through 2004 in parentheses.

Equations (9) and (10) were estimated with three-stage least squares using Tennessee annual time-series data for the 1992–2004 period. The Roundup price (*RUPR*) was taken from Economic Research Service (1997) and National Agricultural Statistics Service (2005, 2003, 2000, 1996a, 1996b). Cotoran (*COPR*), Roundup-Ready seed (*RSPR*), and conventional seed (*CSPR*) prices were taken from annual Tennessee field crop and cotton budgets (Johnson 1992–1993; Gerloff 1994–1999; Gerloff 2000–2004). The U.S. index of prices paid by farmers for fuel (*FUPR*) was taken from the Council of Economic Advisors. Data for the rainfall variables (*RAIN, DRAIN,* and *FRAIN*) were received from the National Climatic Data Center. The percentages of Tennessee cotton acreage in conservation-tillage (*CAC*) and conventional tillage (100-*CAC*), and total cotton acreage (*CTAC*) were found in Tennessee Department of Agriculture (1996–2003, 2004). Data used in the conditional probability analysis for the share of Tennessee cotton acreage in conservation-tillage practices provided by Doane Marketing Research, Inc. were not used for *CAC* because those tillage data only covered the 1998–2004 period. Tillage data from Tennessee Department of Agriculture allowed estimation of Equations (9) and (10) with time-series data for 1992 through 2004.

The *HAC* data for 1995 through 1997 were

not available from Doane. *HAC* was zero for 1992 through 1994 because herbicide-resistant cotton seed was not available to farmers in those years, and it was assumed zero for 1995 and 1996 because herbicide-resistant cotton seed adoption in Tennessee was sufficiently small (Alesii and Bradley, personal communication) for *HAC* to be considered zero without appreciably affecting the analysis. Data for *HAC* for 1998 through 2004 were received from Doane Marketing Research, Inc. Monsanto (Alesii and Bradley, personal communication) provided their best estimate for *HAC* in 1997 of about half the Doane 1998 level, which was used in the logit analysis. Acreage elasticities were calculated at the means of the data for 1997–2004 (instead of 1992–2004) to provide a more consistent view of acreage responsiveness during the period when herbicide-resistant seed was available and being adopted by farmers.

The price variables in Equations (9) and (10) were used as proxies for prices of inputs hypothesized to make the most difference in relative profitability for the respective technology choices. Other prices were not considered because of general colinearity among prices and to preserve degrees of freedom. Price ratios were used for similar reasons.

Prices of cotton lint produced with herbicide-resistant and conventional seed and with conservation and conventional tillage practices were not included in Equations (9) and (10) for two reasons. First, prices for cotton lint produced with the different technologies are not different unless these technologies produce lint of different qualities. Concern has been expressed about a potential loss in lint quality from herbicide-resistant seed (e.g., Bourland and Johnson; Coley; Ethridge and Hequet; Kerby et al.; Lewis; Verhalen, Greenhagen, and Thacker), although York et al. found no difference in lint quality compared with conventional cultivars in official North Carolina cultivar trails. Daniel et al. and Bauer and Busscher found no differences in lint quality among tillage systems. Even if differences in price discounts for lint quality existed, they would likely have little effect on the results because their magnitudes would be small relative to the magnitudes of the prices of lint produced with these technologies. Second, separate time-series data do not exist for prices of lint produced with the technologies evaluated in this analysis.

The expected lint price might still be included in Equations (9) and (10) if changes in the lint price changed the relative profitabilities for each technology choice because of differences in yields and/or production costs. Nevertheless, the expected lint price was excluded for five reasons. First, research suggests that lint yields are about the same for conservation and conventional tillage practices (e.g., Bradley, 1991, 1997; Bronson et al.; Buman et al.; Daniel et al.; Hudson; Keeling, Segarra, and Abernathy; York et al.). Second, differences in budgeted costs between no-tillage and conventional-tillage cotton in Tennessee were from 4% to 6% of total cost regardless of seed technology (Gerloff 2003), suggesting little potential for changes in relative profitabilities as the lint price changes. Third, although some evidence suggests lower lint yields from herbicide-resistant seed (Verhalen, Greenhagen, and Thacker), modeling by Fernandez-Cornejo and McBride (2000) indicated increased lint yields with adoption of herbicide-resistant seed, and Marra, Pardey, and Alston reported research that indicated herbicide-resistant lint yields between 120 lb/acre higher and 164 lb/acre lower than conventional seed yields. Other researchers who conducted field trials found similar yields between the two seed technologies (e.g., Goldman et al.; Keeling et al.; Vencill; York et al.). Fourth, differences in budgeted costs between Roundup Ready and conventional seed cotton were only about 1% of total cost regardless of tillage practice (Gerloff 2003), leaving little room for changes in relative profitabilities as the lint price changes. Fifth, even if the expected lint price affected the acreage allocation decisions in Equations (9) and (10), much of its influence would be transmitted to the decisions through *CTAC*. The expected lint price (among other things) determines *CTAC*, which in turn influences acreage-allocation decisions for the technology choices portrayed in Equations (9) and (10). Thus, the expected

lint price (e.g., lagged price) and *CTAC* would capture similar effects and be highly correlated, producing extreme multicollinearity.

Economic theory and other attributes of the variables in Equations (9) and (10) allowed formation of *a priori* hypotheses about the signs of the parameters. The motivating hypothesis for this research was that adoption of conservation-tillage practices positively influences adoption of herbicide-resistant cotton seed and that adoption of herbicide-resistant seed positively influences adoption of conservation-tillage practices; thus, β_1 and γ_1 were both expected to be positive, indicating that a change in the probability of adopting conservation-tillage cotton (*CAC*) positively influences the probability of adopting herbicide-resistant cotton seed and that a change in the probability of adopting herbicide-resistant cotton seed (*HAC*) positively influences the probability of adopting conservation-tillage practices.

Herbicide-resistant and conventional seed cotton use two distinct herbicide systems. As the cost of one system changes relative to the other, the relative profitability of herbicide-resistant and conventional seed cotton changes and the probability of a profit-maximizing farmer choosing one technology over the other changes. Roundup (*RUPR*) and Cotoran (*COPR*) prices were included in Equation (9) as proxies for the prices of herbicides used to produce herbicide-resistant and conventional seed cotton, respectively. The price of Roundup was chosen because herbicide-resistant cotton is produced almost entirely with Roundup-Ready seed and Roundup cannot be used over top of conventional seed cotton. The price of Cotoran was used because non-Roundup herbicides (e.g., Cotoran and others) are a small part of the cost of producing herbicide-resistant cotton, and Cotoran was a herbicide consistently recommended for conventional seed cotton in the University of Tennessee cotton budgets (Johnson 1992–1993; Gerloff 1994–1999; Gerloff 2000–2004). With Roundup being an input in the production of herbicide-resistant cotton, a change in *RUPR* was expected to negatively influence the probability of adopting herbicide-resistant cotton seed and positively influence the use of conventional cotton seed. Conversely, a change in *COPR* was expected to negatively influence the use of conventional cotton seed and positively influence the probability of adopting herbicide-resistant cotton seed; thus, β_2 was expected to be negative. Similarly, Roundup-Ready cotton seed and conventional cotton seed are inputs in the production of herbicide-resistant cotton and conventional seed cotton, respectively; therefore, β_3 was expected to be negative.

Although herbicide-resistant BXN (Buctril-resistant) cotton seed was first introduced in 1995 (Ward et al. 1995) and Roundup-Ready cotton seed became commercially available in 1996 (Johnson 1996), insufficient supply was available to meet farmer demand until 1999, when most farmers were able to purchase herbicide-resistant cotton seed if they wanted it. The binary variable *D* was included in Equation (9) to account for differences in years when sufficient herbicide-resistant seed was available to meet demand compared with years when herbicide-resistant seed was not available or not available in quantities sufficient to meet demand. Thus, β_4 was expected to be positive.

The sign of γ_2 was expected to be negative because herbicides are a more important input in the production of conservation-tillage cotton and fuel is a more important input in the production of conventional-tillage cotton. Roundup is a commonly used burn-down herbicide in conservation-tillage systems; hence its price was used as a proxy for prices of herbicides used in conservation-tillage systems. A decrease in the price of Roundup (*RUPR*) relative to the price of fuel (*FUPR*) would decrease the cost of producing conservation-tillage cotton relative to the cost of producing conventional-tillage cotton, encouraging farmers to move away from conventional-tillage towards conservation-tillage cotton production.

Conservation-tillage practices reduce the risk of late planting because fewer machinery operations are required and crops can generally be planted when conditions are too wet for conventional-tillage operations (Bates and Denton; Harper; Phillips and Hendrix). Heavy

Table 2. Adoption of Herbicide-Resistant and Conservation-Tillage Cotton for 1998–2004

Proportion of Tennessee Cotton Acreage	1998	1999	2000	2001	2002	2003	2004
Herbicide-resistant, $P(H)$	0.091	0.677	0.845	0.934	0.959	0.998	0.995
Conservation-tillage, $P(C)$	0.364	0.549	0.670	0.777	0.709	0.735	0.782
Herbicide-resistant and conservation-tillage, $P(HC)$	0.061	0.410	0.625	0.732	0.696	0.733	0.781

Source: Doane Marketing Research, Inc.

rainfall during April and May when farmers are engaged in tillage and planting operations makes timely tillage and planting more difficult, increasing the risk of late planting. Heavy spring rainfall was hypothesized to encourage cotton farmers to rent no-till planting equipment, custom hire no-till planting operations, or retrofit their conventional planters for no-till planting (Bradley 2001). Conversely, light spring rainfall might encourage farmers to engage in what some call "recreational tillage" because many farmers feel they should be out working in the field when the weather is good (e.g., Alesii and Bradley, personal communication; Delta Farm Press; Fletcher). The latter occurs because farmers who are affected by heavy spring rainfall are at the margin of conservation-tillage adoption and seldom convert completely by selling their tillage equipment (Dumler). These marginal adopters can bring their tillage equipment back online when the weather is good if they have doubts about the relative profitabilities of the two tillage practices. Therefore, γ_3 was expected to be positive. A positive γ_3 implies that increases in rainfall encourage adoption of conservation-tillage practices by the same amount as decreases in rainfall encourage abandonment of conservation-tillage practices. *DRAIN* was included in Equation (10) to test the hypothesis that April and May rainfall of more than one-half standard deviation above its mean has a different effect on adoption of conservation-tillage practices than rainfall of lesser amounts; thus, γ_4 was expected to be positive.

Heavy rainfall in the previous year (*NRAIN*) may have a different effect on tillage decisions than heavy spring rainfall. It may cause farmers to rut their fields during harvest, requiring spring tillage; thus, the sign of γ_5 would be negative. Alternatively, heavy rainfall in the fall may cause farmers to look toward future spring tillage operations and begin planning for conversion to conservation tillage to avoid a perceived risk of late planting. If farmers apply past heavy rainfall to their tillage decisions in this way, γ_5 would be positive; thus, the sign of γ_5 was ambiguous.

Theoretically, cotton is produced on the "best" cotton land in terms of potential profit compared with other crops. Consequently, changes in cotton acreage would typically occur on marginal cotton land that may be more erodible than land that is already in cotton production. We hypothesized that farmers are more likely to use conservation-tillage practices on this marginal land than on the less-erodible land already in cotton production; thus, γ_6 was expected to be positive. Farmers who increase cotton acreage or who produce cotton for the first time may be less risk averse than those who do not, and they may be more willing to adopt new technologies. If this hypothesis were correct, β_5 would be positive, and the positive expectation for γ_6 would be reinforced.

Results

Bayes' Theorem

Shares of Tennessee cotton acreage produced with each technology and with both technologies for 1998 through 2004 are presented in Table 2 and the conditional probabilities in Equations (1) through (4) are presented in Table 3. In all years except in 2003, the conditional probability of using herbicide-resistant seed given conservation-tillage practices, $P(H|C)$, is greater than the conditional prob-

Table 3. Conditional Probabilities Showing the Relationships Between Adoption of Herbicide-Resistant Cotton Seed and Conservation-Tillage Cotton Production Practices, 1998–2004

Conditional Probability	1998	1999	2000	2001	2002	2003	2004
$P(H\|C)$	0.169	0.747	0.932	0.968	0.981	0.997	0.999
$P(H\|\bar{C})$	0.047	0.593	0.668	0.817	0.905	1.000	0.981
$P(C\|H)$	0.674	0.605	0.740	0.805	0.726	0.735	0.785
$P(C\|\bar{H})$	0.333	0.431	0.294	0.377	0.331	1.000	0.143

[a] $P(H|C)$ and $P(H|\bar{C})$ are conditional probabilities of a Tennessee cotton acre being produced with herbicide-resistant seed (H) given that it is produced with conservation-tillage practices (C) or conventional-tillage practices ($\bar{C}$), respectively. $P(C|H)$ and $P(C|\bar{H})$ are conditional probabilities of a Tennessee cotton acre being produced with C given that it is produced with H or conventional cotton seed ($\bar{H}$), respectively.

ability of using herbicide-resistant seed given conventional tillage practices, $P(H|\bar{C})$, which indicates that cotton farmers who had adopted conservation-tillage practices had a higher probability of adopting herbicide-resistant cotton seed than those farmers who had not adopted conservation-tillage practices. This finding suggests that diffusion of herbicide-resistant seed technology was faster among farmers who used conservation-tillage practices than among those who did not. Also, the gap between $P(H|C)$ and $P(H|\bar{C})$ narrows over time, and in 2003 and 2004 these conditional probabilities are almost equal to each other and equal to the marginal probability of adopting herbicide-resistant seed ($P(H)$ in Table 2), suggesting that differences in tillage practices had less influence on the probability of adopting herbicide-resistant seed in later years because almost all Tennessee cotton acreage was in herbicide-resistant seed in 2003 and 2004 regardless of tillage method.

Results also suggest that adoption of herbicide-resistant cotton seed influenced the probability of adopting conservation-tillage practices as indicated by $P(C|H)$ being greater than $P(C|\bar{H})$ every year except 2003 (Table 3). In this case, however, the gap between the two conditional probabilities does not narrow over time, indicating that adoption of herbicide-resistant seed continued to have an influence through time on the probability of adopting conservation-tillage practices. The conditional probability of 1 in 2003 resulted from only 1,088 Tennessee cotton acres being produced with conventional cotton seed in that year, all of which were produced with conservation-tillage practices.

The Bayes' results suggest a simultaneous relationship between adoption of herbicide-resistant cotton seed and adoption of conservation-tillage practices. These results bode well for the simultaneity hypothesis in the logit analysis.

Logit Analysis

Results from the simultaneous logit model estimated with three-stage least squares are presented in Table 4. All coefficients but one have their hypothesized signs and the high system weighted-average R^2 (0.95) suggests a good fit to the data. Multicollinearity diagnostics (Belsley, Kuh, and Welsch) indicated collinearity between the intercept and *CTAC* in both equations. Thus, multicollinearity may have seriously degraded the standard errors of the coefficients for *CTAC*, rendering the results from hypothesis testing inconclusive for those coefficients (Belsley, Kuh, and Welsch).

Results from the estimation of Equation (9) in Table 4 suggest that the probability of adopting conservation-tillage practices (*CAC*) significantly influenced the probability of adopting herbicide-resistant cotton seed and results from the estimation of Equation (10) indicate that the probability of adopting herbicide-resistant seed (*HAC*) significantly influenced the probability of adopting conservation-tillage practices for Tennessee cotton production. As suggested by the conditional probability results in Table 3 and the 1997–

[e] Percentage change in the number of cotton acres in conservation-tillage practices for a 1% change in the variable in the row. Elasticities in brackets are for conventional-tillage practices.
[f] Elasticities calculated using the sum of the coefficients for RAIN and DRAIN at the mean of RAIN.
*, **, *** Significantly different from zero at the 10%, 5%, and 1% levels, respectively.

2004 mean elasticities in Table 4, these influences are not symmetric. While both elasticities are positive, the number of cotton acres in herbicide-resistant seed increases (decreases) by 1.74% for a 1% increase (decrease) in the probability of adopting conservation-tillage practices (*CAC*), while the number of cotton acres in conservation-tillage practices increases (decreases) by only 0.24% for a 1% increase (decrease) in the probability of adopting herbicide-resistant seed (*HAC*).

Results for Equation 9 (Table 4) also indicate that the short-run supply of Tennessee cotton acreage in herbicide-resistant seed increases (decreases) by 0.78% when the Roundup Ready cotton seed price decreases (increases) by 1% relative to the conventional cotton seed price (*RSPR/CSPR*) and that the probability of adopting herbicide-resistant seed was higher during the 1999–2004 period than in earlier years when it was not available, or before sufficient supply of herbicide-resistant seed was produced to meet demand, as evidenced by the positive coefficient for D.

Findings from Equation (10) suggest that the short-run supply of Tennessee cotton acreage in conservation-tillage increases (decreases) by 0.36% when the price of Roundup decreases (increases) by 1% relative to the price of fuel (*RUPR/FUPR*) (Table 4). In addition, the finding that the coefficient for *RAIN* is statistically significant, while the coefficient for *DRAIN* is not, suggests that symmetry exists in cotton farmers' response to increases or decreases in spring rainfall. The elasticity for *RAIN* indicates that conservation-tillage cotton acreage increases by 0.46% when spring rainfall increases by 1% and it decreases by the same amount when rainfall decreases by 1%, other things remaining constant. The positive coefficient for *NRAIN* suggests that heavy rainfall in the fall of the previous year increases the probability that cotton farmers will adopt conservation-tillage practices in the spring.

Conclusions

Results suggest that the introduction of herbicide-resistant cotton seed in Tennessee increased the probability that farmers would adopt conservation-tillage practices. Along with the direct benefits of increased profit potential and the substitution of nonresidual herbicides for residual herbicides, the introduction of herbicide-resistant cotton seed indirectly contributed to increased conservation of Tennessee soils. This indirect environmental benefit of reduced soil erosion should not be ignored when considering the costs and benefits of herbicide-resistant cotton production. Also, farmers who had previously adopted conservation-tillage practices were more likely to adopt herbicide-resistant cotton seed, indirectly reducing their use of residual herbicides and increasing their profit potential as they reduced erosion. Thus, the synergistic relationship between adoption of herbicide-resistant cotton seed and adoption of conservation-tillage practices for cotton production likely contributed to reduced soil erosion, reduced residual herbicide use, and increased profit during a period of low cotton prices.

Abstract

Genetically modified (GM) crops have been used commercially for more than 10 years. Available impact studies of insect-resistant and herbicide-tolerant crops show that these technologies are beneficial to farmers and consumers, producing large aggregate welfare gains as well as positive effects for the environment and human health. The advantages of future applications could even be much bigger. Given a conducive institutional framework, GM crops can contribute significantly to global food security and poverty reduction. Nonetheless, widespread public reservations have led to a complex system of regulations. Overregulation has become a real threat for the further development and use of GM crops. The costs in terms of foregone benefits may be large, especially for developing countries. Economics research has an important role to play in designing efficient regulatory mechanisms and agricultural innovation systems.

1. INTRODUCTION

A genetically modified (GM) crop is a plant used for agricultural purposes into which one or several genes coding for desirable traits have been inserted through the process of genetic engineering. These genes may stem not only from the same or other plant species, but also from organisms totally unrelated to the recipient crop. The basic techniques of plant genetic engineering were developed in the early 1980s, and the first GM crops became commercially available in the mid-1990s. Since then, GM crop adoption has increased rapidly. In 2008, GM crops were being grown on 9% of the global arable land (James 2008).

The crop traits targeted through genetic engineering are not completely different from those pursued by conventional breeding. However, because genetic engineering allows for the direct gene transfer across species boundaries, some traits that were previously difficult or impossible to breed can now be developed with relative ease. Three categories of GM traits can be distinguished: First-generation GM crops involve improvements in agronomic traits, such as better resistance to pests and diseases. Second-generation GM crops involve enhanced quality traits, such as higher nutrient contents of food products. Third-generation crops are plants designed to produce special substances for pharmaceutical or industrial purposes.

The potentials of GM crops are manifold. Against the background of a dwindling natural resource base, productivity increases in global agriculture are important to ensure sufficient availability of food and other raw materials for a growing population (von Braun 2007). GM crops can also bring about environmental benefits. Furthermore, new seed technologies have, in the past, played an important role for rural income growth and poverty alleviation in developing countries (e.g., Hazell & Ramasamy 1991, Fan et al. 2005). These effects are also expected for GM crops (FAO 2004). Finally, nutritionally enhanced crops could help improve the health status of consumers (e.g., Bouis 2007, Unnevehr et al. 2007).

In spite of these potentials, the development and use of GM crops have aroused significant opposition. Public reservations are particularly strong in Europe, but they have also spilled over to other countries and regions through trade regulations, public media, and outreach efforts of antibiotech lobbying groups (e.g., Pinstrup-Andersen & Schioler 2001, Miller & Conko 2004, Herring 2007, Paarlberg 2008). The major concerns are related to potential environmental and health risks, but there are also fears about adverse social implications (e.g., Altieri 2001, Friends of the Earth 2008). For instance, some believe that GM technology could undermine traditional knowledge systems in developing countries. Given the increasing privatization of crop improvement research and proliferation of intellectual property rights (IPRs), there are also concerns about the potential monopolization of seed markets and exploitation of smallholder farmers (e.g., Sharma 2004).

Because GM crops are associated with new potentials and issues, their emergence has also triggered substantial research dealing with economic and policy aspects. This article reviews the available research on the economics of GM crops. Section 2 gives a brief overview of the status of commercialized GM crops and expected trends for the future. Then, work related to the analysis of impacts at the micro and macro level is discussed. Whereas Sections 3 and 4 address impacts of first-generation GM applications, Section 5 refers to second-generation crops from an ex ante perspective. Sections 6 and 7 focus on consumer acceptance and the economics of regulation, including aspects of biosafety as

well as food labeling and IPRs. In the concluding section, policy and research implications are discussed.

2. STATUS OF GM CROPS

2.1. Commercialized GM Crops

The commercial application of GM crops began in the mid-1990s. Since then, the technology has spread rapidly around the world, both in industrialized and developing countries (**Figure 1**). In 2008, GM crops were being grown on 125 million ha in 25 countries. The countries with the biggest share of the GM crop area were the United States (50%), Argentina (17%), Brazil (13%), India (6%), Canada (6%), and China (3%) (James 2008). Strikingly, among the countries of the European Union (EU), only Spain grows GM crops on a significant scale. Although a few other EU countries have approved individual GM technologies, the commercial area is still negligible, because of public-acceptance problems and unfavorable regulatory frameworks.

In spite of the widespread international use of GM crops, the portfolio of available crop-trait combinations is still very limited. At present, only a few first-generation technologies have been commercialized. The dominant technology is herbicide tolerance (HT) in soybeans, which made up 53% of the global GM crop area in 2008. HT soybeans are currently grown mostly in the United States, Argentina, Brazil, and other South American countries. This technology accounts for 70% of worldwide soybean production.

GM maize is the second-most dominant crop and covered 30% of the global GM area and 24% of total maize production in 2008 (James 2008). GM maize involves HT and insect resistance, partly as separate and partly also as stacked technologies. Insect resistance is based on different genes from the soil bacterium *Bacillus thuringiensis* (Bt). These Bt genes control the European corn borer, the corn rootworm, and different stemborers (Romeis et al. 2008). Bt maize is grown mostly in North and South America, but it is also planted to a significant extent in South Africa and the Philippines.

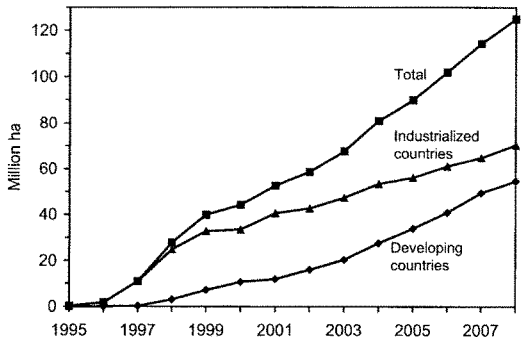

Figure 1

Development of the global area using genetically modified crops (1995–2008).

Annu. Rev. Resour. Econ. 2009.1:665-694. Downloaded from arjournals.annualreviews.org
by Reprints Desk, Inc. on 12/15/09. For personal use only.

GM crops with significant area shares also include cotton and canola. Bt cotton with resistance to bollworms and budworms is particularly relevant in developing countries. In 2008, India had the largest Bt cotton area with 7.6 million ha, followed by China with 3.8 million ha. South Africa, Argentina, Mexico, and a few other countries use this technology as well. In the United States, Bt and HT cotton are employed, partly with stacked genes. Until now, HT canola was grown mostly in Canada and the United States. A few other GM crops, including HT alfalfa and sugarbeet as well as virus-resistant papaya and squash, have been approved in individual countries, so far covering only relatively small areas.

2.2. GM Crops in the Pipeline

A couple of GM technologies previously developed for food crops either were never commercialized or were withdrawn from the market because of consumer-acceptance and marketing problems. Examples include Bt and virus-resistant potato as well as HT wheat. Yet, such technologies may be reintroduced, should public acceptance improve. A number of other GM crop technologies that provide insect resistance or HT are ready to be commercialized. For instance, Bt rice has been field tested extensively in China and other countries (Huang et al. 2005, Cohen et al. 2008). Different Bt vegetables—including eggplant, cauliflower, and cabbage—are likely to be commercialized soon in India and other countries in Asia and Africa (Krishna & Qaim 2007, Shelton et al. 2008). HT rice is also in a relatively advanced phase within the research and development (R&D) pipeline (Hareau et al. 2006).

Other first-generation GM technologies that are being developed include fungal, bacterial, and virus resistance in major cereal as well as root and tuber crops (Halford 2006). Their market introduction can be expected in the short to medium run. Plant tolerance to abiotic stress—such as drought, heat, and salt—is also being worked on intensively. Yet, because the underlying genetic mechanisms are complex, the work is at a more basic level, so significant commercial releases can be expected only in the medium run (Herdt 2006, Ramasamy et al. 2007).

Second-generation GM technologies in the pipeline include product quality improvements for nutrition and industrial purposes. Examples are oilseeds with improved fatty acid profiles; high-amylose maize; staple foods with enhanced contents of essential amino acids, minerals, and vitamins; and GM functional foods with diverse health benefits (Jefferson-Moore & Traxler 2005, Pew Initiative on Food and Biotechnology 2007).

Enhancing food crops with higher nutrient contents through conventional or GM breeding is also called biofortification. A well-known example of a GM biofortified crop is Golden Rice, which contains significant amounts of provitamin A. Golden Rice could become commercially available in some Asian countries by 2012 (Stein et al. 2006, Potrykus 2008). Other biofortification projects include the development of GM sorghum, cassava, banana, and rice enhanced with multiple nutrients (Qaim et al. 2007). Such crops may become commercially available over the next 5–10 years.

Third-generation GM crops involve molecular farming where the crop is used to produce either pharmaceuticals such as monoclonal antibodies and vaccines or industrial products such as enzymes and biodegradable plastics (Moschini 2006, Halford 2006). Although concepts have been proven for a number of these technologies, product development and regulatory aspects are even more complex than they are for first- and second-

generation crops. Substances produced in the plants must be guaranteed not to enter the regular food chain with a zero-tolerance threshold. Therefore, plants that are not used for food and feed purposes will likely be chosen for product development, or approvals for third-generation GM crops will be given for use under contained conditions only. In either case, this brief overview reveals that the GM crops available so far represent only a very small fraction of the large future potentials of plant genetic engineering.

3. MICROLEVEL IMPACTS OF FIRST-GENERATION GM CROPS

Because HT and insect-resistant Bt crops have already been used for a number of years, numerous microlevel impact studies have been carried out in different countries. Many such studies are based on random sample surveys, comparing the performance of adopters and nonadopters of GM crops (Kalaitzandonakes 2003, Naseem & Pray 2004, Qaim 2005, Gandhi & Namboodiri 2006). However, such with-without comparisons can be associated with a selectivity bias. On the one hand, if adopting farmers are more skillful than their nonadopting counterparts, the net technological impacts may be overestimated, because the group of adopters may show better performance even without GM technology. On the other hand, if the technology is adopted only by farmers under specific conditions, net impacts may be underestimated. For instance, Bt technology is expected to be particularly beneficial in high pest pressure environments. Therefore, simply comparing the productivity of adopters in high pest pressure environments with that of nonadopters in low pest pressure environments would lead to a downward bias in impact assessment.

Different approaches have been used to reduce a potential selectivity bias. For instance, some authors have observed developments over time, involving several rounds of data collection (e.g., Pray et al. 2002, Sadashivappa & Qaim 2009). Others have combined survey data of GM farmers with calculations of what would have been without technology adoption (e.g., Gianessi et al. 2002, Brookes & Barfoot 2008). In addition, within-farm comparisons have been made in situations where adopting farmers continued to use conventional crops on part of their land (e.g., Qaim & de Janvry 2005). Econometric approaches to deal with selectivity issues are explained below.

3.1. Farm-Level Impacts of HT Crops

HT crops are tolerant to certain broad-spectrum herbicides such as glyphosate and glufosinate, which are more effective, less toxic, and usually cheaper than selective herbicides. Accordingly, farmers who adopt HT technology benefit in terms of lower herbicide expenditures. Total herbicide quantities applied were reduced in some situations, but not in others. In Argentina, herbicide quantities were increased significantly (Qaim & Traxler 2005), in large part owing to the fact that herbicide sprays were substituted for tillage. In Argentina, the share of soybean farmers using no-till doubled to almost 90% since the introduction of HT technology (Trigo & Cap 2006), whereas in the United States and Canada, no-till practices expanded through HT adoption (Kalaitzandonakes 2003, Fernandez-Cornejo & Caswell 2006). In terms of the yields achieved, no significant difference between HT and conventional crops is seen in most cases. Only in a few examples when certain weeds were difficult to control with selective herbicides did the adoption of HT and the switch to broad-spectrum herbicides result in better weed control and higher crop

yields. These include HT soybeans in Romania and HT maize in Argentina (Brookes & Barfoot 2008).

Overall, HT technology reduces the cost of production through lower expenditures for herbicides, labor, machinery, and fuel. Yet, because HT crops were developed and commercialized by private companies, a technology fee is charged on seeds, which varies among crops as well as countries. Several early studies for HT soybeans in the United States showed that the fee was of a similar magnitude or sometimes higher than the average cost reduction, so that gross margin effects were small or partly negative (e.g., Duffy 2001, Fernandez-Cornejo et al. 2002). Comparable results were also obtained for HT cotton and HT canola in the United States and Canada (Fulton & Keyowski 1999, Marra et al. 2002, Phillips 2003, Naseem & Pray 2004). The main reasons for farmers in such situations to continue using HT technologies were easier weed control and savings in terms of management time. Fernandez-Cornejo et al. (2005) showed that the saved management time for U.S. soybean farmers translated in part into higher off-farm incomes. Moreover, farmers are heterogeneous, such that many adopters have benefited in spite of zero or negative mean gross margin effects. The average farm-level profits seem to increase over time, partly as a result of seed-price adjustments and farmer-learning effects.

In South American countries, the average gross margin effects of HT crops, especially HT soybeans, are larger than in North America (Trigo & Cap 2006). While the agronomic advantages are similar, the fee charged on seeds is lower, as HT technology is not patented there. Many soybean farmers in South America use farm-saved GM seeds. Qaim & Traxler (2005) showed that the average gross margin gains through HT soybean adoption are in a magnitude of more than $20 per ha for Argentina.

3.2. Farm-Level Impacts of Bt Crops

Insect-resistant Bt crops have different effects than do HT crops. Bt crops produce proteins that are toxic to larvae of some lepidopteran and coleopteran insect species. Therefore, Bt is a pest-control agent that can be used as a substitute for chemical insecticides. Following Lichtenberg & Zilberman (1986) and Zilberman et al. (2004), this can be expressed in a damage-control framework:

$$Y = F(x)[1 - D(z, Bt; N)],$$

where Y is the effective crop yield, and $F(\cdot)$is potential yield without insect damage, which depends on variable inputs, x. $D(\cdot)$is the damage function determining the fraction of potential output being lost to insect pests; it can take values in the 0–1 interval. Crop losses depend on exogenous pest pressure, N, and they can be reduced through the application of chemical insecticides, z, and/or the use of Bt technology. If pest pressure is high and farmers use a lot of chemical insecticides in the conventional crop, Bt adoption should lead to substantial insecticide reductions.[1] However, Bt technology can also impact effective crop yields. Even though the Bt gene does not affect potential yield, $F(\cdot)$, it can lead to a reduction in crop losses, $D(\cdot)$, when there is previously uncontrolled pest damage, thus leading to a higher Y.

[1]Pemsl et al. (2008) pointed out that natural pest-control agents such as beneficial insects could also reduce crop losses but that these are often suppressed through chemical insecticides. Therefore, even without Bt, a reduction in chemical insecticides may be possible in specific situations. However, compared with chemical insecticides, Bt is much less harmful to beneficial insects (Shelton et al. 2009).

Insecticide reduction and yield effects are closely related: Farmers who use small amounts of insecticides in their conventional crop in spite of high pest pressure will realize a sizeable yield effect through Bt adoption, whereas the insecticide reduction effect will dominate in situations when farmers initially use higher amounts of chemical inputs. The same principles also hold for other pest-resistant GM crops. In general, yield effects will be more pronounced in developing rather than in developed countries, because pest pressure is often higher in the tropics and subtropics and resource-poor farmers face more severe constraints in chemical pest control (Qaim & Zilberman 2003).

3.2.1. Empirical evidence. The Bt-insecticide-yield linkages are diagrammed in **Figure 2** using field trial data with Bt cotton in India. As shown, Bt does not completely eliminate the need for insecticide sprays because some crop damage still occurs when the technology is used. The reason is that Bt toxins are very specific to certain pest species, whereas other insect pests, especially sucking pests, remain unaffected.

What do the agronomic impacts look like under practical farmer conditions? **Table 1** confirms that both insecticide-reducing and yield-increasing effects can be observed internationally. Yield effects of Bt cotton are highest in Argentina and India. For Argentina, the explanation is simple: Conventional cotton farmers underutilize chemical insecticides, so that insect pests are not effectively controlled (Qaim & de Janvry 2005). In India, however, insecticide use in conventional cotton is much higher (Qaim et al. 2006). This suggests that factors other than insecticide quantity influence damage control in conventional cotton and, thus, the yield effects of Bt technology. These factors include insecticide quality, insecticide resistance, and the correct choice of products and timing of sprays.

For Bt maize, similar effects are observable, albeit generally at a lower magnitude (**Table 1**). Except for Spain, where the percentage reduction in insecticide use is large, the more important result of the use of Bt maize is an increase in effective yields. In the United States, for instance, Bt maize is used mainly against the European corn borer, which is not

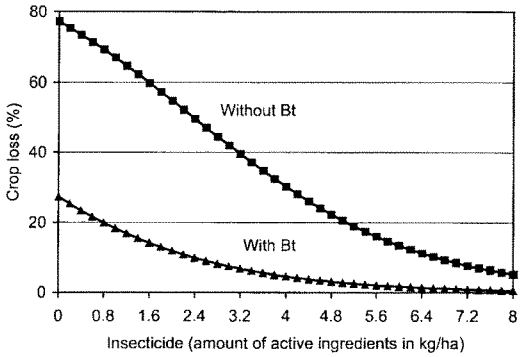

Figure 2

Relationship between insecticide use and cotton crop losses with and without Bt in India.

often controlled by chemical means (Carpenter et al. 2002).[2] In Argentina and South Africa, mean yield effects are higher because pest pressure is more severe than it is in temperate climates. The average yield gain of 11% shown in **Table 1** for South Africa refers to large commercial farms. These farms have been growing yellow Bt maize hybrids for several years. Gouse et al. (2006) analyzed on-farm trials that were carried out with smallholder farmers and white Bt maize hybrids in South Africa. They found average yield gains of 32% on Bt plots. In the Philippines, average yield advantages are 34%.

Preliminary evidence based on field-trial observations also exists for other Bt crops. Huang et al. (2005) observed high insecticide reductions but relatively small yield effects for Bt rice in China, whereas Krishna & Qaim (2008b) reported significant insecticide and yield effects for Bt eggplant in India.

[2]More recently, a different Bt maize technology has been commercialized in the United States to control the corn rootworm complex, against which significant amounts of chemical insecticides are used in conventional agriculture. However, representative studies on the impacts of this new Bt maize technology under farmer conditions are not available.

3.2.2. Econometric estimates. Econometric analyses with different model specifications confirm the net insecticide-reducing and yield-increasing effects of Bt technology. For Bt maize, Fernandez-Cornejo & Li (2005) provided estimates for the United States, and Yorobe & Quicoy (2006) did so for the Philippines. More studies are available for Bt cotton: Huang et al. (2002a) employed an insecticide-use model and a production function with a damage-control specification to estimate the effects in China. A similar analysis was done by Qaim & de Janvry (2005) in Argentina. Bennett et al. (2006) estimated Cobb-Douglas-type production functions for a sample of farmers in India.

Qaim et al. (2006) also estimated productivity effects of Bt cotton in India, differentiating between Bt gene and germplasm effects. They showed that part of the impact variability observed in India during the first years of adoption was due to the incorporation of the Bt gene in only a few cotton varieties that were not suitable for all locations. In such situations, a yield drift can be observed; that is, the positive Bt gene effect is counteracted by a negative germplasm effect. This underlines the finding that the benefits of GM can be fully realized only when the technology is inserted into a number of locally adapted varieties.

Thirtle et al. (2003) used a stochastic frontier approach with data from farmers in South Africa to show that Bt adoption helps to increase the technical efficiency of cotton production in the small-farm sector. Kambhampati et al. (2006) did a similar analysis for India. Many of these econometric analyses used instrumental variable approaches to avoid or reduce selectivity issues and problems of endogeneity. One study by Crost et al. (2007) also used panel data techniques for the estimation of Bt productivity effects.

3.2.3. Gross margin effects. The gross margin effects of Bt technologies are also shown in **Table 1**. In all countries noted, Bt-adopting farmers benefit; that is, the economic advantages associated with insecticide savings and higher effective yields more than outweigh the technology fee charged on GM seeds. The absolute gains differ remarkably among countries and crops. On average, the gross margin gains are higher for Bt cotton than for Bt maize, and they are also higher in developing as opposed to developed countries. In addition to agroecological and socioeconomic differences, the GM seed costs are often lower in developing countries, owing to weaker IPRs, seed reproduction by farmers, subsidies, or other types of government price interventions (Basu & Qaim 2007, Sadashivappa & Qaim 2009).

Agricultural policies are also partly responsible for the different gross margin effects. For instance, in the United States, China, and Mexico, the cotton sector is subsidized, which encourages intensive production schemes and high overall yields. The situation is similar for maize in Spain. By contrast, Argentinean farmers are not subsidized; instead, they face world-market prices. Especially for cotton, world-market prices have been declining over the past 10 years, thus eroding the economic benefits resulting from technological yield gains. Furthermore, within countries, farmer conditions are heterogeneous so that the effects are variable (Qaim et al. 2006, Pemsl & Waibel 2007).

3.3. Poverty and Distribution Effects

Seventy-five percent of all poor people in the world are smallholder farmers or rural laborers. Therefore, GM crops may also have important implications for poverty and income distribution in developing countries. If only rich farmers were to benefit, inequality

Annu. Rev. Resour. Econ. 2009.1:665-694. Downloaded from arjournals.annualreviews.org
by Reprints Desk, Inc. on 12/15/09. For personal use only.

would increase. Yet, if resource-poor farmers could access GM crops suitable for their situations, the poverty and equity effects may be positive. Apart from technological characteristics, this also depends on the institutional setting at national and local levels (Qaim et al. 2000, Evenson et al. 2002). For instance, strong IPRs and high seed prices as well as information, credit, and infrastructure constraints can hinder poor farmers' proper access to GM seeds, even if the underlying technology is suitable for smallholder agriculture (e.g., Qaim & de Janvry 2003, Thirtle et al. 2003, Qaim 2005, Edmeades & Smale 2006).

So far, HT crops have not been widely adopted in the small-farm sector. Smallholders often weed manually, so that HT crops are inappropriate, unless labor shortages or weeds that are difficult to control justify conversion to chemical practices. The situation is very different for Bt crops. Especially in China, India, and South Africa, Bt cotton is often grown by farms with less than 3 ha of land (Huang et al. 2002a,b; Qaim et al. 2008). In South Africa, many smallholders grow Bt white maize as their staple food (Gouse et al. 2006). Several studies show that Bt technology advantages for small-scale farmers are of a similar magnitude as those of larger-scale producers. In some cases, the advantages can be even greater (Pray et al. 2001, Morse et al. 2004, Qaim et al. 2008).[3]

However, few studies exist that have analyzed wider socioeconomic outcomes, including effects on rural employment and household incomes. This dearth of broader microlevel research may be the reason for the ongoing controversy surrounding the poverty and rural development implications of GM crops. Subramanian & Qaim (2009a,b) provide the first comprehensive work in this direction. Building on a village social accounting matrix and multiplier model, they examined direct and indirect effects of Bt cotton adoption in India. Their results show that the technology is employment generating, especially for hired female agricultural laborers, which is due to significantly higher yields in need of harvesting. The technology also generates employment in other sectors linked to cotton production, e.g., trade and services.

Simulated impacts on household incomes are shown in **Figure 3**. Each additional hectare of Bt cotton produces 82% higher aggregate incomes than are obtained from conventional cotton, implying a remarkable gain in overall economic welfare through technology adoption in India. For landless households, the positive income effects are relatively small. More female employment for cotton harvesting is counteracted by less male employment for spraying operations. However, all types of farm households—including those below the poverty line—benefit considerably more from Bt than from conventional cotton. These findings demonstrate that GM crops can contribute significantly to poverty reduction and rural development, when they are suited to the small-farm sector and embedded in a conducive institutional environment.

3.4. Environmental and Health Effects

In addition to the economic and social impacts of GM crops, there are also environmental and health implications. In the public debate, potential environmental risks, such as undesirable gene flow or impacts on nontarget organisms, are often in the fore. Food safety concerns are also raised. Shelton et al. (2009), Weaver & Morris (2005), and

[3]Especially for India, biotech critics still report that Bt cotton ruins smallholder farmers. However, such reports do not build on representative data (Qaim et al. 2006, 2008). Gruère et al. (2008) showed that the occasional claim of a link between Bt cotton adoption and farmer suicides cannot be substantiated.

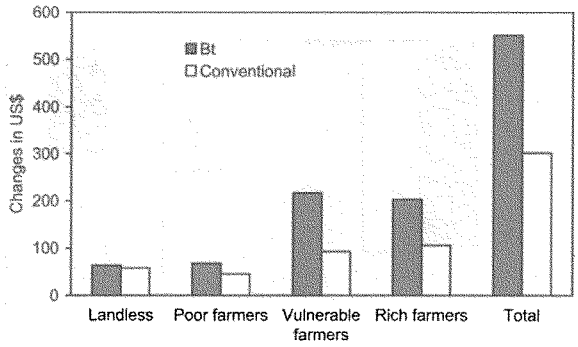

Figure 3

Household income effects of Bt cotton compared with conventional cotton in India. The results are based on simulations with a social accounting matrix and multiplier model for a typical cotton-growing village in the Indian state of Maharashtra. Two simulations were run, both considering an expansion in the village cotton area by 1 ha. The first scenario assumes that the additional hectare is cultivated with Bt cotton, whereas the second assumes that it is cultivated with conventional cotton. Accordingly, differences between the two scenarios can be interpreted as net impacts of Bt technology adoption. Adapted from Subramanian & Qaim (2009a).

Bradford et al. (2005) have reviewed such risks, concluding that most are not specific to the technique of genetic modification but would be present for any conventionally produced crops with the same heritable traits. Although potential risks need to be further analyzed and managed, GM crops can also induce substantial environmental and health benefits.

3.4.1. Environmental benefits. Adoption of HT crops does not lead to reductions in herbicide quantities in most cases, but selective herbicides, which are often relatively toxic to the environment, are substituted by much less toxic broad-spectrum herbicides. Moreover, tillage operations are cut and no-till practices expanded, helping to reduce soil erosion, fuel use, and greenhouse gas emissions (Qaim & Traxler 2005, Brookes & Barfoot 2008).

For Bt crops, the main environmental benefits are related to reductions in chemical insecticide applications. Reductions in pesticide use have been particularly significant in cotton, the most pesticide-consuming crop worldwide. Brookes & Barfoot (2008) estimated that between 1996 and 2006 Bt cotton was responsible for global savings of 128 million kg of pesticide active ingredients, reducing the environmental impact of total cotton pesticides by 25%. **Figure 4** shows that Bt adoption leads to overproportional reductions in the most toxic insecticides.

In the first years of Bt crop deployment, it was predicted that insect populations would soon develop Bt resistance, which would undermine the technology's effectiveness and lead to declining insecticide reductions over time. However, until now, Bt resistance has not been observed under field conditions, which may be due to successful resistance management strategies, such as the planting of non-Bt refuges (Hurley et al. 2001, Bates et al. 2005). In countries where no such strategies are implemented, Bt resistance has also not been reported. However, other factors can lead to changes in Bt effects over time.

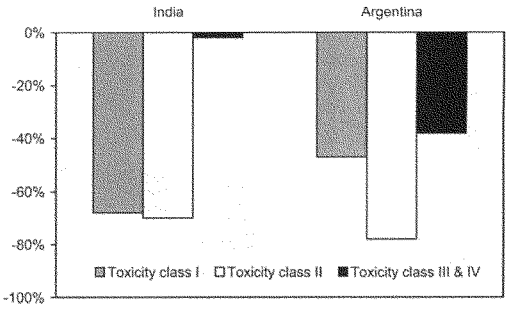

Figure 4

Insecticide reductions through Bt cotton by toxicity class. Results are based on within-farm comparisons obtained from surveys in different cotton-growing regions of India and Argentina. Following the international classification of pesticides, toxicity class I comprises the most toxic products, whereas toxicity class IV comprises the least toxic products. Based on data from Qaim & Zilberman (2003), Qaim et al. (2006), and Qaim & de Janvry (2005).

In China, for instance, insecticide applications increased again after several years of Bt cotton use, in spite of the absence of Bt resistance. Wang et al. (2006) attributed this to secondary pests, which may have become more important through the Bt-induced reduction in broad-spectrum insecticides. Their analysis, however, was based on only one year of observations with increased insecticide applications, making conclusive statements premature (Hu et al. 2006). Using data collected over a period of five years, Sadashivappa & Qaim (2009) did not find any evidence of secondary-pest outbreaks in India.

GM crops may also help preserve agrobiodiversity. Conventional breeding leads to new crop varieties. If a particular new variety produces a large productivity gain, it may spread widely, potentially replacing a large number of older varieties and landraces. This occurred to some extent during the Green Revolution in Asia (Cooper et al. 2005). Developing additional conventional varieties with similar characteristics can be a long and costly process. In contrast, the development of GM traits through genetic engineering can be backcrossed at moderate costs into numerous varieties.[4] Therefore, instead of replacing local varieties, GM versions of these varieties can be made available. Indeed, in most countries where GM technologies have been commercialized, a large number of varieties carrying specific GM traits can be observed (e.g., Qaim 2005, Trigo & Cap 2006, Qaim et al. 2008). More than a technical question, the impact of GM technologies on varietal diversity depends on the design of IPR and biosafety policies, breeding capacities, and other institutional conditions (Zilberman et al. 2007).

3.4.2. Health benefits. GM crops, especially Bt crops, are also associated with health benefits. Direct health advantages for farmers are a result of less insecticide exposure

[4]This is also one reason why genetic engineering is a complementary tool and not a substitute for conventional breeding. GM traits will always have to be incorporated into locally adjusted germplasm.

during spraying operations. Often, the health hazards for farmers applying pesticides are greater in developing as opposed to developed countries because environmental and health regulations are more lax, most pesticides are applied manually, and farmers are less educated and less informed about negative side effects. Pray et al. (2001) and Huang et al. (2003) showed that the frequency of pesticide poisonings was significantly lower among Bt cotton adopters than among nonadopters in China. Hossain et al. (2004) used econometric models to establish that this observation is causally related to Bt technology. Bennett et al. (2003) made the same observation for Bt cotton in South Africa, and there is first evidence that similar effects can also be expected for other Bt crops in smallholder agriculture, such as Bt rice in China (Huang et al. 2005, 2008). Using econometric estimates and a cost-of-illness approach, Krishna & Qaim (2008b) projected that Bt eggplant in India may produce farmer health benefits worth approximately $4 million per year.

For consumers, Bt crops can yield health benefits through lower pesticide residues in food and water. Furthermore, in a variety of field studies, Bt maize was shown to contain significantly lower levels of certain mycotoxins, which can cause cancer and other diseases in humans (Wu 2006). Especially in maize, insect damage contributes significantly to mycotoxin contamination. In the United States and other developed countries, maize is carefully inspected, so lower mycotoxin levels may be most responsible for reducing the costs of testing and grading. But in many developing countries, strict mycotoxin inspections are uncommon. In such situations, Bt technology could contribute to lowering the total health burden (Wu 2006, Qaim et al. 2008).

4. MACROLEVEL IMPACTS OF FIRST-GENERATION GM CROPS

Numerous studies using macrolevel economic surplus models have analyzed the broader welfare effects of GM crops. When the market of only one single crop is considered, partial equilibrium models are used, whereas general equilibrium models are employed when indirect effects and spillovers to other markets and sectors are also of interest.

4.1. Partial Equilibrium Approaches

Whenever new crop technologies are adopted on a large scale, the productivity increase will cause the crop's supply curve to shift downward, leading to a change in producer and consumer surplus (Alston et al. 1995). Because most GM technologies currently available have been commercialized by the private sector, technology rents accrued by innovating companies need to be considered (Moschini & Lapan 1997).

Price et al. (2003) estimated that in the late 1990s Bt cotton generated a total annual economic surplus gain of approximately $164 million in the United States, of which 37% was captured by farmers, 18% by consumers, and 45% by the innovating companies. Falck-Zepeda et al. (2000b) also reported similar results. Because Bt cotton adoption in the United States has increased since then, absolute surplus gains are higher today, but relative surplus distribution remains approximately the same (Fernandez-Cornejo & Caswell 2006).

For Bt cotton in China, Pray et al. (2001) estimated economic surplus gains of approximately $140 million in 1999, with only 1.5% going to the innovating companies and the rest captured by farmers. IPR protection in China is weak, and use of farm-saved Bt cottonseeds is widespread. Under these conditions, it is difficult for companies to capture innovation rents. Cotton consumers did not benefit in 1999 because the government

Annu. Rev. Resour. Econ. 2009.1:665-694. Downloaded from arjournals.annualreviews.org
by Reprints Desk, Inc. on 12/15/09. For personal use only.

controlled output markets, thus preventing a price decrease. Recently, markets have been liberalized, so Chinese consumers now benefit from Bt cotton technology. In India, Bt cotton surplus gains were projected at $315 million for 2005 (Qaim 2003). Because cotton prices there are not fully liberalized, consumer benefits were not considered. Farmers capture two thirds of the overall surplus gains; the rest accrues to biotech and seed companies. Bt cotton in India is commercialized in hybrids, so use of farm-saved seeds is low. Thus, the private sector innovation rent is higher than in China.

For Bt maize in the United States, Wu (2002) estimated a total surplus gain of $334 million in 2001. Approximately half of the gain accrued to producers, followed by industry profits (31%). The consumer share was relatively small. For Bt maize in Spain, Demont & Tollens (2004) calculated welfare gains of approximately $2 million in 2003, of which 60% went to farmers and 40% to seed companies. The relatively low absolute gain is due to the fact that Bt maize in 2003 covered only an area of approximately 25,000 ha. Similar effects were shown during the early years of Bt maize adoption in the Philippines (Yorobe & Quicoy 2006).

A number of studies have examined the partial equilibrium effects of HT soybeans (e.g., Moschini et al. 2000, Falck-Zepeda et al. 2000a, Qaim & Traxler 2005). Most of these studies use multiregion models. Worldwide welfare gains of HT soybeans were on the order of US$1 billion in the late 1990s. Gains have grown since then as a result of increased adoption. At the global level, downstream sectors and consumers are the main beneficiaries, capturing more than 50% of surplus gains. The effects vary strongly by country, however. Within the United States, farmers capture approximately 20% of the national welfare gains versus almost 60% accruing to Monsanto as the innovating company. By contrast, in Argentina, the farmer surplus share is 90%. These differences are largely due to different levels of IPR protection (Qaim & Traxler 2005).

In addition to such ex post studies, ex ante studies for GM crops have also been carried out in different countries. Examples include analyses for Bt maize and different HT crops in the EU (Demont et al. 2004, 2008), HT rice in Uruguay (Hareau et al. 2006), Bt eggplant in India (Krishna & Qaim 2008b), drought-tolerant rice in India and Bangladesh (Ramasamy et al. 2007), and virus- and insect-resistant sweet potato in Kenya (Qaim 2001). These ex ante studies confirm that GM crops can bring about sizeable welfare gains, with distributional effects dependent on IPRs and other institutional conditions.

4.2. General Equilibrium Approaches

Many of the available general equilibrium studies use the multiregion computable general equilibrium (CGE) model and associated database of the Global Trade Analysis Project (Hertel 1997). This model captures the vertical and horizontal linkages between markets within regions and between regions via bilateral trade flows. The results of several global impact studies are summarized in **Table 2**.

Bt cotton adoption entails global welfare gains in the range of $0.7–1.8 billion per year. The differences across studies partly reflect the use of different versions of the basic model. More importantly, however, the assumed technology adoption rates in different regions matter. Because Bt adoption continues to increase, the aggregate welfare gains are increasing too. Most CGE studies for Bt cotton to date found the biggest regional welfare effects occurred in China (e.g., Huang et al. 2004, Frisvold & Reeves 2007), but India, where the technology was commercialized later, has been catching up rapidly. Anderson et al. (2008)

Table 2 Projected global welfare gains from GM crops (CGE model results)[a]

Reference	Crop	Year of study	Annual welfare gain (US$)
Frisvold & Reeves (2007)	Bt cotton	2005	1.4 billion
Elbehri & MacDonald (2004)	Bt cotton	2001	1.8 billion
Anderson & Yao (2003)	Bt cotton	2005	1.4 billion
Anderson et al. (2008)	Bt cotton	2001	0.7 billion
Nielsen & Anderson (2001)	GM oilseeds and maize	—	9.9 million
Anderson & Yao (2003)	GM soybean and maize	—	7.0 billion
Hareau et al. (2005)	Bt rice	—	2.2 billion
Hareau et al. (2005)	Drought-tolerant rice	—	2.5 billion
Hareau et al. (2005)	HT rice	—	2.1 billion
Anderson & Yao (2003)	GM rice	—	2.0 billion

[a]Abbreviations: CGE, computable general equilibrium; GM, genetically modified; HT, herbicide tolerant.

Annu. Rev. Resour. Econ. 2009.1:665-694. Downloaded from arjournals.annualreviews.org
by Reprints Desk, Inc. on 12/15/09. For personal use only.

estimate that widespread adoption of Bt cotton in India and other countries of South Asia will result in additional regional welfare gains on the order of $1 billion per year.

Larger international markets result in bigger effects for GM oilseeds and maize. With widespread international adoption of HT and insect resistance in these crops, annual welfare gains could be approximately $10 billion (Nielsen & Anderson 2001). A ban on production and imports by the EU, however, could reduce these global gains by two thirds, because of foregone benefits for domestic consumers and the far-reaching influence of EU policies on international trade flows and production decisions in exporting regions (Tothova & Oehmke 2005).

For GM rice, large global welfare gains are projected as well. For other rice technologies, such as Bt, HT, and drought tolerance, and assuming moderate adoption levels in rice-producing regions, Hareau et al. (2005) estimated global welfare gains of $2.1–2.5 billion per year, with India and China gaining the most. Huang et al. (2004) projected that the welfare gains in China alone could reach over $4 billion when different first-generation GM rice technologies are widely adopted. The studies available to date provide lower bound estimates of the global welfare effects of GM crops, because positive environmental and health externalities have not been properly quantified.

5. POTENTIAL IMPACTS OF SECOND-GENERATION GM CROPS

First-generation GM crops involve direct productivity and income effects, which can be evaluated at the micro level and then integrated into macrolevel modeling approaches. Second-generation crops, which involve enhanced quality attributes, must be evaluated differently. Quality improvements generally lead to a marginal utility increase and a higher willingness to pay (WTP) among consumers. In a market model, this can be represented as an upward shift in the crop's demand function. There are no ex post impact studies available for second-generation GM crops, because such crops have not been widely adopted. However, several authors have carried out conceptual analyses and ex ante

Annu. Rev. Resour. Econ. 2009.1:665-694. Downloaded from arjournals.annualreviews.org
by Reprints Desk, Inc. on 12/15/09. For personal use only.

simulations of the welfare effects under different conditions in developed countries (e.g., Jefferson-Moore & Traxler 2005, Giannakas & Yiannaka 2008).

In developing countries, the situation is different, especially when looking at technologies that are targeted to the poor, such as biofortified GM crops. Widespread production and consumption of biofortified staple crops could reduce micronutrient deficiencies, improve health outcomes, and provide economic benefits (Bouis 2007). Yet, it is uncertain if they would command higher market prices, because the poor are often not aware of their micronutrient deficiencies and may not be willing or able to pay a quality premium. Therefore, biofortified crops in developing countries may not lead to an upward shift in demand, so social welfare effects must be evaluated differently (Qaim et al. 2007).

Dawe et al. (2002) looked at the potential nutritional effects of Golden Rice by analyzing likely improvements in vitamin A intakes in the Philippines. This approach implicitly builds on a measure of program success that has been used for other micronutrient interventions, namely the achieved reduction in the number of people with micronutrient intakes below a defined threshold. However, since micronutrient intake is not an end in itself but only a means to ensure healthy body functions, it is more appropriate to go further and quantify health outcomes directly. Zimmermann & Qaim (2004) and Stein et al. (2006) suggested an alternative approach in their analyses of the potential health benefits of Golden Rice. They defined the benefit of the technology as the difference in health costs related to vitamin A deficiency with and without Golden Rice.

In their ex ante analysis, Stein et al. (2008) used representative household data from India to show that Golden Rice could reduce the health costs of vitamin A deficiency by up to 60%. They also calculated a high cost-effectiveness of Golden Rice, which compares favorably with other nutrition and health interventions, and a high social rate of return, which compares favorably with other agricultural R&D investments (Qaim et al. 2007). Anderson et al. (2005) used a macro CGE model to simulate the benefits of Golden Rice at the global level. Modeling consumer health effects among the poor as an increase in the productivity of unskilled laborers, they estimated worldwide welfare gains of over $15 billion per year, with most of the benefits accruing in Asia. In China, for instance, Golden Rice was projected to entail a 2% growth in national income (Anderson et al. 2005).

Significant economic and health benefits can also be expected for other biofortified crops, such as iron- and zinc-dense staple foods or crops containing higher amounts of essential amino acids (Qaim et al. 2007). The potentially high cost-effectiveness of biofortification in developing countries is due to the fact that the approach is self-targeting to the poor, with biofortified seeds spreading through existing formal and informal distribution channels. However, possible issues of consumer acceptance must be considered. Especially when no price premium is paid in the output market, suitable strategies to convince farmers to adopt such crops are needed. A combination of quality traits with interesting agronomic traits may be a practicable avenue.

6. CONSUMER ACCEPTANCE OF GM CROPS

In spite of the great potential of GM crops and the benefits that have already materialized, public attitudes toward the technology are often negative, and consumer acceptance remains an issue.[5] Consumer perceptions are often dominated by health, environmental,

[5]This is in contrast to pharmaceutical applications of GM technologies, which are widely accepted by the public.

social, and ethical concerns, which are not always based on the best information but which have emerged as important driving forces of biotechnology policies (Miller & Conko 2004, Paarlberg 2008). One reason for the partial acceptance may be that most GM crops now available involve agronomic traits with limited direct benefits to consumers. Consumer acceptance may increase when second-generation, quality-enhanced GM foods or crops with combined agronomic and quality traits are introduced.

Aspects of GM crop acceptance have been widely analyzed in the literature; most studies determine consumers' WTP for GM-free foods or the willingness to accept a discount for GM foods. These findings help us understand the values consumers attach to the GM attribute especially in the absence of observable market data. There are two approaches used for estimating WTP. The first approach involves choice modeling or contingent valuation surveys to obtain stated-preference data from consumers. Most of the available studies for GM crops build on this approach, both in developed (e.g., Lusk 2003, McCluskey et al. 2003, Moon & Balasubramanian 2004) and developing countries (e.g., Kimenju & De Groote 2008, Krishna & Qaim 2008a). The advantage of stated-preference surveys is that representative data can be obtained. The disadvantage, however, is the potential hypothetical bias, as consumers state their preferences without any direct financial implications. The second approach avoids this bias through experimental auctions, although samples are usually smaller and not representative of the total population. The experiments are often designed such that participants bid with real money or are presented with opportunities to exchange a given GM product for a corresponding GM-free product or vice versa. Such experimental auctions have been used for analyzing consumer acceptance in the United States and the EU (e.g., Huffman et al. 2003, Lusk et al. 2006).

Lusk et al. (2005) provide a meta analysis, regressing the WTP results from individual studies on a set of explanatory variables. Across all studies in the analysis, the weighted mean WTP for GM-free products is a premium of 23% more than that for GM products. However, remarkable differences arise. The WTP is significantly higher in Europe than in the United States, and it is significantly lower for processed than for fresh GM foods. Studies using experimental auctions result in a lower WTP for GM-free foods on average. Individual analyses also show a significant influence of consumer characteristics such as age, education, income, or gender, but the direction of the influence is not uniform.

A difference in WTP for GM and GM-free products indicates that many consumers do not consider these options as perfect substitutes. In that case, introducing GM technology would be associated with a negative externality, which would need to be accounted for in welfare economics studies (Giannakas & Fulton 2002, Lapan & Moschini 2004). However, past experience shows that both stated-preference and experimental data do not always correctly predict actual consumer behavior. Moreover, consumer responses are strongly dependent on the type of information available at a certain point (Huffman et al. 2003), so GM acceptance may potentially change rapidly. The public media play an important role. Especially in Europe, media reports about GM crops have been predominantly negative.

In general, available studies suggest that second-generation GM foods will be more acceptable to consumers than first-generation products (Lusk et al. 2005). This supports the hypothesis that GM acceptance levels will rise when quality-enhanced crops with more direct consumer benefits become available. There are also indications that consumers in developing countries have more positive attitudes toward GM food than their counterparts in developed countries (e.g., Kimenju & De Groote 2008, Krishna & Qaim 2008a).

One possible explanation is that they are generally poorer and sometimes food insecure; thus they may be more open to productivity-increasing technologies.

7. ECONOMICS OF GM CROP REGULATION

Because GM crops are associated with several potential market failures, the technology is heavily regulated. For instance, GM crops may be associated with environmental and health externalities, so biosafety and food safety regulations have been put in place. For consumers, the GM characteristic of food products is a credence attribute, indicating that labeling regulations can help to reduce transaction costs and problems of asymmetric information. The development of GM technologies leads to public goods that can easily be reproduced, so IPR protection is needed as an incentive for private sector R&D investments. However, because every regulation is associated with trade-offs, the optimal level should be determined on the basis of solid economics research (Just et al. 2006).

7.1. Biosafety and Food Safety

Governments have an important role in ensuring that novel foods are safe for human consumption and that novel agricultural inputs do not cause major negative impacts on the environment and long-term agricultural production possibilities. Most countries, with the notable exception of the United States, consider GM crops to be novel foods, regardless of the characteristics of their final product. Hence, new laws and institutions to regulate potential biosafety and food safety issues have been established, requiring that GM products be approved before they may be grown in, consumed in, or imported into a country (Herdt 2006). Because approval processes are not internationally harmonized, they have become a major barrier to the spread of GM crops and technologies around the world. For instance, the EU has not yet approved some of the GM maize technologies that are used in the United States and Argentina, which obstructs trade not only in technologies but also in commodity and food markets. In the EU, this is related to public-acceptance problems. In other parts of the world, however, the lack of GM crop approvals is often due to human and financial capital constraints. Smaller developing countries, in particular, have been unable to legislate and operate a biosafety regulatory system to date. This has shut them off from some of the international markets (Pray et al. 2006).

In countries where a biosafety system is in place, most of regulators' efforts are put into preventing the commercialization of products that may harm people or the environment (i.e., type I errors). Often, regulators are extremely cautious, requiring many regulatory trials over a long period of time. However, lengthy biosafety and food safety testing procedures come at a cost. Kalaitzandonakes et al. (2007) estimated the private compliance costs for regulatory approval of a new Bt or HT maize technology in one country at $6–15 million. Commercializing the same technology in other countries will entail additional costs. Beyond these direct regulatory costs, there are indirect costs in terms of foregone benefits (preventing the use of safe products is referred to as type II errors). Pray et al. (2005) estimated that a two-year delay in the approval of Bt cotton in India led to aggregated losses to farmers of more than $100 million.

Such high regulatory costs slow down overall innovation rates. They also impede the commercialization of GM technologies in minor crops and small countries, as markets in

Annu. Rev. Resour. Econ. 2009.1:665-694. Downloaded from arjournals.annualreviews.org
by Reprints Desk, Inc. on 12/15/09. For personal use only.

such situations are not large enough to justify the fixed-cost investments. Expensive regulations are also difficult to handle by small firms and public sector organizations, thereby contributing to the further concentration of the agricultural biotech industry. Were such lengthy and complex procedures necessary to regulate high-risk products, then the costs involved would be justified. But this does not seem to be the case. Because the use of genetic engineering does not entail unique risks, it is illogical to subject GM crops to a much higher degree of scrutiny than conventionally bred crops (Bradford et al. 2005). The regulatory complexity observed today appears to be the outcome of the politicized public debate and the lobbying success of antibiotech interest groups (Miller & Conko 2004).

Some reform of the GM regulatory framework will be necessary, and economists have an important role in this respect in terms of quantifying costs and benefits. Lichtenberg & Zilberman (1988) suggested a safety rule approach for more efficient pesticide legislation under uncertainty. The same approach could also be useful in the context of GM crops. It combines a probabilistic risk assessment model with a safety rule decision mechanisms that is equivalent to the use of significance levels for statistical decision making (Sexton et al. 2007). The safety rule approach can be employed for cost-benefit or risk-benefit analyses. Hence, transparent criteria and maximization techniques are used to bring science and objectivity to decision-making processes that are often influenced by political economy considerations and a precautionary approach.

7.2. Labeling and Coexistence

Several countries have introduced or considered introducing a food-labeling system. In general, mandatory or voluntary labeling is possible. Mandatory labeling is often used to warn consumers of specific health risks (e.g., cigarettes), whereas voluntary labeling is more common to differentiate products with desirable characteristics for marketing purposes (e.g., organic). Both systems can convey the same information to consumers. Given that only GM products that are considered to be safe are approved for market release, no warning of risks is required on labels. Therefore, the issue is mainly one of heterogeneous consumer preferences, which—from an economics perspective—would be best addressed through voluntary labeling of GM-free products (Golan et al. 2001). The EU, however, has established a mandatory system, which is more costly and can reinforce the notion that GM products are inherently unsafe. The motivation underlying the EU approach is that consumers have a right to know, which is different from the need to know approach in the context of risk communication. Moschini (2008) argued that the right to know approach is too open ended and potentially unbounded, because it can be invoked for virtually anything.

Labeling involves market segregation and a system of identity preservation, which can be quite costly. The cost is negatively correlated with the threshold levels allowed for the adventitious presence of GM material. Again, these thresholds are not related to risks but are a political decision; very low thresholds can lead to prohibitive segregation costs. Giannakas & Fulton (2002) and Lence & Hayes (2005) showed that labeling in general and segregation costs in particular can influence the welfare effects of GM crops significantly. Dissimilar approaches across countries can also lead to serious problems in international trade.

Labeling and segregation are also related to coexistence. The EU, in particular, has established rules to ensure the coexistence of GM crops with conventional and GM

farming, which involve a number of technical and legal specifications, from minimum distance requirements for cultivation to liability and insurance measures (Beckmann et al. 2006). The high degrees of complexity, uncertainty, and direct costs associated with these coexistence rules represent clear disincentives for EU farmers to adopt GM crops (Demont & Devos 2008, Breustedt et al. 2008).

7.3. Intellectual Property Rights and Public-Private Partnerships

In the United States and most other developed countries, living organisms and parts thereof have been patentable since the 1980s. This has spurred a tremendous amount of private sector biotechnology research. Nowadays, more than 75% of all patents in agricultural biotechnology are held by the private sector, mostly by a few large multinational corporations (Graff et al. 2003). Although strong patents and other forms of IPRs provide an incentive for private sector R&D, they are associated with higher prices and the usual static welfare losses in monopoly situations. As noted above, the degree of IPR protection in a country has an influence on GM crop adoption and benefit distribution. When GM seed prices are too high, resource-poor farmers face access problems (Qaim & de Janvry 2003). Therefore, the optimal level of IPR protection and enforcement is situation specific (Giannakas 2002).

The proliferation of IPRs on genes, processes, and technologies has led to access and freedom-to-operate problems within the biotechnology industry. Because the development of a single GM crop may require the use of dozens of patented intermediate technologies, licenses have to be negotiated with multiple parties, involving high transaction costs (Santaniello et al. 2000). In that sense, the freedom-to-operate problem may contribute to further industry concentration. Public sector research organizations, in particular, are at a disadvantage because they often have relatively little to offer in return for licenses from private companies. Even the largest public sector patent holders, such as the University of California and the United States Department of Agriculture, own less than 2% of total agricultural biotechnology patents versus the more than 10% owned by individual multinational companies such as Monsanto and DuPont (Graff et al. 2003).

However, public sector organizations combined hold 24% of the patents, and in some areas they could develop GM crops without relying on patents from the private sector. Graff & Zilberman (2001) suggested an IPR clearinghouse mechanism to reduce transaction costs for such public sector collaborations and joint ventures. A working example is the Public Intellectual Property Resource for Agriculture (PIPRA), bringing together intellectual property from more than 40 universities and public agencies and helping make their technologies available to innovators around the world (http://www.pipra.org).

Such public sector initiatives are important, as certain research and technology areas will not be addressed by private companies because of the limited size of the potential markets or other constraints. Examples include technologies designed especially for poor farmers and consumers in developing countries (Qaim et al. 2000, Lipton 2001). In such areas, more public research is needed. Moreover, more public-private partnerships should be sought to harness the comparative strengths of both sectors (Rausser et al. 2000, Byerlee & Fischer 2002). Usually, universities are better suited to carry out basic research, whereas private companies have advantages in more applied research and development

Annu. Rev. Resour. Econ. 2009.1:665-694. Downloaded from arjournals.annualreviews.org
by Reprints Desk, Inc. on 12/15/09. For personal use only.

(Rajagopal et al. 2009). There are numerous examples of public-private research cooperation in agricultural biotechnology, but none of these projects has yet led to a commercialized GM crop. Ex ante studies show that well-designed partnerships can be advantageous for all parties involved (Krishna & Qaim 2007, 2008b). Nonetheless, more research is needed to develop best practices for the transfer of technologies and know-how as well as the development and commercialization of GM crops.

8. CONCLUSION

GM crops have been used commercially for more than 10 years. To date, most of the GM crops employed have been HT and insect resistant. Available impact studies show that these crops are beneficial to farmers and consumers and produce large aggregate welfare gains. Moreover, GM crops bring about environmental and health benefits. GM crops may also be well suited for small-scale farmers, because such seed technologies are scale neutral. The empirical evidence shows that Bt crops in particular can have significant income-increasing and poverty-reducing effects. Farmers in developing countries sometimes benefit more than farmers in developed countries, which is partly a result of weaker IPR protection and, thus, lower seed prices. Yet, income distribution effects also depend on the wider institutional setting, including farmers' access to suitable seed varieties, credit, information, and other input and output markets. More public and institutional support will be needed to realize the benefits for the poor on a larger scale.

GM technologies currently in the research pipeline include crops that are tolerant to abiotic stresses and crops that contain higher amounts of nutrients than traditional crops. The benefits of such applications could be much greater than the ones already observed. Against the background of a dwindling natural resource base and growing demand for agricultural products, GM crops could contribute significantly to food security and sustainable development at the global level. New technologies are crucial for the necessary production increases.

In spite of these potentials, public opinion regarding GM crops remains divided, especially in Europe. Concerns about new risks and lobbying efforts of antibiotech groups have led to complex and costly biosafety, food safety, and labeling regulations, which slow down innovation rates and lead to a bias against small countries, minor crops, small firms, and public research organizations. Overregulation has become a real threat for the further development and use of GM crops. The costs of regulation in terms of foregone benefits may be large, especially for developing countries. This is not to say that zero regulation would be desirable, but the trade-offs associated with regulation should be considered. In the public arena, the risks of GM crops seem to be overrated, while the benefits are underrated.

Economics research has an important role to play in finding ways to maximize the net social benefits. More work is needed to quantify possible indirect effects of GM crops, including socioeconomic outcomes as well as environmental and health impacts. Furthermore, economists need to contribute to the design of efficient regulations and innovation systems in light of changing framework conditions. Although the gradual move from public to private crop improvement research is a positive sign of better-functioning markets, certain institutional factors seem to contribute to increasing industry concentration. This could lead to adverse outcomes in terms of technology development and access. Such issues need further analysis.

SUMMARY POINTS

1. GM crops have been used commercially for more than 10 years in developed and developing countries. So far, herbicide-tolerant and insect-resistant Bt crops have been the primary ones employed.
2. Impact studies show that these crops are beneficial to farmers and consumers and produce large aggregate welfare gains. In many cases, farmers in developing countries benefit more than farmers in developed countries.
3. Moreover, GM crops bring about environmental and health benefits. Bt crops in particular allow significant reductions in chemical pesticides.
4. Bt crops can also be suitable for small-scale farmers. Evidence from India and other developing countries shows that they contribute to higher household incomes and poverty reduction, when embedded in a conducive institutional environment.
5. Future GM crop applications, involving tolerance to abiotic stress and higher nutrient contents, may lead to much larger benefits.
6. Against the background of a dwindling natural resource base and growing demand for agricultural products, GM crops can contribute significantly to food security and sustainable development at the global level.
7. In spite of these potentials, public opinion still regards the use of GM crops as controversial. Concerns about new risks have led to complex and costly biosafety, food safety, and labeling regulations.

FUTURE ISSUES

1. Overregulation has become a real threat for the further development and use of GM crops. The costs in terms of foregone benefits may be large, especially for developing countries.
2. Economics research has an important role to play in finding ways to maximize the net social benefits. More work is needed to quantify possible indirect effects of GM crops, including socioeconomic outcomes as well as environmental and health impacts.
3. Furthermore, economists need to contribute to designing efficient regulatory mechanisms and innovation systems.
4. Although the gradual move from public to private crop-improvement research is a positive sign of better-functioning markets, certain institutional factors seem to contribute to increasing industry concentration.
5. Especially with a view to small-scale farmers, more public research and institutional support are needed to complement private sector efforts.

Following 15 yr of successful use, glyphosate failed to control a population of the widespread grass weed rigid ryegrass in Australia. This population proved to be resistant to glyphosate in pot dose-response experiments conducted outdoors, exhibiting 7- to 11-fold resistance when compared to a susceptible population. Some cross-resistance to diclofop-methyl (about 2.5-fold) was also observed. Similar levels of control of the resistant and susceptible populations were obtained following application of amitrole, chlorsulfuron, fluazifop-P-butyl, paraquat, sethoxydim, simazine, or tralkoxydim. The presence of glyphosate resistance in a major weed species indicates a need for changes in glyphosate use patterns.

Nomenclature Amitrole; chlorsulfuron; diclofop-methyl; fluazifop-P-butyl; glyphosate; paraquat; sethoxydim; simazine; tralkoxydim; rigid ryegrass, *Lolium rigidum* Gaud. LOLRI.

Keywords Herbicide resistance, glyphosate resistance, LOLRI.

Glyphosate is the world's most widely used herbicide, accounting for 11% of worldwide herbicide sales (Powles et al. 1997). It is a nonselective herbicide with no soil activity (Grossbard and Atkinson 1985). Therefore, it is an ideal herbicide for use preplant, in fallow fields, and for spot or directed use to control an extensive range of annual and perennial weeds. Glyphosate has been widely used for all of these purposes for more than 20 yr (Bradshaw et al. 1997). Recently, genetically-engineered glyphosate-tolerant crops, notably soybean [*Glycine max* (L.) Merr.] and cotton (*Gossypium hirsutum* L.), have been marketed in North America under the Roundup Ready® label (Padgette et al. 1996; Powles et al. 1997). This development will undoubtably increase glyphosate use.

The intensive use of herbicides in agriculture has led to the appearance of resistant weed populations (Holt et al. 1993; Powles and Holtum 1994). In a few agricultural areas, the development of widespread herbicide resistance in weeds has compromised the use of certain herbicide chemistries (Powles et al. 1997). In some cases, such as the acetolactate-inhibiting sulfonylurea herbicides, resistance has appeared remarkably rapidly (Gill 1995; Saari et al. 1994); however, for other herbicides, resistance has appeared sporadically or not at all. This is so for glyphosate, where, through more than two decades of use, no cases of herbicide resistance from field use have been reported (Bradshaw et al. 1997; Dyer 1994).

Rigid ryegrass is a widely established grass weed of crops in southern Australia that has displayed a propensity to evolve resistance to herbicides (Hall et al. 1994; Preston et al. 1996). Rigid ryegrass is present in large numbers over the 40 million ha that embrace the southern Australian winter cropping and pasture region, and currently, populations of this species display resistance to most of the major herbicide chemistries in use in Australia, except glyphosate (Hall et al. 1994; Powles et al. 1997; Preston et al. 1996). However, glyphosate is now widely used to control rigid ryegrass across this region, and the intense selection pressure thus applied to this particularly resistance-prone species makes glyphosate resistance a likely outcome. A preliminary report (Pratley et al. 1996) has suggested glyphosate resistance can evolve in rigid ryegrass.

Here, we document evolved resistance to glyphosate in a population of rigid ryegrass from an orchard in Australia following two to three annual applications of glyphosate for 15 yr.

Materials and Methods

The putative resistant biotype of rigid ryegrass was originally obtained from an orchard near Orange, New South Wales, Australia. Glyphosate at 720 to 1,440 g ae ha^{-1} had been used two or three times a year for 15 yr to control weeds within rows of trees. Seed from plants growing in the orchard was collected in December 1995. Seedlings from this seed were treated with glyphosate at 450 g ae ha^{-1} on two separate occasions during May 1996 at the three-leaf stage and the three-tiller stage. Survivors of this treatment were crossed among themselves as described by Tardif et al. (1996), and the resulting F_1 seed was used for all further

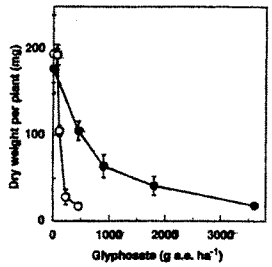

FIGURE 2. Dry weight of the known susceptible (○) and putative resistant (●) populations of rigid ryegrass 21 d after application (DAA) of varying rates of glyphosate isopropylamine. Data are from a single dose-response experiment with four replicates conducted on seedlings growing in pots. Points are mean dry weight per plant ± SE.

experiments. A known susceptible rigid ryegrass population was used as a control in all experiments.

Pot dose-response experiments were conducted outdoors during autumn and winter, the normal growing season for this species in southern Australia. Seed was germinated in a germination cabinet 12 h, 19 C, 30 μmol m^{-2} s^{-1} light period, 12 h, 19 C dark period for 6 d. Germinated seedlings were transplanted to 17-cm-diam pots containing potting soil with 12 seedlings per pot and were grown outdoors. Glyphosate was applied at a range of rates from 0 to 7,200 g ae ha^{-1} to plants at the two- to three-leaf stage of development. Four glyphosate dose-response experiments were conducted. Experiment 1 used glyphosate ammonium[1] applied on April 16, 1997; Experiment 2 used glyphosate ammonium applied on May 5, 1997; Experiment 3 used glyphosate ammonium applied on June 6, 1997; and Experiment 4 used glyphosate trimesium[2] applied on August 22, 1997. Other herbicides used—amitrole, chlorsulfuron, fluazifop-P-butyl, paraquat, sethoxydim, simazine, and tralkoxydim—were applied at the lowest normal use rate to control rigid ryegrass in Australia, except for diclofop-methyl, which was applied at rates ranging from 0 to 1,500 g ai ha^{-1}. These herbicides were applied to plants at the two- to three-leaf stage from May to August 1997. For each herbicide rate, four replicate pots were used. Herbicides were applied with a laboratory moving boom sprayer equipped with T-jet fan nozzles, at a speed of 1 m s^{-1}. Output from the sprayer was calibrated at 139 L ha^{-1} at a pressure of 250 kPa. All herbicides were applied as commercial formulations, with adjuvants as recommended by the herbicide manufacturers.

Plants were returned outdoors after treatment, and the response to herbicides was recorded after 21 d. Plants were recorded as alive if they had strongly tillered since application of the herbicide. Shoots were removed at soil level and dried at 60 C for 72 h to a constant weight. Mortality data were subject to probit analysis using the computer program POLOPC (1987) to determine LD_{50} values. Probit analysis gives equations of the following form:

$$Y = 5 + (a + b \log_e) \qquad [1]$$

where Y is the expected probit, a is the intercept and b the slope of the probit line, and $\log_e$ is the log of the dose rate (Finney 1971). The LD_{50} can be calculated from this equation by solving for a probit of 5.

Results and Discussion

The known susceptible population of rigid ryegrass was readily controlled by glyphosate, with very few survivors at rates of 450 g ae ha^{-1} or higher (Figure 1). In contrast, the putative resistant population was markedly less affected by glyphosate, requiring high rates for substantial mortality. Glyphosate at 450 g ae ha^{-1} dramatically reduced dry weight accumulation of the susceptible population and also clearly damaged the resistant plants (Figure 2); however, most of the latter plants survived. At this rate, dry weight accumulations of the susceptible and resistant populations were 9 and 59% of untreated controls, respectively.

This experiment was repeated three times with the isopropylamine salt formulation of glyphosate and once with the trimesium salt formulation of glyphosate, and in each case, the orchard population displayed resistance. The concentration of herbicide required to kill 50% (LD_{50}) of the susceptible population varied between 59 and 174 g ae ha^{-1}, depending on the season and type of formulation (Table 1). The LD_{50} for the resistant population varied between 600 and 1,800 g ae ha^{-1}. On all occasions, the resistant population proved to be between 7- and 11-fold resistant. Lower rates of glyphosate isopropylamine were required to control both populations in May and June during cooler weather, compared to April. The recommended rate of glyphosate trimesium for control of annual ryegrass is 33% higher than that for glyphosate isopropylamine. Therefore, it is not surprising that LD_{50}'s for glyphosate trimesium were higher than those obtained for glyphosate isopropylamine under similar environmental conditions.

There have been a number of previous reports of tolerance of populations of plant species to glyphosate. Plant breeders have deliberately selected lines of perennial ryegrass (*Lolium perenne* L.) (Johnston and Faulkner 1991), birdsfoot trefoil (*Lotus corniculatus* L.) (Boerboom et al. 1990, 1991), *Festuca longifolia* Thuill., and red fescue (*Festuca rubra* L.) (Johnston et al. 1989) to attain low level glyphosate toler-

TABLE 1. Amount of glyphosate required for 50% mortality of susceptible and resistant populations of rigid ryegrass in four separate experiments of the type shown in Figure 1. Values are LD_{50}, calculated by probit analysis of the full dose response. Values in parenthesis represent the 95% confidence intervals. R/S is the ratio of LD_{50} of the resistant population to that of the susceptible population.

Experiment	Herbicide formulation	Susceptible	Resistant	R/S
		LD_{50} (g ae ha^{-1})		
1	Glyphosate isopropylamine	174 (156, 200)	1,718 (1,463, 2,137)	10
2	Glyphosate isopropylamine	106 (95, 119)	746 (507, 998)	7
3	Glyphosate isopropylamine	59 (24, 82)	623 (471, 764)	11
4	Glyphosate trimesium	154 (135, 174)	1,258 (1,009, 1,525)	8

ance. Several naturally occurring lines of field bindweed (*Convolvulus arvensis* L.) displayed glyphosate tolerance without selection from glyphosate (DeGennaro and Weller 1984; Duncan and Weller 1987; Westwood and Weller 1997). In all of these cases, resistance appeared to be about two- to fivefold compared to normal lines of the same species. In none of the above cases had resistance appeared in weed species as the result of normal commercial use of glyphosate in the field. A preliminary report, based on a single dose-response experiment conducted under glasshouse conditions, suggests that evolved resistance may have occurred in another population of rigid ryegrass from northern Victoria (Pratley et al. 1996). Here, we have established (Figure 1; Table 1) that substantial resistance to glyphosate is present in a glyphosate-selected field population of rigid ryegrass.

Herbicide cross-resistance (resistance to dissimilar herbicides) is common in populations of rigid ryegrass (Hall et al. 1994; Preston et al. 1996). Cross-resistance poses a serious practical problem for weed control, as it can dramatically reduce the alternative herbicide options available. Therefore, the resistant population was examined for resistance to a range of other herbicides applied at the lowest recommended field rate to both resistant and susceptible populations. The resistant population proved to be as sensitive as the susceptible population to all of these herbicides except diclofop-methyl (Table 2). The possibility of resistance to diclofop-methyl was further examined by conducting a full dose-response experiment (Figure 3). This experiment established that a difference in response to diclofop-methyl was evident between the resistant and susceptible populations; however, the glyphosate-resistant population was only about 2.5-fold resistant to diclofop-methyl at the LD_{50}. This result is significant, as the ryegrass population had not previously been exposed to diclofop-methyl.

Considering the highly successful long-term use of glyphosate (Bradshaw et al. 1997), it is remarkable that more examples of resistant plants have not been identified. Several explanations have been put forward to explain this observation, including the inability to generate functional target-site mutations within enolpyruvylshikimate-3-phosphate (EPSP) synthase in plants (Padgette et al. 1991), and the low rates of metabolism of glyphosate in plants (Komoba et al. 1992). This has led some authors to predict that evolved glyphosate resistance in weeds is unlikely (Bradshaw et al. 1997). The present study has demonstrated that evolved resistance to glyphosate has now appeared in rigid ryegrass.

Worldwide, rigid ryegrass is by far the most resistance-prone weed species, with extensive resistance to numerous herbicides (Hall et al. 1994; Powles et al. 1997; Preston et al. 1996). That resistance has now occurred in a glyphosate-selected field population of rigid ryegrass (Figure 1; Table 1) demonstrates that glyphosate resistance can occur following persistent use. Given the importance of glyphosate in world agriculture, its current high use, and impending increased usage with transgenic crops, the evolution of glyphosate resistance is a significant development in world agriculture. It would be prudent to accept that resistance can occur to this highly valuable herbicide and to encourage glyphosate use patterns within integrated strategies that do not impose a strong selection pressure for resistance.

TABLE 2. Response of susceptible and resistant populations of rigid ryegrass to alternative herbicides applied at the lowest recommended rate. Herbicides were applied to seedlings growing in pots at the two- to three-leaf stage. Values are percent survival ±SE of four replicates.

Herbicide and rate (g active ingredient ha^{-1})	Susceptible	Resistant
	Survival (%)	
Amitrole (700)	40 ± 5	45 ± 5
Chlorsulfuron (15)	3 ± 3	0
Diclofop-methyl (375)	27 ± 6	79 ± 1
Fluazifop-P-butyl (53)	0	0
Paraquat (200)	0	0
Sethoxydim (186.8)	0	0
Simazine (1620)	5 ± 3	2 ± 2
Tralkoxydim (200)	0	0

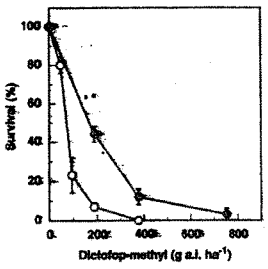

FIGURE 3. Response of the known susceptible (○) and glyphosate resistant (●) populations of rigid ryegrass to varying dose rates of diclofop-methyl. Data are from a single dose response experiment with four replicates conducted on seedlings growing in pots. Points are mean survival ± SE.

Experiments were conducted to determine potential mechanisms of glyphosate resistance in *Lolium rigidum* from Australia. ^{14}C-Glyphosate uptake, translocation, and metabolism were compared between resistant (R) and sensitive (S) biotypes. The R seed (48118a) represented the F_1 progenies of plants having survived a 1.73-kg ae ha^{-1} (4.8 L ha^{-1}) application of a Roundup® formulation. The S seed was a sensitive biotype of *L. rigidum* from Australia. Plants (one to four tillers, 2 to 4 wk old) were presprayed with a high (1.26 kg ae ha^{-1}) or a low (0.28 kg ae ha^{-1}) dose of formulated glyphosate. The first leaf of the first tiller, which was shielded from the spray, was immediately treated with a ^{14}C-glyphosate solution via manual application to the adaxial surface. Harvest was made 6 days after treatment (DAT), and glyphosate residues in the leaf wash, treated leaf, roots, and shoots were quantified based on radioactivity as percentage of applied dose. The overall radioactivity recoveries were very good (90.2 to 97.3% of applied dose). R and S plants showed comparable uptake at the high (79.2 vs. 78.0%) or the low (64.0 vs. 64.7%) doses of glyphosate. About one-half of the absorbed glyphosate in both R and S (32.9 to 38.3% appl.) was translocated into the plant and distributed almost equally into roots (13.6 to 16.0% appl.) and shoots (18.1 to 22.6% appl.). Autoradiography studies demonstrated no difference in tissue localization of glyphosate between the R and S plants. For metabolism studies, tissues from individual plants were homogenized in water, and extracts were analyzed by anion exchange high-pressure liquid chromatography (HPLC) with radioactivity detection. There was little to no metabolism of glyphosate in extracts from various tissues of either R or S plants. Based on these results, we conclude that neither uptake, translocation, nor metabolism play a major role in glyphosate resistance in *L. rigidum*.

Nomenclature: Glyphosate; *Lolium rigidum*, LOLRI, rigid ryegrass.

Key words: Herbicide resistance, glyphosate resistance, LOLRI.

Herbicide resistance is a frequent topic of review in the literature stemming from an increasing number of cases worldwide (Heap 1997; Holt et al. 1993; Moss and Rubin 1993). An international survey documented over 216 weed species that have evolved resistance to herbicides (Heap 1997). About one-third of these cases involve triazine resistance. Resistance to acetolactate synthase (ALS) inhibitors shows the fastest increase.

Among herbicide-resistant weeds, *Lolium rigidum* is perhaps the most infamous. *Lolium rigidum* is the first example of a weed that demonstrated cross-resistance to multiple herbicide chemistries including aryloxyphenoxyproprionates, cyclohexanediones, sulfonylureas, and dinitroanilines (Powles et al. 1990). Studies have shown that the mechanism of *L. rigidum* resistance is not due to any barrier to herbicide uptake or translocation but to induction of several herbicide degradation enzymes (Preston et al. 1996). Several factors have been attributed to the development of herbicide resistance in *L. rigidum* in Australia, including wide distribution; diverse genetic background; a requirement for cross-pollination facilitating outcrossing; and high selection pressure from repeated use of the same herbicides (Tardif et al. 1997).

Evolvement of weed resistance to glyphosate in the environment has been perceived to be a highly unlikely event (Bradshaw et al. 1997). However, *L. rigidum* resistance to glyphosate has been detected in Australia. The first case of resistance was observed in a field in Echuca, Australia, where glyphosate had been applied repeatedly for presowing control of weeds (Pratley et al. 1996). The second case was reported recently in an orchard in Australia following multiple annual applications of glyphosate for 15 yr (Powles et al. 1998). Pratley et al. (1999) describe bioevaluation of glyphosate resistance in *L. rigidum* from the Echuca site. The present manuscript examines the uptake, translocation, and metabolism of ^{14}C-glyphosate in the resistant *L. rigidum*.

Materials and Methods

R and S seed of *L. rigidum*[1] was provided by Charles Sturt University, Wagga Wagga, Australia. The R seed represented the F1 progenies of plants having survived a 4.8-L ha^{-1} (1.73 kg ae ha^{-1}) application of Roundup (360 g L^{-1}). The S seed was a sensitive biotype of *L. rigidum* from Australia.

Glyphosate, ^{14}C-labeled at the phosphonomethylene (C-3) site,[2] was obtained from New England Nuclear. The specific activity of ^{14}C-glyphosate was 1,457 MBq mmol^{-1} (517,000 dpm μg^{-1}), and it was determined to be 99.5% pure by HPLC analysis. ^{14}C-Glyphosate was neutralized with NaOH, diluted with water to a concentration of 0.50 μg μl^{-1}, and stored at −20 C. MON 0818[3] (an ethoxylated tallowamine surfactant used in Roundup), glyphosate-isopropylamine salt[4] (MON 0139), and Roundup Original[5] were provided by Monsanto.

Uptake and Translocation Studies

Seed was germinated in soil (50/50 Metromix blend with fertilizer) in 10- by 10-cm pots in the greenhouse (32 C day and 25 C night with supplemental lighting). The average germination for seed was only about 30%. The labeled use rate of glyphosate for the control of *L. rigidum* in Australia is 0.2 to 0.4 kg ha^{-1} (Pratley et al. 1999). R and S *L. rigidum* (two to six leaves, 2 to 4 wk old) was presprayed with a high (1.26 kg ha^{-1}) or a low (0.28 kg ha^{-1}) dose of Roundup Original (187.1 L ha^{-1} spray volume). Just prior to spraying, the first leaf of the first tiller was covered with a wax paper sleeve to prevent interception of the spray solution. Immediately after the spray, the sleeve was removed, and a ^{14}C-glyphosate dosing solution was applied. The ^{14}C-glyphosate dosing solutions were prepared to match the volume, the surfactant concentration, and the glyphosate concentration of the spray solutions. A representative *L. rigidum* leaf blade was sprayed initially with water; the average volume of spray interception was 6 µl. Calculations showed that for the 0.28-kg ha^{-1} dose, the spray solution contained 0.03% MON 0818 and 1.5 µg ae $µl^{-1}$ glyphosate; the corresponding 1.26-kg ha^{-1} spray solution contained 0.14% MON 0818 and 6.8 µg ae $µl^{-1}$ glyphosate. ^{14}C-Glyphosate (782,000 dpm or 1.51 µg) was mixed with MON 0818 and MON 0139 so that in 6-µl volume, it contained the same surfactant and glyphosate concentrations as the spray solutions. The dose was applied as 6- by 1-µl drops to the adaxial leaf surface.

Following application of ^{14}C-glyphosate, plants were transferred to a growth chamber (12-h day/night, 29 C day, 25 C night, 60% humidity, 450 µE m^{-2} s^{-1} light). At harvest (6 DAT), the ^{14}C-treated leaf was excised at the base and spray washed with water then methanol (~10 ml each). The washes were pooled and analyzed for radioactivity. The treated leaf was then placed in a combustion cone. The rest of the plant was washed to remove soil from the roots. The plant was then separated into roots and shoots, and these tissues were placed in individual combustion cones that were dried overnight at 70 C.

Quantitation of Radioactivity

Analysis of tissue radioactivity was accomplished using a Packard 387 sample oxidizer with Oximate 80 robotics.[6] The oxidizer, which was routinely tested by combustion of standard samples, recovered > 98% of radioactivity with no carryover to successive samples. ^{14}C-Glyphosate in tissue was completely oxidized to $^{14}CO_2$, which was trapped in a liquid scintillation cocktail and quantitated by Tracor Analytic counters.[7] Based on initial applied radioactivity per plant, percentages were calculated for residues localized in the treated leaf. Total translocation of glyphosate into the plant was calculated by addition of radioactivity from the shoot and root sections. The sum of the localized, translocated, and leaf wash provided total radioactivity recovery.

We had planned to use 10 plants per treatment that were carefully matched in size and growth stage. But because of low and unpredictable germination, the actual number of replicates per treatment ranged from 5 to 20 plants. Because each plant was dosed and processed individually, uptake and translocation of glyphosate were calculated for each replicate plant. Average and standard errors were calculated from the replicates within a treatment.

Metabolism Studies

Plants (R and S) employed for these studies were treated the same as those in the uptake and translocation studies. Metabolism of glyphosate was examined in tissue extracts from the treated leaf, shoots, and roots of each plant. Tissues were initially minced into small pieces using scissors and homogenized using a Polytron tissue miser[8] in water (~0.75 ml). Homogenates were centrifuged (14,000 × *g* at 4 C for 25 min), and aliquots of supernatants were analyzed for radioactivity. Approximately 200- to 500-µl volumes of tissue extracts containing 30,000 to 200,000 dpm were analyzed by HPLC. Metabolites (glyphosate and aminomethyl phosphonic acid, AMPA) were identified based on retention times, and percentage distribution was quantified based on radioactivity.

HPLC Analysis

The HPLC system was assembled using components from Waters Associates[9] with a flow-through radioactivity detector from Radiomatics.[10] An Alltech strong anion exchange (SAX) column[11] (5 µm, 10 by 250 mm) was employed at a flow rate of 3 ml min^{-1}. The solvent gradient employed two buffers, 5 and 100 mM KH_2PO_4, pH 2.0 with 4% methanol. The gradient was programmed as follows: 5 mM (100%) for 2 min, 5 to 100 mM (100%) linearly in 3 min, and 100 mM for 10 min. The radioactivity detector (RAD) employed a scintillant[12] at a flow rate of 9 ml min^{-1}. Mixtures of ^{14}C-standards were routinely analyzed prior to sample analyses. The following retention times were typically obtained: AMPA, 5.5 min; glyphosate, 11.5 min; and N-acetyl AMPA, 14.4 min.

Autoradiography Studies

Plants used for these studies were treated the same as those in uptake and translocation studies. R and S plants (four each) were presprayed with glyphosate at 0.28 kg ae ha^{-1}, and the shielded leaf was treated with a ^{14}C-glyphosate solution. Plants were maintained in the growth chamber and harvested 2 and 5 DAT. Plants were washed, pressed, dried, and exposed to x-ray film[13] at −80 C for 4 d.

Results and Discussion

Significant resistance to glyphosate was demonstrated in R plants during spray titration studies (Pratley et al. 1996, 1999). While S plants were completely killed at < 0.22 kg ae ha^{-1} of glyphosate, the R plants had 93% survival. Furthermore, 30% of R plants were unaffected by a treatment of 0.43 kg ae ha^{-1} glyphosate.

Uptake and Translocation Studies

Both R and S plants were presprayed with a high or low rate of formulated glyphosate followed by manual application of ^{14}C-glyphosate to the first leaf of the first tiller, which was shielded from the spray. Even though the glyphosate dose varied, all plants received the same amount of radioactivity.

TABLE 1. Total recovery and uptake of ^{14}C-glyphosate in R and S rigid ryegrass (*L. rigidum*) 6 DAT.

Biotype (*n* reps)	Rate (kg ae ha^{-1})	Fractions	^{14}C-Glyphosate as % appl dose (average ± SE)
R (20)	1.26	Total recovery	97.3 ± 1.5
		Uptake	79.2 ± 4.0
		Leaf wash	18.1 ± 4.4
S (5)		Total recovery	96.1 ± 5.3
		Uptake	78.0 ± 4.2
		Leaf wash	18.1 ± 3.4
R (7)	0.28	Total recovery	92.1 ± 5.5
		Uptake	64.7 ± 6.2
		Leaf wash	27.4 ± 6.4
S (10)		Total recovery	90.2 ± 3.9
		Uptake	64.0 ± 6.0
		Leaf wash	26.2 ± 7.0

Total recoveries of applied radioactivity 6 DAT were calculated for the replicates within each treatment and averaged from 90.2 ± 3.9 to 97.3 ± 1.5% (Table 1). Based on the excellent radioactivity recovery, all calculations are reported as percentages of applied dose. Total plant uptake was nearly identical for R and S plants within the same treatment dose. At the high dose (1.26 kg ae ha^{-1}), uptake in R and S plants was 79.2 ± 4.0 and 78.0 ± 4.2%, respectively. At the low dose (0.28 kg ae ha^{-1}), uptake in R and S was 64.7 ± 6.2 and 64.0 ± 6.0%, respectively. The high dose demonstrated slightly higher uptake, presumably due to the higher surfactant and glyphosate concentration in the dosing solution. Glyphosate not recovered from plants was recovered in the treated leaf wash. Recovery ranged from 18.1 ± 4.4 to 27.4 ± 6.4% of the applied dose.

Table 2 shows the distribution of radioactivity into plant tissues, which included the treated leaf, roots, and shoots. Radioactivity in the treated leaf represented glyphosate that was loaded into the leaf (and hence, not removed by the wash) but not translocated in the plant. Once again, little to no difference was detected between the R and S plants in radioactivity localized in the treated leaf. For both R and S, the high dose localized more radioactivity (45.1 ± 4.4 and 45.1 ± 6.2%, respectively) than the low dose (26.4 ± 6.1 and 28.8 ± 7.0%, respectively). Total translocation of glyphosate was similar in R and S plants and ranged from 18.1 ± 2.2 to 22.6 ± 2.2% in shoots and from 13.6 ± 2.0 to 15.8 ± 2.6% in roots. In contrast to uptake, similar translocation was observed at both high and low doses of glyphosate. These results indicate that although uptake was higher at the high dose, increased localization of glyphosate in the treated leaf resulted in comparable translocation as the low dose. The high dose not only contained more glyphosate but also more surfactant. We speculate that the high surfactant concentration caused greater tissue injury in the treated leaf, thus negatively affecting translocation (Feng et al. 1998). The conclusion is that there is little to no difference in glyphosate uptake and translocation between R and S plants.

Autoradiography Studies

The translocation results provided a quantitative but gross distribution of glyphosate in shoots and roots. Autoradiography studies were conducted to provide a more detailed, albeit qualitative analysis of tissue distribution. R and S plants, as in the above studies, were presprayed with 0.28 kg ha^{-1} glyphosate followed by treatment with ^{14}C-glyphosate dosing solution. R and S plants visualized 2 and 5 DAT demonstrated little difference in tissue distribution. In general, the highest concentration of glyphosate was observed in the treated leaf, followed by other leaves of the same tiller, and then leaves of other tillers. Roots proximate to the treated leaf received more glyphosate. Young shoots and the crown showed more glyphosate than the older tillers and leaves. Translocation of glyphosate in both R and S *L. rigidum* appeared similar to other plants (Klevorn and Wyse 1984; Wallace and Bellinder 1995) and proceeded from source to sink tissues (Franz et al. 1997).

TABLE 2. Translocation of ^{14}C-glyphosate to shoots and roots of R and S rigid ryegrass (*L. rigidum*) 6 DAT.

Biotype (*n* reps)	Rate (kg ae ha^{-1})	Tissue fractions	^{14}C-Glyphosate as % appl dose (average ± SE)
R (20)	1.26	Shoot	18.1 ± 2.2
		Root	16.0 ± 1.6
		Total translocation	34.2 ± 3.4
		Treated leaf	45.1 ± 4.4
S (5)		Shoot	19.3 ± 2.4
		Root	13.6 ± 2.0
		Total translocation	32.9 ± 3.9
		Treated leaf	45.1 ± 6.2
R (7)	0.28	Shoot	22.6 ± 2.2
		Root	15.7 ± 4.6
		Total translocation	38.3 ± 5.7
		Treated leaf	26.4 ± 6.1
S (10)		Shoot	19.3 ± 3.3
		Root	15.8 ± 2.6
		Total translocation	35.2 ± 5.6
		Treated leaf	28.8 ± 7.0

Metabolism Studies

These studies employed plants that were treated the same as those in the uptake and translocation studies. Instead of combustion, the tissues were homogenized and extracts analyzed by SAX-HPLC/RAD. Tissues (roots, shoots, and the treated leaf) from individual R and S plants were harvested 6 DAT and analyzed.

HPLC was calibrated with a mixture of ^{14}C standards including glyphosate and AMPA. Analysis of the dosing solution showed two peaks identified based on retention time as glyphosate (83.6%) and AMPA (12.7%) (Table 3). Al-

TABLE 3. Distribution of radioactivity as glyphosate or AMPA in tissue extracts of R and S rigid ryegrass (*L. rigidum*) as determined by SAX-HPLC 6 DAT.

Biotype (*n* reps)	Rate (kg ae ha^{-1})	Fractions	^{14}C-Glyphosate as % distribution (average ± SE)
Dosing solution	None	Glyphosate	83.6
		AMPA	12.7
R (9)	1.26	Glyphosate	78.4 ± 2.4
		AMPA	16.6 ± 2.0
S (6)	0.28	Glyphosate	86.5 ± 1.8
		AMPA	12.2 ± 1.8

though the purity of the original ^{14}C-glyphosate was very high (99.5%), storage of glyphosate as a dilute water solution at −20 C must have caused some degradation to AMPA over time. Analysis of tissue extracts (treated leaf, roots, and shoots) from R and S plants consistently displayed two major peaks identified as glyphosate and AMPA. Because no difference in distribution was detected among various tissues of plants, we averaged all the results within R and S biotypes (Table 3). The distribution of radioactivity between glyphosate and AMPA in R plants was 78.4 ± 2.4 and 16.6 ± 2.0%, respectively. In comparison, the distribution in S plants was 86.5 ± 1.8 and 12.2 ± 1.8% for glyphosate and AMPA, respectively. Although R plants showed slightly lower glyphosate and higher AMPA than S plants, this minor difference in composition is believed to be insufficient to account for the level of resistance observed in whole plants. Previous work using Roundup Ready *Glycine max* (L.) Merr. (soybean) and *Brassica napus* L. (canola) seedlings containing the glyphosate degradation gene (Barry et al. 1992) showed almost complete conversion of glyphosate to AMPA within a few days after treatment (unpublished data).

The results of these studies demonstrated similar patterns of glyphosate uptake, translocation, and metabolism in R and S biotypes. *Lolium rigidum* plants displayed extensive uptake of glyphosate (~70% of the applied dose). About one-half of the absorbed dose was exported from the treated leaf into the plant, with nearly equal distribution between shoots and roots. Our results suggest that neither uptake, translocation, nor metabolism play a major role in glyphosate resistance in *L. rigidum*.

Powles et al. (1998) recently reported evolved resistance to glyphosate in *L. rigidum* in an orchard in Australia; the mechanism of resistance is currently under investigation. Through recurrent selection, glyphosate resistance has also been demonstrated in *Lolium perenne* L. (perennial ryegrass), although the mechanism remains unknown (Johnston and Faulkner 1991). The mechanism of glyphosate resistance has also been examined in sensitive and resistant *Convolvulus arvensis* L. (field bindweed). Neither absorption nor translocation could account for differential sensitivity of R and S biotypes to glyphosate (Westwood et al. 1997). Further studies demonstrated increased shikimate pathway activity and higher concentration of phenolics in R than in S plants (Westwood and Weller 1997). The authors concluded that multiple mechanisms at cellular and metabolic levels accounted for glyphosate resistance in *C. arvensis*. Our own investigations in *L. rigidum* are also progressing toward cellular or biochemical mechanisms of resistance. Studies are underway to determine the sensitivity of EPSPS (5-enolpyruvyl-shikimate-3-phosphate synthase) to glyphosate and the overexpression of EPSPS as potential mechanisms of resistance in *L. rigidum*.

Adoption of Best Management Practices to Control Weed Resistance by Corn, Cotton, and Soybean Growers

George B. Frisvold
University of Arizona

Terrance M. Hurley
University of Minnesota

Paul D. Mitchell
University of Wisconsin

This study examined adoption of 10 best management practices (BMPs) to control weed resistance to herbicides using data from a survey of more than 1,000 US corn, cotton, and soybean growers. Count-data models were estimated to explain the total number of BMPs frequently practiced. Ordered-probit regressions were used to explain the frequency of individual BMP adoption. Growers practicing a greater number of BMPs frequently had more education, but less farming experience; grew cotton; expected higher yields relative to the county average; and farmed in counties with a lower coefficient of variation (CV) for yield of their primary crop. Yield expectations and variability were significant predictors of adoption of individual BMPs. Most growers frequently adopted the same seven BMPs. Extension efforts may be more effective if they targeted the three practices with low adoption rates. Counties with a high-yield CV would be areas to look for low BMP adoption.

Key words: weed, herbicide, resistance management, corn, cotton, soybeans, adoption.

Introduction

In 2008, agricultural producers planted more than 80% of US cotton and corn acreage and more than 90% of soybean acreage to transgenic glyphosate-tolerant, Roundup Ready® (RR) seed varieties (US Department of Agriculture Agricultural Marketing Service [USDA AMS], 2008; USDA National Agricultural Statistics Service [NASS], 2008). Many studies report significant pecuniary and non-pecuniary benefits to growers from using glyphosate-resistant varieties (Gianessi, 2008; Marra, Pardey, & Alston, 2002; Marra & Piggott, 2006; Mensah, 2007; Piggott & Marra, 2008).

The evolution of glyphosate-resistant weeds threatens the sustainability of these benefits, however. The number and range of glyphosate-resistant weeds has been increasing in the United States since commercialization of RR crops (Heap, 2009). The evolution of weed resistance to herbicides also poses problems for other herbicide-resistant crops, such as LibertyLink® or Clearfield® crops. The potential for pests or weeds to develop resistance in response to frequent applications of a narrow set of chemicals with the same mode of action is well established in the literature (Carlson & Wetzstein, 1993; Holt & Lebaron, 1990; Powles & Shaner, 2001; Shaner, 1995). Beckie (2006, pp. 793) identifies, "recurrent application of highly efficacious herbicides with the same site of action" and "annual weed species that occur in high population densities" as key risk factors for the evolution of herbicide resistance in weeds.

However, strategies for reducing the risk of pest resistance are also well-documented (Burgos et al., 2006; Culpepper, York, & Kichler, 2008; Gressel & Segel, 1990; Monsanto, 2009a, 2009b; Mueller, Mitchell, Young, & Culpepper, 2005; Nalewaja, 1999; Prather, DiTomaso, & Holt, 2000; Steckel, Hayes, & Rhodes, 2004; Stewart, 2008). Commodity groups, extension specialists, and Monsanto have recommended that growers adopt various best management practices (BMPs) to prevent or delay the spread of glyphosate-resistant weeds (Burgos et al., 2006; Culpepper et al., 2008; Monsanto, 2009a, 2009b; Steckel et al., 2004; Stewart, 2008). These strategies fall under the more general rubric of integrated weed management (IWM), components of which include weed scouting; avoidance on over-reliance on a compound or compounds with a single mode of action against weeds; preventing herbicide-resistant gene spread, non-chemical control such as tillage, and crop rotations. A key element of this strategy is diversifying herbicides used, relying on multiple compounds with different modes of action.

This study examines the frequency of grower adoption of 10 different BMPs to prevent or delay weed resistance. Primary survey data on more than a thousand US corn, cotton, and soybean growers was used to characterize the nature of BMP adoption. Count-data models were estimated to explain the total number of BMPs frequently practiced. Ordered-probit regressions were used to explain the frequency of individual BMP adoption.

Previous Studies

There are four strands of literature pertinent to the understanding of grower adoption of BMPs. First, weed science studies describe how weed resistance to herbicides evolves, the approaches to prevent and respond to resistance, and the roles of different BMPs in prevention and response (e.g., Beckie, 2006; Green, 2007). These are not economic studies *per se*, but do consider economic incentives and trade-offs. Second are normative, economic modeling approaches (e.g., Gorddard, Pannell, & Hertzler, 1995; Llewellyn, Lindner, Pannell, & Powles, 2001; Pannell & Zilberman, 2001; Weersink, Llewellyn, & Pannell, 2005). Here, the susceptibility of weeds to herbicides is examined as an exhaustible resource. Growers face an intemporal trade-off between weed-management practices that maximize short-run returns versus practices that delay resistance. Delaying resistance may be less profitable in the short-run, but more profitable in the long run. Third, positive, empirical analyses collect and analyze data on grower perceptions and behavior regarding weed resistance (e.g., Hammond, Luschei, Boerboom, & Nowak, 2006; Johnson & Gibson, 2006; Wilson, Tucker, Hooker, LeJeune, & Doohan, 2008). While the economic models highlight how growers *should* manage resistance, these empirical studies examine what steps growers *actually take* to manage it. These studies also shed light on grower rationales for their behavior. Fourth, there is the econometric approach (Llewellyn et al., 2007). The first step in this approach is to develop a dynamic economic model of weed management, including resistance management. Results from the theoretical model guide variable selection and statistical specification for multivariate regression analysis. Finally, the multivariate regression analysis tests hypotheses generated from the theoretical model. Thus, the prescriptive, theoretical model informs specification of the descriptive, statistical model. In turn, statistical model results test the validity of and hypotheses generated by the theoretical model.

Conceptual Framework

Following Llewellyn et al. (2001, 2007), we treat the adoption of weed resistance BMPs as a dynamic optimization problem. A grower chooses application rates of a preferred herbicide, H_t, and adoption of different BMPs, $\boldsymbol{M}_t$, to maximize the net present value (NPV) of returns.

$$\text{Max } NPV = \sum_{t=0\ldots n} \{P_t Y_t[1 - \delta_t(N_t, R_t, H_t, \boldsymbol{M}_t)] - C_H H_t - C_M(M_t) - V_t\}\,\beta \quad (1)$$

with respect to H_t, $\boldsymbol{M}_t$, subject to

$$R_t - R_{t-1} = f(N_t, R_t, H_t, \boldsymbol{M}_t, X_t);\ \partial f/\partial H_t > 0;\ \partial f/\boldsymbol{M}_t < 0;\ \partial f/X_t > 0, \quad (2)$$

where

P_t = crop price
Y_t = crop yield
δ_t = percent yield loss from weed damage
N_t = pre-treatment weed population
R_t = weed resistance to the herbicide
H_t = level of herbicide use
$\boldsymbol{M}_t$ = vector of resistance management practices
X_t = behavior of neighbors or external factors that increase resistance
C_H = cost of herbicide treatment
C_M = cost of resistance management
V_t = other variable costs
β = discount factor

Equation 2 characterizes the evolution of resistance. Initially, use of the herbicide reduces damage ($\partial\delta_0/\partial H_t < 0$), but also increases resistance ($\partial f/\partial H_t > 0$). Evolution of resistance renders the herbicide less effective ($\partial^2\delta_0/\partial H_t\,\partial R_t > 0$). Resistance-management BMPs, $\boldsymbol{M}_t$, slow the evolution of resistance ($\partial f/\boldsymbol{M}_t < 0$), but entail additional costs, $C_M(\boldsymbol{M}_t)$. BMPs may reduce damage in the current period ($\partial\delta_t/\partial\boldsymbol{M}_t < 0$). However, these alternatives may be less effective or more expensive than frequent applications of the preferred herbicide. For example, repeated applications of glyphosate may be more profitable (at least in the short-run) than applying tank mixes or additional residual herbicides.[1] Many growers manage herbicide-resistant crops in combination with no-till practices. While supplemental tillage offers the option of non-chemical control, it would require growers to forego some benefits of no-till systems (such as reduced fuel costs or soil erosion).

This stylized model captures key features of weed BMP adoption. First, BMPs are costly to adopt. Yet they

1. *The model presented here treats use of multiple herbicides with different modes of action as part of the set of BMPs in $\boldsymbol{M}_t$. A more complete, but more complicated, model could consider resistance evolution of different classes of herbicides, not just the preferred herbicide. This would involve multiple equations such as f(), but could allow for examination of the "optimal rotation" of herbicides.*

slow resistance and can, in some cases, substitute for herbicide applications in reducing current damage. Thus, some BMPs may be profitable to adopt apart from their contribution to resistance management. If BMPs reduce current profitability, however, growers will not adopt them unless (a) they effectively slow resistance, (b) their contribution to future profitability counteracts their short-run costs, and (c) growers recognize the BMPs' contribution to future profitability.

Even if the damage function $\delta()$ and resistance-evolution equation $f()$ are such that adoption of BMPs increases the NPV of long-run profits, growers may still not adopt them. Growers must have sufficient information about $\delta()$ and $f()$ to expect that their own adoption of BMPs is profitable in the long run. A potential role of extension is to increase knowledge about $\delta()$ and $f()$. There is more scope for individual growers learning about the effect of practices on current weed damage, $\delta()$, than on the evolution of resistance, $f()$. High variability in production outcomes, however, may make such learning more difficult.

Another factor affecting grower adoption is whether growers perceive weed resistance to be subject to their own control. Pannell and Zilberman (2001) have argued that resistance management is subject to greater individual control than insect pest management, indicating that common pool externalities discouraging resistance management should be less of a problem. If, however, growers perceive that resistance depends on external factors rather than their own actions (i.e., the effect of $\partial f / X_t$ dominates the effect of $\partial f / M_t$), this will discourage BMP adoption. In a study of Ohio farmer perceptions of weed management, Wilson et al. (2008) found growers attributed weed introduction and spread to external natural factors and neighbor behavior. At the same time, they placed less emphasis on the importance of their own actions.

The evolution of resistance may also spur adoption of BMPs. As resistance to an herbicide develops, relying solely on that herbicide becomes less effective at managing weeds. In effect, as $\partial \delta_t / \partial H_t$ approaches zero, growers may be forced to shift to other weed-control methods. Various studies suggest that development of herbicide-resistant weeds in Australia and Canada has spurred greater adoption of BMPs (Llewellyn et al., 2004; Powles, Preston, Jutsum, & Bryan, 1997; Wilson et al., 2008). Thus, one may see use of BMPs not to prevent resistance but as a means of mitigating it.

This simple model suggests testable hypotheses. First, growers will be more likely to adopt BMPs that have immediate benefits in terms of controlling current weed populations. Second, this effect will be stronger for growers with higher potential yields because percent reductions in damage have a higher payoff. In contrast, growers will be less likely to adopt practices that do not provide obvious, short-run benefits. Third, growers experiencing resistance problems may increase BMPs as their traditional means of control becomes less effective. Fourth, implementing complex, interrelated BMPs may require more human capital. So, one may expect more use of BMPs among growers with more education. Greater education helps lower costs of implementing BMPs (C_H). Fifth, greater variability in agronomic and economic outcomes may discourage BMP adoption. Pannell and Zilberman (2001) note the importance of observability and trialability in encouraging adoption of new technologies. In areas with highly variable production outcomes, growers may have more difficulty assessing the effects of and returns to BMP adoption.

Data

Data were collected via a telephone survey conducted by Marketing Horizons for Monsanto in November/December of 2007. The survey was designed to be a random, representative sample of corn, cotton, and soybean growers from the Great Plains eastward. Data collection was restricted to farms with 250 or more acres of the targeted crop. Responses were obtained from 401 cotton growers, 402 corn growers, and 402 soybean growers. While growers were "targeted" to respond to questions about a particular crop, they often also produced other crops. For example, many cotton growers who were asked detailed questions about cotton production also grew corn or soybeans.

The survey included four sections. The first asked questions about operator and farm characteristics. These included operator education and experience, acres operated, percentage of operated land owned, acres of different crops grown, acreage planted with herbicide-tolerant crops, crop-rotation practices, and extent of livestock production. The second section asked growers about their current weed management; adoption of weed-resistance BMPs; herbicides and/or tillage used for pre-plant, pre-emergent, and post-emergent weed control; and timing and frequency of post-emergent weed management. The third section asked growers about their attitudes regarding various weed-management concerns, such as crop yield, crop-yield risk, crop price, crop-price risk, herbicide costs, seed costs, overhead costs, labor and management time, crop safety, operator and worker safety, environmental safety, erosion control, and conve-

Table 1. Frequency of weed resistance best management practice (BMP) adoption (percent of respondents practicing).

BMP	Always	Often	Sometimes	Rarely	Never
Scout before	57%	26%	11%	3%	2%
Scout after	51%	29%	15%	2%	1%
Clean field	60%	14%	13%	5%	8%
Control early	54%	35%	9%	1%	0%
Control escapes	45%	34%	15%	4%	2%
Clean equipment	15%	11%	20%	22%	31%
New seed	87%	7%	3%	1%	2%
Different modes	18%	21%	33%	15%	13%
Supplemental tillage	11%	10%	26%	21%	32%
Use label rate	74%	19%	4%	1%	0%

nience. The fourth section asked growers about the cost of their weed-management program and the value of the benefits they derived using a RR weed-management program.

For this study, weed-resistance management practices were categorized into 10 separate BMPs:

1. Scouting fields before applying herbicides
2. Scouting fields after herbicide applications
3. Start with a clean field, using either a burndown herbicide application or tillage
4. Controlling weeds early when they are relatively small
5. Controlling weed escapes and preventing weeds from setting seeds
6. Cleaning equipment before moving from field to field to minimize spread of weed seed
7. Using new commercial seed that is as free from weed seed as possible
8. Using multiple herbicides with different modes of action
9. Using tillage to supplement herbicide applications
10. Using the herbicide-label recommended application rate

Growers could choose among five responses when asked how frequently they adopted a BMP: (1) always, (2) often, (3) sometimes, (4) rarely, and (5) never. (Growers could respond, "don't know," but these accounted for 0.3% of responses). Six BMPs were always practiced by a majority of growers (Table 1). There were three BMPs, however, that a significant share of growers never practiced. These included cleaning equipment before moving between fields (31%), using multiple herbicides with different modes of action (13%), and using supplemental tillage (32%).

Table 2. Frequency of weed resistance BMP adoption (percent of respondents).

BMP	Often or always	Sometimes	Rarely or never
Scout before	83%	11%	5%
Scout after	81%	15%	4%
Clean field	75%	13%	12%
Control early	89%	9%	2%
Control escapes	79%	15%	6%
Clean equipment	25%	20%	54%
New seed	94%	3%	2%
Different modes	39%	33%	28%
Supplemental tillage	21%	26%	53%
Use label rate	93%	4%	1%

Table 2 combines the share of BMPs practiced often or always, then rarely or never for the same data. There are seven practices that 75% of growers practice frequently (often or always; Table 2): use new seed (94%), follow label rate (93%), start with a clean field (75%), scout before (83%), scout after (81%), control weeds early (89%), and control weed escapes (79%). Again, one can see that the remaining three BMPs—using multiple herbicides with different modes of action, cleaning equipment, and supplemental tillage —were practiced less frequently (Table 2).

Adoption patterns were remarkably similar across producer groups. Seven of the BMPs were practiced by 71% or more of corn, cotton, or soybean producers (Figures 1a, 1b, 1c). Moreover, these were the same seven practices. All three of the producer groups used multiple herbicides with different modes of action, cleaned equipment, or practiced supplemental tillage much less frequently. Less than half of any of these producers practiced these three BMPs often or always. More corn producers used multiple herbicides with different modes

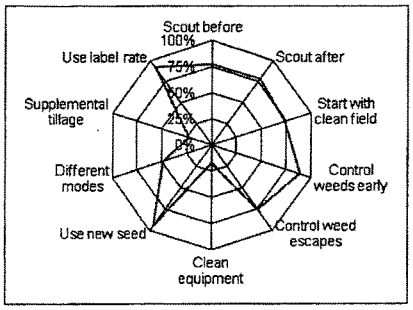

Figure 1a. Percent of corn growers adopting BMPs often or always.

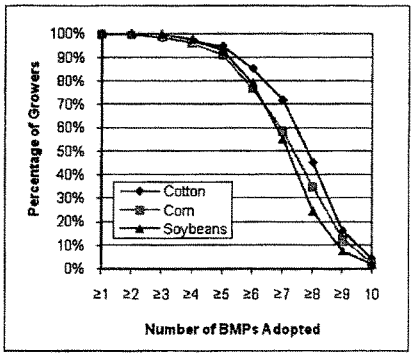

Figure 2. Percentage of growers often or always adopting BMPs by total number of BMPs adopted and targeted crop.

of action often or always (49%) than either cotton (38%) or soybean (28%) growers.

Cotton growers were more likely to practice more BMPs often or always than were corn or soybean growers (Figure 2). More than 70% of cotton growers practice seven or more BMPs often or always, compared to 58% of corn producers and 55% of soybean producers. About 45% of cotton growers practiced eight or more BMPs often or always compared to 35% for corn growers and 24% for soybean growers. About 95% of cotton growers often or always adopted five or more BMPs.

Methods

Integrated weed management (IWM) involves adoption of multiple, interrelated practices. For empirical research, this raises questions about how one measures adoption when "adoption" involves making selections from a suite of different practices. Some studies consider adoption of individual practices, while others attempt to develop indexes characterizing the intensity of adoption. Hollingsworth and Coli (2001) developed a scoring system based on a weighted sum of practices adopted. Hammond et al. (2006) used an index that was an unweighted count of the total number of practices adopted. Llewellyn et al. (2007) considered those growers who adopted three or more practices (out of a possible six) as IWM adopters.

We analyzed data concerning BMP adoption in two ways. First, multivariate count-data analysis was used to identify which factors explained the total number of BMPs a grower adopted frequently (often or always).

For example, which factors help predict whether a grower will adopt eight practices frequently as opposed to seven? Here ,the dependent variable is similar to the unweighted index approach of Hammond et al. (2006). Next, multivariate ordered-probit regressions were estimated to identify factors that help explain how frequently a grower practiced a particular, single BMP.

For the multivariate regression analyses, in addition to the Marketing Horizons survey data, county-specific variables were created using data from the USDA NASS. These included the coefficient of variation (CV) of county crop yields of the targeted crop. CV is the standard deviation of yields divided by the mean of yields over 10 years. The yield CV was included to test the hypothesis that growers in counties with greater yield risk had different patterns of BMP adoption. Growers were asked what they expected their target crop yields would total. An index was created that was the ratio of growers' expected yields to their counties' average yields. This variable was included to test the hypothesis that growers with higher-than-average yields (perhaps better managers or growers farming under conditions that are more favorable) were more likely to adopt BMPs more frequently.

The number of BMPs a grower adopts often or always can only be an integer from 0, 1, 2, ... up to 10. This means a Poisson (or other count data) model is more appropriate than standard linear regression, which can yield parameter estimates that are inefficient, biased, or both and can yield nonsensical predicted values (Greene, 1997; King, 1988). A Poisson regression assumes that the mean and variance of the dependent variable are equal. This assumption can overestimate the statistical significance of regression parameter estimates when there is over-dispersion (variance greater than the mean) or underestimate their statistical significance when there is under-dispersion (variance less than the mean). However, estimation here followed McCullagh and Nelder (1989), who fit a Poisson regression that relaxes this restriction. McCullagh and Nelder use the Pearson chi-square method to estimate a scale parameter s, such that $s = 1$ if the mean and variance are equal, $s > 1$ if the variance exceeds the mean (over-dispersion), and $s < 1$ if the variance is less than the mean (under-dispersion). We also estimate a generalized negative binomial regression as an alternative to a Poisson regression because it also allows for separate estimation of mean and variance (Cameron & Trivedi, 1998; Greene, 1997).

Next, ordered-probit regressions were estimated separately for each of the 10 BMPs. When asked how frequently they adopted a given BMP, respondents could answer 1-always, 2-often, 3-sometimes, 4-rarely, or 5-never. In addition, respondents could answer "don't know," but few responded this way, so we deleted these few observations from the regression analysis.

Table 3. Descriptive statistics for variables used in regressions.

	Means	St. dev.
Number of BMPs practiced often or always	6.838	1.540
Corn producer (=1 if targeted producer; = 0 otherwise)	0.342	
Soybean producer (=1 if targeted producer; = 0 otherwise)	0.355	
Cotton producer (=1 if targeted producer; = 0 otherwise)	0.303	
Years of education	14.042	1.816
Years farming	29.799	12.116
Crop acreage (acres)	1422	1196
Percent of land owned	41.611	32.060
Raises livestock (=1 if yes; = 0 otherwise)	0.368	
Percent RR (percent of targeted crop planted to RR varieties)	87.026	28.275
Yield difference (percent difference of grower's expected targeted crop yield compared to county 10-year average)	29.559	44.120
Yield CV (county 10-year coefficient of variation of targeted of yield of grower's targeted crop)	0.177	0.084
Resistance concern (=1 if yes if grower indicated weed resistance was a concern; = 0 otherwise)	0.516	
Herfindahl index (Measure of crop specialization = 1 for complete specialization; minimum value of 0.25)	0.536	0.160
Custom applications (percent of herbicide applications to targeted crop made by custom applicators)	28.577	41.871
County resistance (=1 if weed resistance reported in county; = 0 otherwise)	0.126	
CRD resistance (percent of counties in 'crop reporting' with reports of weed resistance)	8.932	20.679
Number of observations	1,006

The set of covariates used in the regression models included (1) dummy variables for target crop grown and whether a grower sold livestock; (2) years of grower education and farming experience; (3) total crop acres and percent of cropland owned; (4) the percentage of target crop planted to RR seed varieties in the previous year; (5) percent of herbicide applications carried out by a custom applicator; (6) a Herfindahl index based on the proportion of the crop acreage planted to corn, cotton, soybean, and other crops, which increases as a grower becomes more specialized; (7) a dummy variable indicating that the grower listed weed resistance as a concern in an open-ended question about weed management concerns—growers were not asked directly if resistance was a concern; (8) grower expected yield as a percent of county average yield and the coefficient of variation of target crop yield in the grower's county; and (9) measures of reported herbicide resistance. Two measures of reported herbicide resistance were constructed based on proprietary data obtained from Monsanto. These were (a) a dummy variable indicating weed resistance to herbicides has been reported in a grower's county and (b) the percentage of counties in a grower's crop reporting district where weed resistance has been reported.

Table 3 reports descriptive statistics for variables used in the regressions. The sample included 1,006 observations after deleting those observations with missing data. Adoption rates of RR varieties are high, with an average of 87% of the acres of targeted crops planted to those varieties. Grower yield expectations also seem high relative to county averages. On average, growers expected their yields to exceed their county's 10-year average by 29%. This may reflect optimism on the part of producers, but recall that (a) growers were surveyed about their primary crop, and (b) our sample includes larger producers, only those growing 250 or more acres of the targeted crop. So, it might not be too surprising that relatively large growers, specializing in production of a crop expect

higher-than-average yields. Or, growers' responses may reflect their potential yield, perhaps reflecting the highest yield they obtained in recent years.

Results—Count-Data Analysis

Table 4 reports count-data regression results where the dependent variable is the total number of weed BMPs that a grower reported using either often or always. Table 4 reports results for generalized Poisson and negative binomial regressions with and without state fixed effects. The Poisson and negative binomial specifications yield similar results, with both models suggesting under-dispersion. Based on the likelihood statistics, we can reject the hypothesis of no state-level effects. However, only three states individually had statistically significant effects. The default state is Iowa, and the regression coefficients for Illinois, Indiana, and Kansas were all positive and significant. This suggests that, compared to Iowa, growers in these states tend to practice more BMPs often or always, while growers in other states tend to practice about the same number of weed BMPs as Iowa's growers.

A number of variables were significant across all specifications. The number of BMPs adopted

- increased with a grower's level of education,
- increased for growers with expected yields greater than the county average yield,
- was lower in counties with more variable yields (measured by the county yield CV), and
- was lower in crop- reporting districts reporting more resistance problems.

In regressions with state effects, the number of years of farming experience was negatively associated with the number of BMPs adopted, suggesting that younger farmers tend to adopt more BMPs. Separate models estimated by target crop did not perform well and so are not reported here—for the separate corn and soybean models, the null hypothesis of all zero coefficients (except for the constant) could not be rejected at the 5% level of significance.

In sum, younger, more educated growers who expect to obtain higher-than-average yields practiced a greater number of BMPs often or always. Growers in regions with greater percentage yield variability practiced fewer BMPs. The relationship between local resistance episodes and grower BMP adoption was mixed. Growers in crop-reporting districts with more counties reporting resistance practiced fewer BMPs. Yet, growers farming in counties reporting resistance, tended to adopt more BMPs. This latter relationship was not significant, however.

Cotton growers and larger operators appeared to adopt more BMPs, but this affect was attenuated by including state-specific effects. The attenuating effect of state variables may come from the fact that there was no overlap of growers in surveyed cotton and corn states and only a small overlap between surveyed cotton and soybean growers. Hence, there is a relatively high correlation between the state dummy variables and the cotton grower dummy variable.

Ordered-Probit Results

Table 5 reports results for separate ordered-probit regression for each of the 10 BMPs. The dependent variable is the frequency of practicing a given BMP, where growers could choose between frequencies of never, rarely, sometimes, often, or always. Table 5 reports the effects of explanatory variables that were significant at the 5% and 10% levels. A positive sign (+) indicates an increase in the probability of practicing the BMP more frequently, while a negative minus sign (–) indicates the variable decreased the frequency of adopting the BMP.

Table 6 summarizes results of the ordered-probit regressions by explanatory variable. It reports the variables that had significant effects (at the 10% level) on adoption of each weed-resistance BMP. Results are summarized with and without state effects, with the data pooled across all growers.

In the count-data regressions, targeted cotton producers were more likely to adopt more BMPs often or always, but including state-specific effects attenuated this cotton-grower effect. This pattern repeats itself with frequency of adoption of individual BMPs. Targeted cotton producers appear to have a higher probability of more frequent adoption of a number of individual BMPs in the ordered probits. However, once we include state effects, the statistical significance of these relationships declines. In both ordered probits, soybean producers use multiple herbicides with different modes of action less frequently. In the count-data regression, a negative association existed between being a soybean producer and the number of BMPs adopted often or always, but the association was not significant.

The probit regressions also show that growers who expect yields higher than the county average are more likely to use multiple herbicides with different modes of action. In contrast, growers in counties with greater yield variability less frequently used herbicides with dif-

controlled weed escapes. The positive impact of expected yield and the negative impact of yield variability are consistent with the count-data regressions.

A higher percentage of acreage planted to RR seed varieties was associated with greater use of new seed and less-frequent use of multiple herbicides with different modes of action. RR acreage was associated with more frequently following herbicide-label rates. Growers expressing a concern about resistance in the open-ended questions used supplemental tillage and cleaned equipment less frequently, but used new commercial seed more frequently. Growers operating in a county with reports of weed resistance more frequently used multiple herbicides with different modes of action.

Conclusions

Although cotton growers adopted BMPs somewhat more frequently, BMP adoption patterns were remarkably similar across crops. For all three crops, adoption rates of the same three BMPs were low. These were cleaning equipment, using multiple herbicides with different modes of action, and supplemental tillage. The other seven BMPs were practiced frequently (often or always) by all three grower types.

Generalized Poisson and negative binomial regression results suggest that factors significantly and positively associated with adopting more BMPs include (a) having more education; (b) having less experience (perhaps being younger?); (c) growing cotton; (d) expecting higher yields relative to the county average; and (e) farming in counties with a lower yield coefficient of

variation. In the ordered probits, farming in a county with a larger coefficient of variation of target crop yield *reduced* the probability of frequent adoption of several BMPs. Highly variable production outcomes may hinder the observability and trialability of BMPs (Pannell & Zilberman, 2001). With greater yield variability, it may be more difficult for growers to assess outcomes or benefits of BMP adoption. In contrast, the ratio of a grower's expected yield to the county average yield *increased* the probability of frequent adoption of BMPs. There may be some form of a "good manager" effect at work, where growers with higher yields (or at least higher expected yields) than their neighbors tend to adopt more BMPs more frequently. If BMPs increase current returns by minimizing percent yield loss to weeds, gains from damage reduction would be greater for growers with higher yields.

The survey data suggests that most growers are frequently adopting most BMPs. Extension efforts may thus be more effective by targeting a minority of growers (and a few practices). In particular, counties with a high coefficient of variation of crop yield would be areas to look for low BMP adoption.

Selecting for Weed Resistance: Herbicide Rotation and Mixture

Hugh J. Beckie and Xavier Reboud*

Herbicide rotations and mixtures are widely recommended to manage herbicide resistance. However, little research has quantified how these practices actually affect the selection of herbicide resistance in weeds. A 4-yr experiment was conducted in western Canada from 2004 to 2007 to examine the impact of herbicide rotation and mixture in selecting for acetolactate synthase (ALS) inhibitor resistance in the annual broadleaf weed, field pennycress, co-occurring in wheat. Treatments consisted of the ALS-inhibitor herbicide, ethametsulfuron, applied in a mixture with bromoxynil/MCPA formulated herbicide (photosystem-II inhibitor/synthetic auxin), or in rotation with the non-ALS inhibitor at an ALS-inhibitor application frequency of 0, 25, 50, 75, and 100% (i.e., zero to four applications, respectively) over the 4-yr period. The field pennycress seed bank at the start of the experiment contained 5% ethametsulfuron-resistant seed. Although weed control was only marginally reduced, resistance frequency of progeny of survivors increased markedly after one ALS-inhibitor application. At the end of the experiment, the level of resistance in the seed bank was buffered by susceptible seed, increasing from 29% of recruited seedlings after one application to 85% after four applications of the ALS inhibitor. The level of resistance in the seed bank for the mixture treatment after 4 yr remained similar to that of the nontreated (weedy) control or 0% ALS-inhibitor rotation frequency treatment. The results of this study demonstrate how rapidly ALS-inhibitor resistance can evolve as a consequence of repeated application of herbicides with this site of action, and supports epidemiological information from farmer questionnaire surveys and modeling simulations that mixtures are more effective than rotations in mitigating resistance evolution through herbicide selection.
Nomenclature: Bromoxynil; ethametsulfuron; MCPA; field pennycress, *Thlaspi arvense* L. THLAR; wheat, *Triticum aestivum* L. 'AC Barrie'.
Key words: ALS inhibitor, herbicide resistance, resistance management, seed bank, selection pressure.

Herbicide rotation can be defined as the application of herbicides of different sites of action (i.e., groups) to multiple crops over multiple growing seasons in a field (Beckie 2006). The level of adoption of herbicide rotation for weed resistance management has increased markedly over the past decade in the prairies of western Canada (provinces of Alberta, Saskatchewan, and Manitoba). In 1998, fewer than 50% of farmers practiced herbicide rotation, even though awareness was high (Beckie et al. 1999). By 2003, 70 to 90% of farmers in Saskatchewan and Manitoba, respectively, claimed to rotate herbicides by site of action (Beckie 2007). It is the most common herbicide resistance management practice cited by farmers in survey questionnaires conducted in Canada (Beckie 2007) and Australia (Shaner et al. 1999). At present, over half of the herbicide products sold in Canada have resistance management labeling, which includes group identification symbols on the label and guidelines for resistance management practices in the use directions (M. Downs, PMRA, personal communication). This labeling regulation in Canada, which was first implemented in 1999, probably facilitated the adoption of herbicide rotation. However, the lack of suitable herbicide options associated with crop rotation can be a substantial deterrent to herbicide rotation (Bourgeois et al. 1997; Légère et al. 2000).

Acceptance by farmers of herbicide mixtures for proactive resistance management of broadleaf weeds has been aided by cost-incentive programs from industry, formulated mixtures (e.g., phenoxy plus an ALS inhibitor), and the rapid evolution of resistance in specific cases. A survey of 1,800 farmers in the Canadian prairies from 2001 to 2003 indicated that a majority of them intentionally or inadvertently tank-mix herbicides to delay or manage ALS-inhibitor–resistant broadleaf weeds (Beckie et al. 2008b). For farmers dealing with ALS-inhibitor resistance, the ALS-inhibitor partner may provide relatively broad-spectrum weed control while the non-ALS-inhibitor partner controls the resistant broadleaf weed. However, if mixing partners of different sites of action do not meet the criteria of similar efficacy and persistence, plus different propensity for selecting for resistance in target species, the effectiveness of mixtures for delaying target-site resistance will be reduced. Mixtures may inadvertently accelerate the evolution of multiple resistances if they fail to meet basic criteria for resistance management and are applied repeatedly (Rubin 1991). Moreover, mixtures to prevent or delay metabolic resistance in grass weeds, where this mechanism is most prevalent, may be cost-prohibitive unless the mixed graminicides interact synergistically and can be applied at lower rates. Obstacles to farmer adoption of mixtures for herbicide resistance management include increased cost and availability of suitable mixing partners that meet the criteria outlined above.

Herbicide rotations or mixtures generally have the greatest effect in delaying resistance when the mechanism conferring resistance is target site–based, the target weed species are highly self-pollinated, and seed spread is restricted (Beckie et al. 2001). Based on a compounded resistance frequency model, the probability of herbicide-resistant mutants with multiple mechanisms of resistance (target site–based) in an unselected population is the product of the probabilities of

resistance to each affected herbicide site of action and thus is relatively rare (Wrubel and Gressel 1994). Herbicide mixtures, whose components are equally effective against the target weed species, are predicted through model simulations to delay resistance longer than rotations (Diggle et al. 2003; Powles et al. 1997).

Evolution of herbicide resistance is often attributed to a lack of herbicide rotations or mixtures; i.e., frequent or repeated use of herbicides of the same site of action. Nevertheless, there is epidemiological or anecdotal evidence for the utility of herbicide rotations and mixtures in delaying the evolution of target-site resistance (Beckie 2006). However, little research has quantified how these practices impact herbicide resistance selection in weeds. Only one long-term experiment has examined the effect of frequency of herbicide use on the evolution of resistance. In a large-plot experiment conducted in western Canada from 1979 to 1998, resistance in wild oat (*Avena fatua* L.) to triallate occurred after 18 yr, where the herbicide was applied annually in continuous spring wheat, but not where it was applied 10 times in the wheat phase of a wheat-fallow rotation over the same period (Beckie and Jana 2000).

In this paper, we describe the results of a 4-yr field experiment conducted at two sites in Saskatchewan that examined the impact of herbicide rotation and mixture in selecting for ALS-inhibitor resistance in a broadleaf weed species. The model species chosen was field pennycress (referred to as stinkweed in Canada). Field pennycress is a diploid ($2n = 14$), self-compatible, and readily autogamous (ca. 3% outcrossing; Hume 1990) annual weed that is a member of the Brassicaceae family (reviewed in Best and McIntyre 1975; Warwick et al. 2002). The species has a persistent seed bank of 10 to 20 yr (Van Acker 2009), high fecundity, and the growth habit of a winter or summer annual. Native to Eurasia, this crucifer is widely introduced and naturalized in temperate regions around the world. The species occurs in all the Canadian provinces and territories, and is an economically important weed of field crops in the Canadian prairies. Farmers spend almost $200 million annually to control this weed (J. Leeson, unpublished data). In weed surveys of annual crops in the early 2000s across the prairies, field pennycress ranked seventh in relative abundance (Leeson et al. 2005). Resistance to ALS-inhibitor herbicides in this species was first reported globally in two populations from Alberta in 2000 (Beckie et al. 2007).

Materials and Methods

Sites. The experiment was conducted from 2004 to 2007 at two sites in Saskatchewan, near Watrous and North Battleford. The Watrous site is located in the subhumid Aspen Parkland ecoregion (defined by climate, natural vegetation, and soils) at 51.4° N, 108.6° W; the North Battleford site is located in the subhumid Boreal Transition ecoregion at 52.0° N, 105.2° W. The sites were located on permanent pastureland owned by the Prairie Farm Rehabilitation Administration of Agriculture and Agri-Food Canada. Because herbicide-resistant weed seed was used in the experiment, a large isolation buffer between adjacent cropland was desired. A 1-ha fenced area at each site had been cropped annually since 1997. Observations of field pennycress recruitment from 1997 to 2003 confirmed the absence of a seed bank at each site. The soil at the Watrous site is an Oxbow sandy loam (Udic Haploboroll) with 4.0% organic matter (OM) and pH 7.3; soil at the North Battleford site is a Meeting Lake loam (Boralfic Haploboroll) with 2.5% OM and pH 7.0. All soils were nonsaline. Precipitation and air temperature during the growing season (May to August) were recorded at weather stations nearest to the two sites (26 to 42-km distance).

Experimental Design and Protocol. The experiment was arranged in a randomized complete block design with four replications. Plot dimensions were 4 by 10 m. Treatments consisted of the ALS inhibitor (group-2 herbicide; Mallory-Smith and Retzinger 2003), ethametsulfuron, applied in rotation with a bromoxynil/MCPA formulated herbicide ([280 g/L bromoxynil, a photosystem-II inhibitor] / [280 g/L MCPA ester, a synthetic auxin]) at an ALS-inhibitor rotation frequency of 0, 25, 50, 75, and 100% (i.e., zero to four applications, respectively) over the 4-yr period (Table 1). Both herbicides generally have short soil residual activity under western Canadian climatic conditions (Saskatchewan Ministry of Agriculture 2008). However, the soil persistence and activity of ethametsulfuron, a sulfonylurea herbicide, depends upon soil OM and pH. Each phase of the herbicide rotation was present each year. Thus, the 25% ALS-inhibitor rotation frequency was represented by four treatments: ethametsulfuron applied in yr 1, 2, 3, or 4 ("on" years) with bromoxynil/MCPA applied in the "off" years (Table 1). The 50% ALS-inhibitor rotation frequency was represented by six treatments: ethametsulfuron applied in yr 1 and 2; 1 and 3; 1 and 4; 2 and 3; 2 and 4; and 3 and 4. The 75% ALS-inhibitor rotation frequency was represented by four treatments: ethametsulfuron applied in yr 1, 2, and 3; 1, 2, and 4; 2, 3, and 4; and 1, 3, and 4. The sole mixture treatment was ethametsulfuron plus bromoxynil/MCPA applied each year (Table 1). Additionally, a nontreated (weedy) control and a weed-free control treatment were included.

Herbicides were applied using a hand-held boom equipped with flat fan nozzle tips[1] that delivered a spray volume of 110 L/ha at 275 kPa when the majority of weed seedlings were in the two- to three-leaf stage. Commercial formulations of the herbicides were applied at recommended rates (Saskatchewan Ministry of Agriculture 2008). Ethametsulfuron was applied at 22 g ai/ha, and the bromoxynil/MCPA formulated herbicide at 550 g ai/ha. A nonionic surfactant[2] was added to the ethametsulfuron spray solution at 0.25% (v/v). Sparse populations of other broadleaf weeds were controlled by roguing as required. Wild oat was controlled in all plots by fall-applied granular triallate.

Hard red spring wheat ('AC Barrie') was seeded using a disc drill with 20-cm row spacing in early to mid-May, depending on soil moisture and temperature conditions. The crop was seeded parallel to the short dimension of plots at 80 kg/ha at a 2.5 to 5-cm depth, depending on soil moisture conditions. Fertilizer nitrogen (N), phosphorus (P), and sulphur (S) were seed-placed or side-banded at rates based on soil test recommendations. Plots were tilled (8 to 10 cm deep)

[a] Ethametsulfuron applied at 22 g ai/ha (plus nonionic surfactant at 0.25% v/v); bromoxynil/MCPA formulated herbicide applied at 550 g ai/ha.

length-wise once immediately prior to seeding using a field cultivator with mounted harrows.

The field pennycress seed bank at both sites was established in 2003, the year prior to initiation of the experiment. In late autumn near freeze-up, a ratio of 5 ethametsulfuron-resistant seed : 95 susceptible seed mixture of field pennycress was drilled into the soil at a 2.5-cm maximum depth in the long direction of plots (except for the weed-free control treatment) at a rate of 75 germinable seeds/m^2. The susceptible population originated from central Saskatchewan and was confirmed to contain no resistant individuals; the resistant population, CAB, originated from central Alberta. Seeds from both populations exhibited little dormancy; the germination rate for the seed lots consistently exceeded 95%. The resistant biotype has been well characterized (Beckie et al. 2007). The biotype is highly resistant to ethametsulfuron, exhibits a low level of resistance to metsulfuron and imazethapyr, but is not resistant to florasulam, a triazolopyrimidine ALS inhibitor. Resistance in the CAB population was attributed to a Pro_{197} Leu mutation, conferred by a single, dominant gene.

Data Collection. Crop and weed plant density were measured 3 wk after emergence in four randomly placed 0.25-m^2 quadrats per plot. At 3 wk after herbicide application, weed seedling density was enumerated using the same procedure. Field pennycress aboveground biomass was harvested at maturity. Shoot biomass from each of the four quadrats from each plot was collected in a cotton bag and subsequently dried in a forced-air drying room. Thereafter, plants were threshed and seeds were weighed and counted. Seeds were subsequently stored at ambient room temperature. Wheat grain yield was determined at crop maturity by harvesting aboveground biomass in two 1-m^2 quadrats per plot using procedures similar to those used for the weed harvest. Grain weight was adjusted to 10% moisture content. The crop that remained in each plot was harvested using a small-plot combine, ensuring that residue was contained within the plot area.

Each year in early spring after the preceding harvest, field pennycress seeds from each plot were tested in the greenhouse for resistance to ethametsulfuron. A total of 150 seeds from each sample (one aggregate sample per plot) were screened. Twenty-five seeds were planted in a potting mixture of soil, peat, vermiculite, and sand (3 : 2 : 2 : 2 by volume) plus a slow-release fertilizer (150 g of 26–13–0 per 75 L potting mixture) in trays (each tray considered a replicate) measuring 52 by 26 by 5 cm. Environmental conditions were a 20/16 C day/night temperature regime with a 16-h photoperiod supplemented with 230 $\mu mol/(m^2 \cdot s)$ illumination. Flats were watered daily to field capacity. Seedlings were treated with ethametsulfuron at the two-leaf stage. The herbicide was applied using a moving-nozzle cabinet sprayer equipped with a flat-fan nozzle tip[1] calibrated to deliver 200 L/ha of spray solution at 210 kPa in a single pass over the foliage. A nonionic surfactant[2] was added at 0.25% (v/v). Treatments (and nontreated controls) were replicated three times in this completely randomized experiment and the tests were repeated. In early spring each year, any seeds not tested for resistance were returned to plots in areas where they had been harvested the previous year.

In mid-April of 2008, the year after the experiment was terminated, soil was sampled to determine the viable fraction of the seed bank and percentage of seeds resistant to ethametsulfuron. Twenty-five 5-cm-diam by 10-cm-deep soil cores, sampled in a "W" pattern, were collected from each plot. Cores from each plot were combined and the bulk samples were frozen until late spring/summer of 2008, when four growth periods were conducted in the greenhouse in trays measuring 52 by 26 by 5 cm. Soil in trays was watered twice

daily. A liquid N–P–S fertilizer was applied to each tray once during each of the four growth periods. Field pennycress seedlings were counted and then sprayed by the four-leaf stage with ethametsulfuron at 22 g ai/ha using the procedures described previously. Three wk after spraying, survivors were counted, removed, and the soil was remixed. The sample was returned to the freezer for 3 wk in advance of the second growth period. This procedure was repeated for the third and fourth growth periods.

Data Analyses. Data were logarithmically or square-root transformed prior to ANOVA. Data were subjected to a combined ANOVA using the Proc MIXED procedure in SAS software (SAS 1999). Replicate, site, and year were considered random effects, and herbicide treatment as a fixed effect. Weed response to treatments (seedling density, aboveground biomass, seed production, percentage of seeds produced annually resistant to ethametsulfuron, percentage of viable seeds in the seed bank at the end of the experiment resistant to ethametsulfuron) was analyzed using curvilinear regression. Data were averaged across phases for the 25, 50, or 75% ALS-inhibitor rotation frequencies. Weed responses to ALS-inhibitor rotation frequency were best described by the quadratic (2nd-order polynomial) or exponential models. Regression analyses were performed on treatment means averaged over replications as recommended by Gomez and Gomez (1984). Coefficients of determination (R^2) were calculated as described by Kvalseth (1985) using the residual sum of squares value from the SAS output. Standard errors of the parameter estimates were calculated. Planned orthogonal contrasts (listed in Table 1) were performed to compare specific treatment means when significant treatment effects from ANOVA were indicated ($P \leq 0.05$) (Bertram and Pedersen 2004).

Results and Discussion

Weather Conditions. Total growing season precipitation was above normal for two site-years, and near-normal for six site-years (data not shown). At the time of crop establishment in May, less than 80% of the normal (30-yr mean) monthly precipitation was received for three of the eight site-years. Average growing season temperatures were near normal for all site-years.

Wheat Stand Establishment and Grain Yield. Satisfactory crop plant densities were realized in all years at both sites. Wheat seedling density at 3 wk after emergence ranged from 136 ± 3 (SE) plants/m^2 in 2007 to 241 ± 6 plants/m^2 in 2004. Relatively low stand densities in 2007 were caused by dry soil conditions at planting. Combined ANOVA results indicated no significant effect ($P > 0.05$) of herbicide treatment on wheat grain yield (data not shown). Wheat yield loss by field pennycress interference can vary widely, depending on plant densities and relative time of emergence (Warwick et al. 2002). Based on yield loss equations derived from data from a 10-yr study in Saskatchewan from 1981 to 1990, field pennycress at a density of 52 plants/m^2 would be expected to result in only a 3% grain yield loss in spring wheat (Hume 1993). In the spring of 2004 (first year of the experiment) immediately prior to herbicide treatment, field pennycress seedling densities across all plots at the two sites averaged 48.7 ± 2.1 plants/m^2.

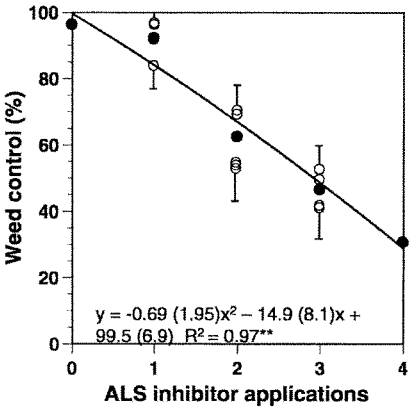

Figure 1. Response of field pennycress seedling density ('●' denotes means, '○' denotes phases of an herbicide rotation; maximum low and high weed control SE bars shown) to ethametsulfuron, an acetolactate synthase (ALS) inhibitor, applied one (25% frequency), two (50% frequency), three (75% frequency), or four (100% frequency) times during the 4-yr experiment (quadratic regression equation with SE in brackets: $y = ax^2 + bx + c$ where a = the curvilinear coefficient, b = the linear coefficient, c = the intercept, y = the dependent variable, and x = the number of ALS-inhibitor applications; R^2 is significant (**) at $P < 0.01$).

Weed Seedling Density-Weed Control. The decline in field pennycress control in wheat was curvilinear with increasing number of ALS-inhibitor applications (Figure 1). Weed control over 4 yr averaged 96% in plots treated annually with bromoxynil/MCPA (0% ALS-inhibitor rotation frequency). Similarly, weed control over 4 yr averaged 97% in the herbicide mixture (ethametsulfuron + bromoxynil/MCPA) treatment (nonsignificant contrast, $P > 0.05$) (Table 2). Field pennycress is normally highly sensitive to ethametsulfuron or bromoxynil/MCPA. After one application of ethametsulfuron (in yr 1, 2, 3, or 4), weed control declined slightly (mean of 92%). Nonetheless, this level of control was less than that of the mixture treatment (significant contrast, $P \leq 0.05$). Maximum low and high weed control SE bars shown in Figure 1 indicate the variability in weed control among the phases of a given ALS-inhibitor rotation frequency.

Field pennycress seedling density was only suppressed (i.e., < 80% efficacy) by two or more ALS-inhibitor applications. After two applications of ethametsulfuron (in yr 2, 3, or 4), weed control had declined to 62%; after three applications of the ALS inhibitor (yr 3 or 4), weed control averaged 46%, declining to 31% after four consecutive annual ALS-inhibitor applications. Therefore, starting with a weed population comprising 5% ALS-inhibitor–resistant individuals, weed

Table 2. Field pennycress response averaged over 4 yr of the experiment (seed bank after 4 yr) for the 0 and 25% acetolactate synthase (ALS) inhibitor (ethametsulfuron) rotation frequency treatments and mixture (ALS inhibitor plus bromoxynil/MCPA) treatment.

	Seedling density	Biomass at maturity	Seed production	Resistant seed[a]	Resistant seed bank[a]
	% control	g/m^2	number/m^2	%	%
0% ALS-inhibitor frequency (treatment 3, Table 1)	96	0.3	155	2	4
25% ALS-inhibitor frequency (treatments 4–7 averaged, Table 1)	92	11.0	1210	59	29
Mixture (treatment 19, Table 1)	97	0.6	178	3	8
Contrast[b]: 0% ALS inhibitor *vs.* mixture	NS	NS	NS	NS	NS
Contrast: 25% ALS inhibitor *vs.* mixture	*	*	*	*	*

[a] The percentage of seeds resistant to ethametsulfuron in the nontreated control was 5% when averaged over 4 yr (annual seed production) and in the seed bank at the end of the experiment—not significantly different ($P > 0.05$) from the 0% ALS-inhibitor rotation frequency treatment or mixture treatment.

[b] *, significant at $P \leq 0.05$; NS, nonsignificant.

control would not noticeably decline after one application of an ALS inhibitor, but would be unacceptable (i.e., < 80% efficacy) after only two applications.

Weed Biomass and Seed Production. Both field pennycress biomass at maturity and seed production responded similarly as seedling density to increasing number of ALS-inhibitor applications (Figures 2 and 3). Responses were best described by the quadratic function. The greatest variation in biomass and seed return responses among phases, similar to that of weed seedling density, was observed in plots with the 50% (two-application) ALS-inhibitor rotation frequency. After four ALS-inhibitor applications, field pennycress plant biomass exceeded 100 g/m^2 (i.e., 1,000 kg or 1.0 tonne/ha). Whereas 155 seeds/m^2 were produced in plots with the 0% ALS-inhibitor rotation frequency, 1,210, 5,770, 16,600, and 25,700 seeds/m^2 were produced where ethametsulfuron was applied one (25%), two (50%), three (75%), and four times (100%), respectively.

In field studies in Saskatchewan, Hume (1993) found that spring-emerging field pennycress in wheat produced about 14,000 seeds per plant. Given its persistent seed bank, field pennycress control by herbicides and crop competition is essential to minimize seed production, a basic tenant of herbicide-resistance management. Four-yr means of weed biomass (0.6 g/m^2) and seed production (178 seeds/m^2) responses for the herbicide mixture treatment were similar to those for the 0% ALS-inhibitor rotation frequency treatment (nonsignificant contrasts, $P > 0.05$), indicating control of both resistant and susceptible field pennycress by bromoxynil/MCPA. However, means for both plant variables were significantly different between the 25% ALS-inhibitor rotation frequency and the mixture treatment (Table 2).

Percentage Resistant Seeds. Greater than 95% of seeds tested were viable (data not shown). In contrast to weed density, biomass, and seed production, the percentage of seeds resistant to ethametsulfuron as a function of its application frequency was best described by an exponential (reciprocal) model (Figure 4). The resistance percentage increased rapidly from 2% (0% ALS-inhibitor rotation frequency) to nearly 60% after only one ALS-inhibitor application (25% rotation frequency). After two applications, the resistance percentage had increased to 92%, but changed little with one or two additional applications over the 4-yr period. For the mixture treatment, the percentage of seed resistant to the ALS inhibitor averaged 3%, similar to that of the 0% ALS-inhibitor rotation frequency treatment (nonsignificant contrast, $P > 0.05$). In the nontreated control treatment, a 4-yr mean of 5% resistance was measured, unchanged from the resistance frequency established at the beginning of the experiment.

The rapid increase in resistance frequency of progeny of surviving plants after only one ALS-inhibitor application helps explain the frequent observations by farmers of good weed control in one year but failure the next, when using the same herbicide or product with the same site of action. Weed

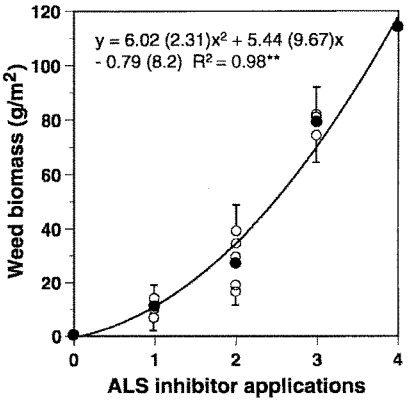

Figure 2. Response of field pennycress biomass at maturity ('●' denotes means, '○' denotes phases of an herbicide rotation; maximum low and high biomass SE bars shown) to ethametsulfuron, an acetolactate synthase (ALS) inhibitor, applied one (25% frequency), two (50% frequency), three (75% frequency), or four (100% frequency) times during the 4-yr experiment (quadratic regression equation with SE in brackets: $y = ax^2 + bx + c$ where a = the curvilinear coefficient, b = the linear coefficient, c = the intercept, y = the dependent variable, and x = the number of ALS-inhibitor applications; R^2 is significant (**) at $P < 0.01$).

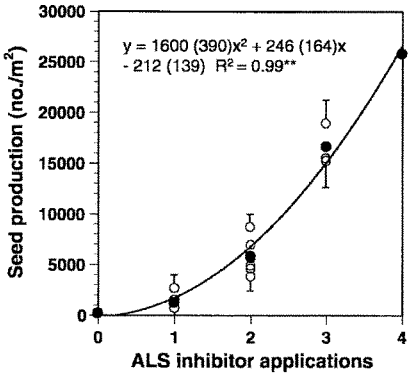

Figure 3. Response of field pennycress seed production ('●' denotes means, '○' denotes phases of an herbicide rotation; maximum low and high seed production SE bars shown) to ethametsulfuron, an acetolactate synthase (ALS) inhibitor, applied one (25% frequency), two (50% frequency), three (75% frequency), or four (100% frequency) times during the 4-yr experiment (quadratic regression equation with SE in brackets: $y = ax^2 + bx + c$ where a = the curvilinear coefficient, b = the linear coefficient, c = the intercept, y = the dependent variable, and x = the number of ALS-inhibitor applications; R^2 is significant (**) at $P < 0.01$).

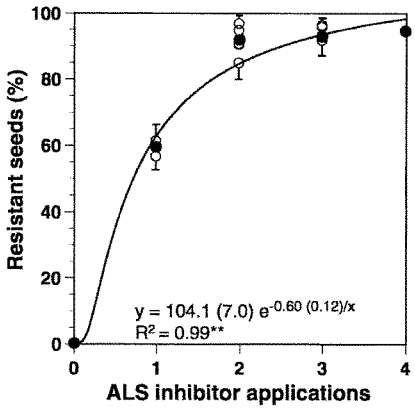

Figure 4. Response of percentage resistance of field pennycress seeds ('●' denotes means, '○' denotes phases of an herbicide rotation; maximum low and high resistant seed percentage SE bars shown) to ethametsulfuron, an acetolactate synthase (ALS) inhibitor, applied one (25% frequency), two (50% frequency), three (75% frequency), or four (100% frequency) times during the 4-yr experiment (exponential reciprocal regression equation with SE in brackets: $y = ce^{-bx}$, where c = the intercept, bc = the initial slope, y = the dependent variable, and x = the number of ALS-inhibitor applications; R^2 is significant (**) at $P < 0.01$).

populations in a field undergoing herbicide resistance selection are typically a mixture of homozygous and heterozygous individuals, with resistance alleles segregating from one generation to the next. The high selection pressure exerted by ethametsulfuron on this mixed resistant/susceptible field pennycress population, with resistant individuals possessing target-site mutation conferred by a single nuclear gene with a high degree of dominance, are ideal conditions for the rapid enrichment of resistance alleles with increasing number of ALS-inhibitor applications.

Percentage Resistant Seedlings in the Seed Bank. The buffering of enrichment of ALS-inhibitor resistance by susceptible seed in the seed bank was apparent at the end of the experiment (Figure 5). The level of resistance in the seed bank in plots with 0% ALS-inhibitor rotation frequency was 4%; this level of resistance rose to 29% after one application, 54% after two applications, 71% after three applications, and 85% after four applications of ethametsulfuron. In the mixture treatment, the level of resistance was 8%; however, orthogonal contrast indicated no significant difference ($P > 0.05$) from either the nontreated control (5%) or the 0% ALS-inhibitor rotation frequency treatment (Table 2). The percentage of recruited seedlings resistant to ethametsulfuron was greater in plots treated with 25% ALS-inhibitor rotation frequency than that of the mixture treatment (Table 2).

The similar resistance frequency in the seed bank of the nontreated control (5%), or the 0% ALS-inhibitor rotation frequency (4%), as that of the initial seed bank established in 2003 suggests little fitness difference between these resistant and susceptible field pennycress populations in the absence of selection pressure. The similar percentage resistance in the seed bank for the 0% ALS-inhibitor rotation frequency and mixture treatments relative to that of the nontreated control indicates essentially zero selection pressure (i.e., resistant and susceptible genotypes controlled equally). Thus, little decline would be expected in the proportion of resistant to susceptible individuals in a field over time after use of the ALS inhibitor was discontinued.

The relatively slow evolution of ALS-inhibitor resistance in field pennycress populations in western Canada is partially due to the longevity of seeds (10–20 yr) in the seed bank. Nevertheless, after four ALS-inhibitor applications, over 80% of seedlings recruited from the seed bank were resistant. For weed species such as kochia [*Kochia scoparia* (L.) Schrad.] with a short-lived seed bank (1–2 yr; Friesen et al. 2009), the seed bank resistance response would probably be depicted by a steeper curve than that observed in this experiment. Similarly, less buffering of resistance evolution by the seed bank would occur under a low soil disturbance no-tillage environment (Beckie et al. 2008b). In the minimum tillage regime used in this study—i.e., one spring tillage operation—partial weed seed burial to tillage depth would favor seed dormancy and persistence (Warwick et al. 2002).

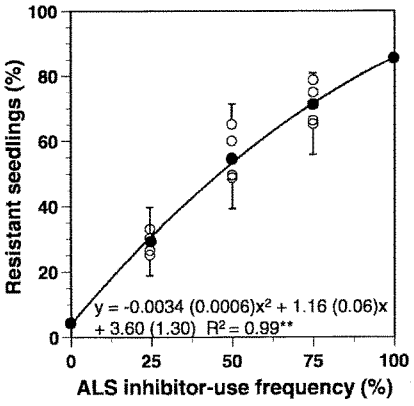

Figure 5. Response of percentage resistant field pennycress seedlings ('●' denotes means, '○' denotes phases of an herbicide rotation; maximum low and high resistant seedling percentage SE bars shown) recruited from the seed bank to ethametsulfuron, an acetolactate synthase (ALS) inhibitor, applied one (25% frequency), two (50% frequency), three (75% frequency), or four (100% frequency) times during the 4-yr experiment (quadratic regression equation with SE in brackets: $y = ax^2 + bx + c$ where a = the curvilinear coefficient, b = the linear coefficient, c = the intercept, y = the dependent variable, and x = the number of ALS-inhibitor applications; R^2 is significant (**) at $P < 0.01$).

The results of this study dramatically illustrate how rapidly ALS-inhibitor resistance can evolve in sensitive weed species with repeated ALS-inhibitor applications. The most relevant data of this study is arguably that of the seed bank resistance enrichment as impacted by herbicide rotation and mixture. The enrichment of resistant alleles is roughly proportional to the number of ALS-inhibitor applications, although a decline in the rate of increase in the level of resistance was apparent after three applications (Figure 5). In the Canadian prairies, the high relative abundance and long persistence of field pennycress in the seed bank favors the existence of a mixed population with some susceptible individuals, even under intense ALS-inhibitor selection pressure. Moreover, some unsprayed seedlings (e.g., spray misses or near water bodies) or those receiving a sub-lethal herbicide dose due to a myriad of factors affecting retention and absorption will survive, reproduce, and thus maintain susceptible genotypes in seed banks, even under high ALS-inhibitor selection pressure.

Because ALS-inhibitor resistance can evolve in field weed populations after fewer than five applications (Beckie 2006), herbicide rotation as a tactic to delay such resistance is probably short-term at best. Based on modeling simulations and results presented herein, a mixture of an ALS inhibitor with a photosystem-II inhibitor (site B, group 6; Mallory-Smith and Retzinger 2003) or auxinic herbicide (group 4) or both is a much more effective tactic than rotation to delay ALS-inhibitor resistance. The unregistered mixture of ethametsulfuron and bromoxynil/MCPA meet the criteria for effective proactive resistance management of field pennycress. If a farmer plans to use an ALS-inhibitor herbicide for broadleaf weed control, we recommend it be tank-mixed with a suitable partner whenever possible to slow the steadily increasing number of cases of ALS-inhibitor resistance in broadleaf weeds in the prairies.

Although small-plot studies are inadequate in assessing the risk of multiple resistance in weeds as a result of repeated use of the same mixture, the rarity of ALS inhibitor plus auxinic or photosystem-II inhibitor multiple resistance in broadleaf weed species in the Canadian prairies (only one case documented in 1996 by Hall et al. 1998) is compelling evidence that alleles resistant to these non-ALS inhibitors introduced over 50 yr ago are present at extremely low frequencies in populations. Indeed, there are few cases of weed resistance in western Canada to synthetic auxins or photosystem-II inhibitors, despite their intensive and widespread use (Beckie et al. 2008a) since the beginning of the agrichemical era. An unusually low rate of mutation of the locus conferring resistance, or alternatively few fit mutations, are speculated to contribute to the slow evolution of resistance to phenoxy and some other low-risk herbicides (Jasieniuk et al. 1996).

The wide disparity in rate of herbicide resistance evolution to ALS inhibitors vs. phenoxy herbicides or photosystem-II inhibitors is best exemplified in kochia. ALS-inhibitor resistance in this species was first documented in the prairies in 1988, 5 yr after introduction of herbicides with this site of action (Friesen et al. 2009). Twenty yr later, about 90% of populations in the Canadian prairies exhibit some level of ALS-inhibitor resistance (Beckie 2009), whereas resistance in this species to non-ALS inhibitors has not been reported. There are few alternative herbicide options to control ALS-inhibitor–resistant kochia in annual legume crops, such as field pea (*Pisum sativum* L.) and lentil (*Lens culinaris* L.) grown on over 2 million ha in Canada in 2008 (Statistics Canada 2008). In these and other crops such as mustard (*Brassica juncea* L. or *Sinapis alba* L.), farmers rely on ALS-inhibitor herbicides to control broadleaf weeds. Although too late for kochia, we believe utilization of herbicide mixtures for proactive resistance management of other broadleaf weeds with a propensity for ALS-inhibitor resistance evolution will be more cost-effective and sustainable in the long-term than ALS-inhibitor herbicides applied in rotation. The challenge for industry is finding suitable non-ALS-inhibitor partners with selectivity in our major dicot crops.

Summary

A simulation study was conducted to examine the effect of pattern of herbicide use on development of resistance to two herbicides with different modes of action in finite weed populations. The effects of the size of the treatment area (analogous to initial weed population), germination fraction and degree of self-pollination in the weed were investigated. The results indicate that the probability of developing resistance to one or both herbicides decreases as the size of the area/initial population decreases. For treatment areas of 100 ha or less with an initial weed seedbank of 100 seeds m^{-2} and initial frequencies of the resistance genes of 10^{-6}, development of resistance to both herbicides (double-resistance) is uncommon within 50 years for all types of weeds if both herbicides are used in all years (used in combination). If herbicides are used in alternate years (rotated) double-resistance almost always occurs in 100 ha areas but is uncommon in areas of 1 ha or less. The results suggest that adoption of practices that limit movement of weeds in conjunction with using herbicides in combination rather than in rotation can substantially delay development of herbicide resistance.

Keywords: simulation, modelling, mixtures, reduction, herbicide resistance.

Introduction

The development of herbicide resistance in weed populations under herbicide selection is an evolutionary phenomenon. Herbicides are very intense selective agents and where genetic variability for herbicide response exists in weed populations, evolution of herbicide resistance can be rapid. The probability and rate of herbicide resistance evolution depends on the interplay between the population dynamics and population genetics of weed populations (Maxwell & Mortimer, 1994; Jasieniuk *et al.*, 1996; Diggle & Neve, 2001). Important evolutionary factors include the intensity of selection (degree of discrimination between genotypes); the frequency of resistance traits in natural (unselected) populations; the mode of inheritance of resistance; the relative fitness of susceptible and resistant biotypes in the presence and absence of herbicide; and gene flow within and between populations. The intrinsic population dynamics of weed populations is also important, especially in the area of seedbank dynamics where it is recognized that a persistent seedbank can act as a buffer to evolution (Mortimer *et al.*, 1993).

Several simulation models of the population genetics and dynamics of herbicide resistance in weed populations have been developed (Gressel & Segel, 1978; Maxwell *et al.*, 1990; Gardner *et al.*, 1998; Cavan *et al.*, 2000). These models differ in their approaches, particularly in relation to population genetics, and the applications and limitations of the various methodologies have been discussed by Diggle and Neve (2001). In particular, the authors draw attention to the benefits of explicitly accounting for each genotype in the population. The common alternative approach of assuming Hardy–Weinberg equilibrium between successive generations may lead to erroneous conclusions about resistance

evolution under conditions that violate the assumption of random mating. Such conditions are common and include incomplete germination, immigration and emigration of seed and pollen (gene flow); staggered flowering time; and any bias towards self-pollination. These factors affect the rate of evolution of herbicide resistance because they determine the frequency of the haplotypes that are involved in mating at any given time.

Where more than one resistance gene is being considered, an assumption of genotypic equilibrium between successive generations is inappropriate, even under conditions of completely random mating. While individual genes reach equilibrium in each generation, equilibrium combinations of genes are only achieved after many generations of random mating. For this reason, simulation of the dynamics of more than one gene in a population requires explicit accounting of each genotype. The evolution of herbicide resistance in the field typically involves simultaneous selection by herbicides with more than one mode of action. Consequently, consideration of two (or more) genes is of practical significance.

Population size is also an important factor in the rate of evolution of herbicide resistance. Where gene flow between adjacent populations is zero, the probability of a resistant individual occurring in a population is a function of population size (weed density × population area) and the initial gene frequency. While mutation rates and hence initial gene frequencies are beyond the control of management, weed population densities are not. Weed control practices that maintain low weed densities can considerably decrease the chance of resistance evolution by reducing the number of resistance alleles in a population (Christoffers, 1999).

A practical consequence of this principle, where more than one rare resistance gene is present in the population, is that individuals with multiple resistances are *extremely* rare prior to herbicide selection (Gressel & Segel, 1990). Hence, within any given local area, multiresistant individuals will, on balance of probabilities, be absent in any one generation.

Rotations and mixtures of herbicides that have discrete modes of action and that are not capable of degradation by a common metabolic pathway (mode of degradation) have long been proposed as a means to prevent or delay resistance evolution (Gressel & Segel, 1990; Wrubel & Gressel, 1994; Powles *et al.*, 1997). Powles *et al.* (1997) modelled herbicide resistance evolution in a weed population of infinite size when two herbicides were rotated annually or used each year as a mixture. In the absence of fitness penalties, (which would cause selection against resistant alleles in 'off' years) the rotation strategy did not increase the number of applications before resistance for either herbicide. When the herbicides were used in mixture, resistance was delayed by approximately 4 years.

When an infinite population is assumed, no matter how improbable, extremely rare double-resistant individuals will always be assumed to be present and influencing the rate of evolution of resistance. By explicitly simulating all genotypes in a finite population a more realistic prediction of the dynamics of the evolutionary process can be achieved. This capability is particularly important when examining the implications of patterns of herbicide use and may modify the relative benefits of alternative herbicide use strategies.

The model described in this paper was developed to investigate the influence of weed life history traits (seed dormancy and plant mating system) and management (population size and genetic isolation) on the rate of resistance evolution under three contrasting herbicide management regimes.

Model development

Overview

The model has been developed to simulate the evolution of herbicide resistance at two discrete, unlinked nuclear gene loci in a weed of broad-area farming. In accordance with most cases where the inheritance of herbicide resistance has been documented (Darmency, 1994) resistance is assumed to be conferred by alleles at a single gene locus. Mutant alleles at these two loci confer resistance to different herbicide modes of action so that evolution of resistance to two distinct herbicides or herbicide modes of action can be tracked within a single weed population (multiple resistance). It is assumed that alleles at the two loci segregate independently.

The herbicides to which resistance is being simulated are hypothetical. Both allow selective post-emergence control of the weed and both are effective enough so that the weed is adequately controlled when either herbicide is used on its own, resulting in 'redundant kill' [control of resistant survivors of one herbicide by a second, chemically dissimilar, herbicide as defined by Comins (1986)] when they are used in combination. There is no capacity for resistance at one locus to confer cross-resistance to other herbicide chemistries. The majority of herbicide resistance traits are inherited in a dominant or semi-dominant manner (Darmency, 1994). Resistance to both herbicides in this model is assumed to be inherited in a completely dominant manner at field-applied rates.

The model is constructed from a number of submodels and is based on the life cycle of a

hypothetical annual weed. The life cycle model simulates the population biology and demographics of a single population over successive generations. The reference point for the life cycle is the soil seedbank. Processes of germination, emergence, establishment, growth and reproduction are regulated by intrinsic population dynamics (density dependence and seedbank dynamics) and extrinsic environmental (climate) and management factors. Population dynamics and the efficacy of weed control strategies together govern transition probabilities between life history stages (Fig. 1).

The model was implemented in the Stella simulation language (version 7) produced by High Performance Systems, Inc., Hanover, NH, USA (http://www.hps-inc.com).

A crop (wheat, *Triticum aestivum* L.) is sown during each year of the simulation. Crop seeding and germination rates and crop establishment characteristics are defined. Competition between the crop and the weed is simulated using a reparameterized version of the hyperbolic equation (see below) used by Firbank and Watkinson (1986) to predict crop yields and weed seed production.

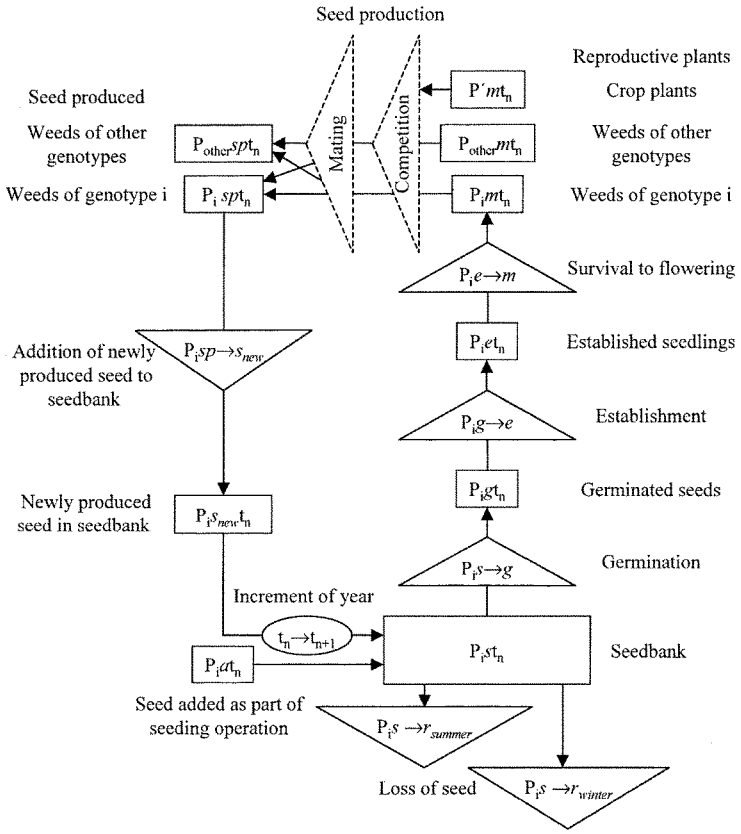

Fig. 1 Life cycle of the weed as represented in the model, illustrated for one genotype (i). Variables representing densities of plants in particular life history stages are enclosed in rectangles. Variables representing transition probabilities between life history stages are enclosed in continuous triangles. More complex relationships between stages are illustrated by broken triangles.

A weed population genetics submodel tracks the fate of herbicide-resistant and susceptible genotypes and alleles within the population. Control efficacies and population dynamics are defined individually for each of the nine possible weed genotypes (see below). A stochastic extinction routine is incorporated into the model to account for the possibility that rare alleles may be totally eradicated from the population.

During the reproductive stage, alleles at the two loci segregate independently into gametes (pollen and ovules) and recombine during completely random mating. The rate of out-crossing may be varied. Following seed-set and maturation, seeds are returned to the soil seedbank.

Weed life cycle

As with previous models of herbicide resistance, the life cycle forms the central element of the model through which changes in population density and the frequency of individual genotypes are accounted. During each generation, individuals of weed population (P) are represented in a number of states; viable seeds in the seedbank (s), germinated seeds (g), established seedlings (e), mature plants (m), seed produced on mature plants (sp), seed removed from the seedbank other than by germination (r), and seed added to the seedbank as a contaminant at crop sowing (a). The starting point for all simulations is the initial weed seedbank (Ps_{initial}) (seeds m^{-2}). The number of mature plants of genotype i in year n (P_imt_n) is defined by equation 1:

$$P_imt_n = (P_ist_n + P_iat_n)\ \ Ps{\rightarrow}g\ Pg{\rightarrow}e\ P_ie{\rightarrow}m, \quad (1)$$

where P_ist_n is the weed seedbank of genotype i in year n, P_iat_n is weed seed of genotype i added to the seedbank as part of the sowing operation in year n, $Ps{\rightarrow}g$ is the fraction of the weed seedbank which germinates, and $Pg{\rightarrow}e$ and $P_ie{\rightarrow}m$ are transition probabilities for individuals becoming established seedlings and mature plants respectively.

Total seed production (P_{sp}) is calculated in a separate competition submodel (see below). The total amount of seed of each genotype that is returned to the soil seedbank at the end of the growing season ($P_is_{\text{new}}t_n$) is the product of total seed production of genotype i in year n ($P_i\text{sp}t_n$) and the fraction of seed produced that reaches the seedbank ($P_{\text{sp}}{\rightarrow}s_{\text{new}}$).

The weed seedbank at the start of the following year (P_ist_{n+1}) is calculated as

$$P_ist_{n+1} = \{[1 - Ps{\rightarrow}g(P_ist_n + P_iat_n)](1 - Ps{\rightarrow}r_{\text{winter}}) + P_is_{\text{new}}t_n\}(1 - Ps{\rightarrow}r_{\text{summer}}), \quad (2)$$

where $Ps{\rightarrow}r_{\text{winter}}$ and $Ps{\rightarrow}r_{\text{summer}}$ are the fractions of ungerminated weed seeds lost from the seedbank during winter and summer respectively.

Crop/weed competition submodel

Competition between crops and weeds is simulated using a modified version of the hyperbolic function used by Firbank and Watkinson (1986):

$$P_{\text{sp}} = \frac{Pm\ P_{\text{sp max}}\ kP}{1 + (Pm\ kP) + (P'mk\ P'\ A)}, \quad (3)$$

where Pm is the number of mature weed plants, $P'm$ is the number of crop plants, $P_{\text{sp max}}$ is the potential maximum seed production of the weed per unit area, kP is the weed plant size coefficient, the inverse of the weed density (Pm) at which seed production is half of the predicted maximum ($P_{\text{sp max}}$), kP' is the crop plant size coefficient and A is the interspecific antagonism of the weed species by the crop.

Population genetics submodel

The model tracks the frequencies of herbicide-susceptible and resistant alleles at two discrete, independently segregating loci. The two loci confer resistance to two hypothetical herbicides, designated Y and Z, with different modes of action. Both loci are diallelic with the susceptible wild type alleles designated by lower case letters (y and z) and the initially rare mutant resistant alleles by upper case (Y and Z). Resistance alleles are specified as dominant. The model accounts for the frequency of nine genotypes within a single weed population (P_{YYZZ}, P_{YYZz}, P_{YYzz}, P_{YyZZ}, P_{YyZz}, P_{Yyzz}, P_{yyZZ}, P_{yyZz} and P_{yyzz}).

The initial weed population size is the product of the initial seedbank density (Ps_{initial}) and the area (m^2). The initial frequencies of resistant alleles Y and Z are defined as f_{Y} and f_{Z}, respectively, and alleles, assumed initially to be in Hardy–Weinberg equilibrium, are explicitly accounted thereafter.

Extinction

To avoid anomalous results resulting from fractional numbers of plants, the model represents small populations as integer values. Where less than 10 individuals of any genotype are calculated to occur at any stage of the life cycle, an integer number of individuals is derived assuming that the calculated weed density is a probability of occurrence in a Poisson process (Vose, 2000). Where 10 or more individuals are expected, the probability that an extinction event would occur in a Poisson process is less than 1 in 20 000. If the populations of all genotypes that contain any particular allele are resolved to 0 at any time then that allele is considered extinct and will remain extinct unless it is reintroduced as a contaminant during sowing. Random numbers conforming

to Poisson distributions were generated using the Stella simulation software with sequences of random numbers seeded using the system clock. Because the extinction process is effectively random, repeated runs of the model with identical parameters will produce different outcomes.

Mating

Resistance alleles segregate independently. The fraction of self-pollination in the weed species can vary between 1 (autogamous) and 0 (allogamous). The frequencies of pollen haplotypes for each plant genotype are the averages of the frequencies for that plant genotype and the frequencies for the total plant population weighted according to the self-pollination fraction. Ovules and pollen are produced in direct proportion to predicted seed yields and all gamete haplotypes have an equal chance of reproductive success (pollination, embryo development and seed maturation).

Pollen and ovule haplotypes recombine at random to produce diploid zygotes that develop into mature seed. The simplifying assumption of random recombination within the weed population is common to existing models that assume infinite populations, but it is inaccurate because of uneven spatial distribution of genes within the population. This assumption of random recombination becomes less realistic as the simulated area becomes greater, and it will tend to result in an overestimation of the rate that resistant alleles multiply after multi-resistant individuals develop. However, once resistance has developed it is reasonable to assume that it will eventually spread throughout the population. The randomness of recombination does not influence the probability that rare alleles will be present in finite populations and hence it should have minimal influence on the probability that resistance will develop initially.

Parameter values

Weed management practices, together with intrinsic population processes (mortality, loss of viability and competition), act in conjunction to regulate weed population dynamics and ultimately, weed densities in the field. In the model, these processes are defined by the parameters that affect the probability of any individual moving from one life history stage to the next (e.g. from germinated seeds to established seedlings). These parameters have been adapted from those presented by Pannell *et al.* (2003) to approximate conditions and management typical of wheat grown in the cropping belt of Western Australia.

All parameter values are constant for all genotypes of the weed except for the probability that established seedlings will become mature plants ($P_l e \rightarrow m$), which is affected by application of post-emergence herbicides. The values for all constant parameters are given in Table 1. The probability that established seedlings will become mature plants ($P_l e \rightarrow m$) is the product of the probabilities that plants will survive application of herbicides Y and Z ($P_l e \rightarrow m_Y$ and $P_l e \rightarrow m_Z$ respectively). The probabilities of genotypes surviving when herbicides are applied are presented in Table 2. Where herbicides are not applied $P_l e \rightarrow m$ is 1.

We have chosen not to include density-dependent mortality of plants because we anticipate that plant densities will typically be low while herbicides are still effective. For this reason, density-dependent mortality is unlikely to be an important factor in the dynamics that affect initial development of herbicide resistance.

Table 1 Descriptions, variable names, values and units for constant parameters

Parameter description	Variable name	Value	Unit
Density of crop plants	$P'm$	100	plants m^{-2}
Initial weed seedbank	$Ps_{initial}$	100	plants m^{-2}
Initial frequency of allele for resistance to herbicide Y	f_Y	10^{-6}	
Initial frequency of allele for resistance to herbicide Z	f_Z	10^{-6}	
Annual import of unselected weed seed	Pat_n	0.1	plants m^{-2}
Fraction of weed seedbank lost in winter	$Ps \rightarrow r_{winter}$	0.1	
Fraction of weed seedbank lost in summer	$Ps \rightarrow r_{summer}$	0.1	
Fraction of germinated seed that establishes as seedlings	$Pg \rightarrow e$	0.2	
Fraction of seed produced on weeds that reaches the seedbank	$P_{sp} \rightarrow s_{new}$	1	
Maximum viable weed seed production	$P_{sp\ max}$	30000	plants m^{-2}
Weed plant size coefficient	kP	0.04	m^2 $plant^{-1}$
Crop plant size coefficient	kP'	0.09	m^2 $plant^{-1}$
Crop/weed antagonism parameter	A	1.3	

Table 2 Probabilities that plants of specified genotypes will survive applications of herbicides Y and Z

Genotype for gene Y	yy	Yy	YY
Value of $P_e \rightarrow m_Y$ when herbicide Y is applied	0.05	1	1
Genotype for gene Z	zz	Zz	ZZ
Value of $P_e \rightarrow m_Z$ when herbicide Z is applied	0.05	1	1

Accuracy of the model is less important in circumstances where herbicide resistance has already developed and weeds have reached high densities. Such situations are unlikely to occur in practice as farming would not be profitable and farmers would alter their practices accordingly.

Plant life history strategies

Four contrasting plant types were specified for the weed population. These plant types were combinations of high and low germination fraction ($Ps \rightarrow g = 0.9$ or 0.1) and high and low self-pollination fraction (0.99 or 0). All constant weed related parameters have been chosen to approximate *Lolium rigidum* Gaud. (annual ryegrass), which is cross-pollinated and has a high germination fraction similar to that specified above.

Herbicides and herbicide use patterns

In all simulations two herbicides (Y and Z) were available for post-emergence control of the weed population. Both herbicides achieve 95% control of susceptible individuals (see Table 2), they have distinct modes of action and cannot be degraded by a common metabolic pathway (there is no potential for evolved cross-resistance to both herbicides). In the absence of herbicide application there is no fitness penalty associated with resistance to either herbicide. Fitness penalties associated with target-site resistance to the triazine herbicides have been documented in a number of weed species. However, the results for resistance to all other herbicide modes of action have been more equivocal (Holt & Thill, 1994).

Three patterns of herbicide application were defined. These were:

Rotation strategy: Herbicides Y and Z were applied in alternate years beginning with Y in the first year.

Threshold strategy: Herbicide Y was applied in all years until the frequency of the Y resistance allele (Y) exceeded a threshold value of 0.01, after which point Z was applied until the frequency of the Z resistance allele (Z) exceeded the same threshold, whereafter whichever herbicide had the lowest fraction of resistance was applied. Please note that we are using this term in a non-standard way to refer to thresholds of frequencies of resistance alleles rather than thresholds of weed density.

Combination strategy: Both herbicide Y and Z were applied in all years. There were no antagonistic or synergistic interactions between the two herbicides. It is important to note that this strategy involves application of more herbicide than does either of the other two strategies.

For each plant type in combination with each herbicide application strategy 32 repeated 50-year simulations were conducted for each of 19 treatment areas ranging from 10^2 m^2 to 10^8 m^2 on a log scale.

Results

Each model run results in a time series of populations of the nine genotypes. For simplicity these can be identified as four phenotypes: susceptible to both herbicides (yy zz); resistant to Y only (yY zz and YY zz); resistant to Z only (yy zZ and yy ZZ); resistant to both Y and Z (yY zZ, YY zZ, yY ZZ and YY ZZ).

While each of the runs is unique due to stochastic processes, runs that gave similar results can be grouped according to the characteristic dynamics of the populations (seedbanks). For each of the 32 runs of the model for each combination of plant type by herbicide strategy at each treatment area, three outcomes were possible: no resistance develops; resistance develops to a single herbicide; resistance develops to both herbicides.

For example, the outcrossing high germination fraction plant type produced eight typical patterns of seedbank behaviour (Fig. 2). Where no resistance developed the population steadily declined (Fig. 2A and B). This decline was typically more rapid where the herbicides were used in combination (Fig. 2C).

Where herbicides were used in rotation and resistance developed to either of the two herbicides, the population of resistant plants increased exponentially and exceeded the population of susceptible plants at around year 10 (Fig. 2D). From that time the population of resistant plants increased rapidly until stabilizing at numbers in excess of 10 000 seeds m^{-2}. There was also a transient increase in the population of susceptible plants as a consequence of recombination amongst the progeny of heterozygous resistant plants (i.e. yY or zZ). The population of susceptible plants ultimately fell as the frequency of the susceptible allele (i.e. y or z) declined.

In cases where a single resistance emerged under the threshold strategy, control of the population was maintained by the use of the alternate herbicide, with the population of resistant plants remaining below 10 plants m^{-2} (Fig. 2E).

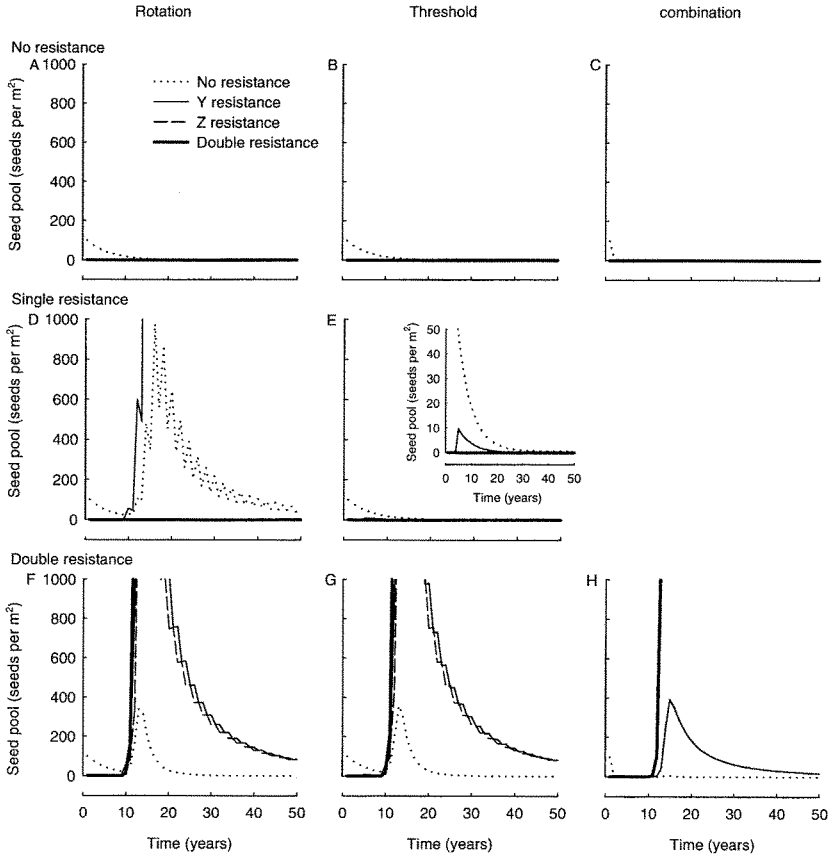

Fig. 2 Selected examples of typical time series of seed pool size for the four phenotypes of the plant type with 0.9 germination fraction and 0 self-pollination fraction for the three classes of developed resistance (rows) for each of the patterns of herbicide use (columns). The probabilities of these typical outcomes vary with treatment area (see Figs 4 and 5).

In all cases where double-resistance developed, the population of double-resistant plants increased rapidly from about year 10 (Fig. 2F–H). Transient increases in the populations of the other three genotypes occurred in response to the recombination effects as described for single resistance (Fig. 2D).

Variations occurred in the timing of development of resistance. In general, resistant populations increased more slowly where the germination fraction was low (0.1) (data not shown). For all types of resistance there were examples where build up of resistance was delayed. An example illustrating development of double-resistance with delayed occurrence of Z resistance is shown in Fig. 3. Delayed resistance of this sort occurred where resistance genes in the initial population became extinct but were reintroduced in contaminant seed.

All model runs were categorized according to the highest resistance status attained by the population during the simulated 50-year period, namely: no resistance; Y resistance only; Z resistance only; and double-resistance. The relative frequencies of these categories

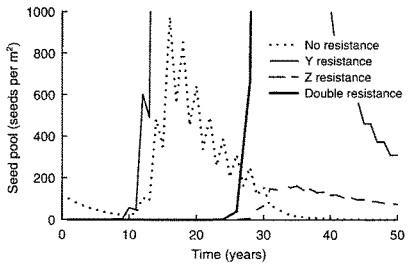

Fig. 3 An example time series of seed pool size for the four phenotypes of the plant type with 0.9 germination fraction and 0 self-pollination fraction illustrating development of double-resistance where Z resistance is delayed. Herbicides were applied in rotation with a 21.4 ha treatment area.

varied in response to the treatment area (≡ initial population size).

For the cross-pollinated plant type with high germination fraction (0.9) for all herbicide use patterns, development of resistance was rare in the smallest treatment areas (Fig. 4). As the area increased, the frequency of single resistances and, subsequently, double-resistance increased. This trend occurred because the probability of extinction of resistance genes decreases as area (≡ initial population size) increases.

The relationship between probability that no resistance would occur and area treated was very similar where herbicides were applied in rotation or according to the threshold strategy (Fig. 4A). In both cases resistance always occurred in some form in treatment areas larger than 20 ha. Where herbicides were used in combination, resistance became frequent only in much larger areas. A treatment area in the order of 100 times larger was required to produce similar probabilities of development of resistance (Fig. 4A).

Where herbicides were applied in combination, resistance to either Y or Z alone did not occur because plants with resistance to only one herbicide were adequately controlled by the other herbicide. Consequently, only populations of double-resistant plants were able to increase. Resistance to herbicide Z alone did not occur where the threshold strategy was used (Fig. 4B). This is because according to this strategy herbicide Z was only applied after resistance to herbicide Y had developed.

Where herbicides were applied in rotation, Y resistance tended to occur more frequently than Z resistance because Y was the first herbicide applied in the rotation (Fig. 4B). Consequently the population initially treated by Z was reduced, increasing the probability of extinction of the Z resistance allele.

The relationship between probability of occurrence of resistance and treatment area was broadly similar for all plant types, but the relative effect of using herbicides in combination was larger for plant types with lower germination fraction or higher fraction of self-pollination. For self-pollinated weeds with a high germination fraction, a treated area in the order of 1000 times larger was required to produce similar probabilities of development of resistance for herbicides used in combination vis-à-vis the other strategies (Fig. 5A). This factor was greater than 10 000 times for weeds with low germination fraction (Fig. 5D and G). In the case of self-pollinated weeds with low germination fraction

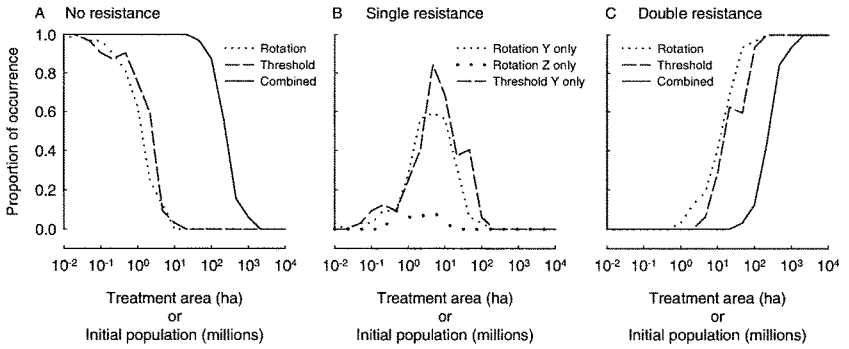

Fig. 4 Proportion of simulation runs where no resistance occurred (A), where resistance to a single herbicide type occurred (B) or where resistance to both herbicide types occurred (C) versus treatment area (≡ initial population size) for the plant type with 0.9 germination fraction and 0 self-pollination fraction.

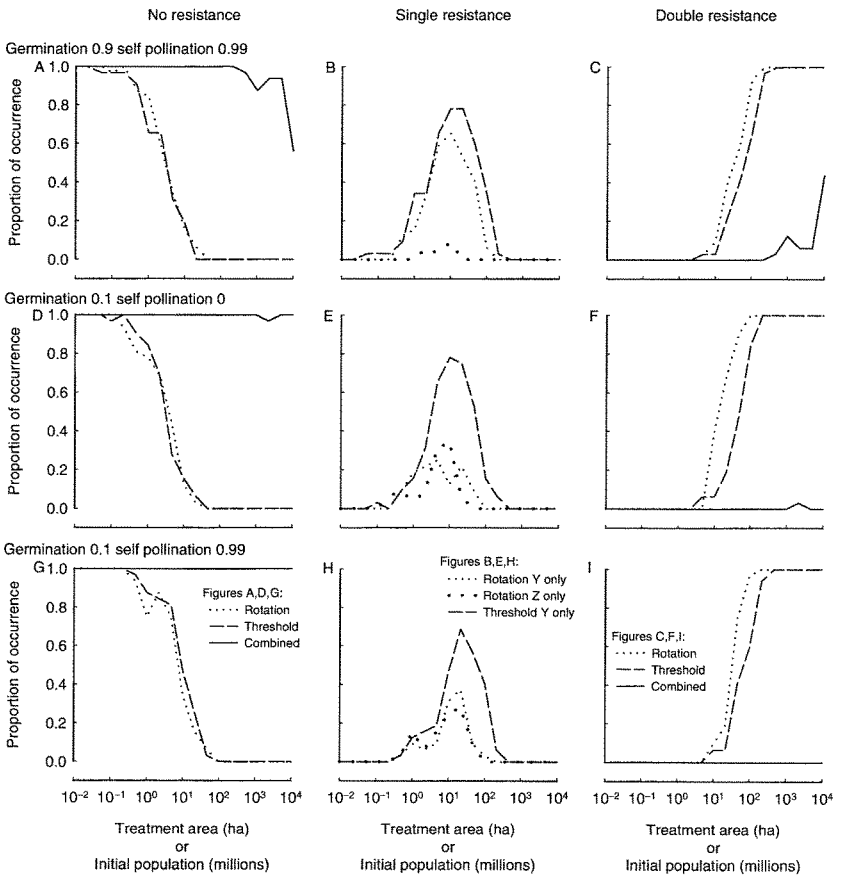

Fig. 5 Proportion of simulation runs where no resistance occurred (A, D and G), where resistance to a single herbicide type occurred (B, E and H) or where resistance to both herbicide types occurred (C, F and I) versus treatment area (≡ initial population size) for three plant types (in rows).

herbicide resistance was never observed where herbicides were used in combination (Fig. 5G).

Where herbicides were applied in rotation, germination fraction had an effect on the relative frequencies of the two types of single resistance. Where germination fraction was low a smaller fraction of the population was exposed to Y in the first year, hence the probability of extinction of the Z resistance allele was reduced and the frequency of Z resistance was higher (Fig. 5E and H versus Fig. 5B).

For all plant types the transition from single resistance to double-resistance occurred at marginally larger treatment area under the threshold strategy than under the rotation strategy (Figs 4C, 5C, F and I).

Under all strategies the transition to increased levels of resistance occurred at marginally larger areas for self-pollinating plant types than for outcrossing plant types (Fig. 4A–C versus 5A–C and 5D–F versus 5G–I). This is due to the decreased incidence of heterozygous-resistant individuals in populations of self-pollinated plants.

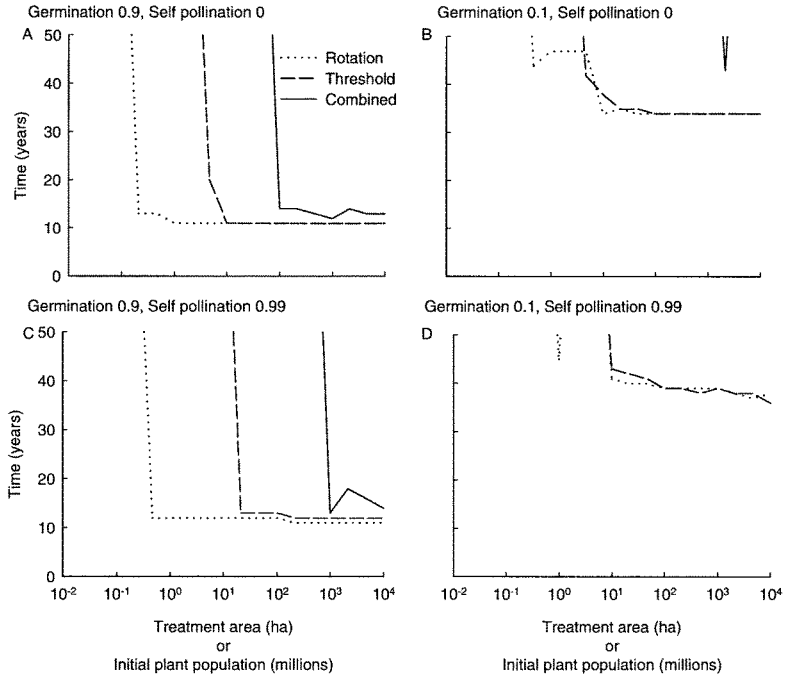

Fig. 6 Year of the time series where the average size of the weed seed pool for all replicate simulation runs exceeded 1000 seeds m^{-2} versus treatment area (≡ initial population size) for the three patterns of herbicide application for the four plant types in separate figures.

The timing of appearance of large populations (indicating the development of resistance) differed markedly between the plant types with high and low germination fractions (Fig. 6). The time taken for the seedbank to exceed 1000 seeds m^{-2} was approximately three times greater in low germination fraction types than in the high germination fraction types (Fig. 6A versus 6B and 6C versus 6D). Where germination fraction is lower a smaller proportion of the population is exposed to herbicides in each year, effectively slowing the rate of resistance evolution in those populations.

At small treatment areas, where resistance generally did not develop, the mean populations never exceeded 1000 seeds m^{-2}. The minimum treatment area where the seed pool did exceed this value was lowest where herbicides were used in rotation and highest where they were used in combination.

For large treatment areas for all plant types the increase in seedbank was equally rapid for the rotation and threshold strategies. In the high germination fraction populations the increase in plant population was only marginally slower where herbicides were used in combination (Fig. 6A and C). In low germination fraction populations the mean seed pool generally did not reach 1000 seeds m^{-2} under the combination strategy (Fig. 6B and D).

Discussion

The importance of population size in relation to rare genes

The first major conclusion from this study is that minimizing the effective weed population size substantially decreases the rate of evolution of herbicide resistance. Clearly, the smaller a population is, the less likely it is that rare resistance genes will be present in the population. Even where resistance genes do occur at low frequencies in small populations, stochastic demographic processes are more likely to result in the extinction

of these genes. When considering two resistance genes, as we have simulated here, the probability of both genes occurring in the same individual is orders of magnitude smaller again. Management practices that effectively segregate weed populations into smaller, genetically isolated units will, therefore, result in a lower incidence of herbicide resistance.

The degree to which weed populations can be segregated and contained will depend in large part on the movement of genes in pollen and seeds or propagules. Gene flow in pollen is something over which land managers have little or no control. However, Maxwell (1992) showed that only 7% of pollination events occurred at distances greater than 1 m in diclopfop-methyl-resistant *Lolium multiflorum* Lam. Rieger *et al.* (2002) have shown that pollen-mediated gene flow from herbicide-resistant to non-herbicide-resistant oilseed rape (*Brassica napus* L.) crops does occur over considerable distances, but only at very low frequencies. Where a weed species has a high degree of outcrossing and viable pollen can travel long distances from source populations, the goal of genetic isolation may be unattainable.

Gene flow by seed movement is a factor that land managers can influence because for many agricultural weeds farm management largely dictates mobility of the seed. Through strict farm hygiene, land managers can limit the importation of weed seed to a farm, the movement of seed between fields on a farm and movement of seed within fields. This may involve improved screening of seed and fodder brought on to the farm to ensure it is free of weeds; the cleaning of machinery between segregated areas; and the catching of weed seeds during the grain harvest so that they are not redistributed. The situation is analogous in many ways to that of a newly invading weed species, except that in this case the 'invading weed' is not visually distinguishable from the existing weed population. Management strategies that reduce rate of movement of the weed would be expected to increase the time until herbicide resistance becomes a problem in areas where resistant individuals were initially absent.

The importance of pattern of herbicide application

A second major conclusion is that rotation of herbicides, commonly recommended as a strategy to delay the development of herbicide resistance in weeds (Powles & Shaner, 2001), is markedly inferior to the use of herbicides in combination, and is not superior to an 'expend and swap' approach typified by the threshold strategy discussed here. This conclusion is contingent on the validity of the first conclusion and on the assumptions made, i.e. that both herbicides achieve efficacy that is high enough to ensure 'redundant kill' (are used at full rates), are not subject to linkage disequilibrium, are not associated with fitness costs and have different modes of action (no cross-resistance).

For large effective areas (population size) there is very little effect of pattern of herbicide application. However, for effective areas less than 100 ha, there was a marked advantage in using the 'combination' strategy in all scenarios tested here. The range of initial populations for which the combination strategy was superior varied markedly with germination fraction and degree of self-pollination in the weed, but it is likely that an effective initial population within this range is achievable for most agricultural weeds, particularly where initial population density is low and where the weed is self-pollinated. The utility of pesticide mixtures as opposed to a threshold approach has been similarly demonstrated for insecticide resistance management (Mani, 1985). However, Comins (1986) qualifies this 'redundant kill' strategy by indicating that it will only be effective where population size is small. The results presented in this paper agree with these conclusions.

It must be noted that the combination strategy has disadvantages that should be considered before deciding to use it in practice. Two of these disadvantages are the cost and the possible ecological implications of using more herbicide. Furthermore, the cost of using more herbicide is immediate, while the returns from delayed occurrence of herbicide resistance will be realized in the future and hence, by classic economic theory, will be reduced in terms of present value.

Another factor that must be considered is that the combination strategy requires farmers to apply two herbicides to control a weed even when the density of that weed is extremely low. Such a strategy could be considered counter intuitive. However, in Western Australia, where many farmers have first hand experience with herbicide resistance in weeds which are difficult to control, a form of the combination strategy is currently recommended to delay the occurrence of glyphosate resistance (Neve *et al.*, 2003).

Previous modelling of herbicide use strategies that have assumed infinite population sizes (which are analogous to the largest population sizes simulated here) have considerably underestimated the benefits of herbicide mixtures and sequences as management tools to prevent or delay herbicide resistance. Such models do not account for the strategically important possibility of local extinction of rare alleles. While the methodology we have used does not explicitly simulate spatial processes, the results do indicate that a quantitative understanding of the spatial dynamics of resistance genes is very important to a fuller understanding

of evolution of herbicide resistance. Improved quantitative understanding of the spatial dynamics could be achieved by embedding a model similar to the one presented here in a spatial framework such as that presented by Richter *et al.* (2002) for the one gene case. With the model presented here it appears highly likely that the rate of development of herbicide resistance can be limited by reducing movement. Furthermore, where movement can be limited, a strategy that uses herbicides in combination would be superior to rotation of herbicides in terms of rate of evolution of resistance.

Feature

Predicting the Evolution and Dynamics of Herbicide Resistance in Weed Populations[1]

BRUCE D. MAXWELL, MARY LYNN ROUSH, and STEVEN R. RADOSEVICH[2]

Abstract. Herbicide resistance jeopardizes the usefulness of valuable chemical tools and, therefore, weed management in many crop systems. Models must be developed to evaluate management tactics that prevent, delay, or reduce resistance. The complexity of biological processes involved in herbicide resistance also requires models to focus research and to integrate experiments. A population model was developed that improves upon previous attempts to predict herbicide resistance dynamics. The model incorporates plant population demographics with the Hardy-Weinberg concept for gene segregation. The model simulates the evolution, spread, and subsequent dynamics of resistance in the presence and absence of a herbicide. Analysis of model simulations identified two sets of biological processes as key factors in the evolution and dynamics of herbicide-resistant weed populations. These are processes that influence ecological fitness and gene flow. Several options are suggested as examples for the management of resistant weed populations.
Additional index words: Population model, resistance management, seed immigration, pollen immigration, population genetics.

INTRODUCTION

Herbicides are used extensively in agriculture because they are cost-effective tools to reduce weed abundance and to improve crop yields. Recent trends in herbicide development have produced extremely specific and selective chemicals that are used intensively and routinely in cropping systems. The intensive and widespread use of such herbicides has precipitated an alarming increase in the evolution of resistance (9, 15, 28), which jeopardizes product usefulness, availability, and longevity (15). Since the first reported cases of herbicide resistance (26, 27, 30), over 50 plant species resistant to triazine herbicides have been reported (25). In addition, numerous weed species have developed resistance to chemical classes of herbicides other than triazines (13, 22, 33, 35).

The complexity of biological processes that influence herbicide resistance dictates a research approach that focuses on the interaction between life history processes and population genetics. Models can serve such a function and can provide a tool for evaluating management tactics. Review papers on the population biology of pesticide resistance have indicated similar approaches for studying and managing resistance (7, 19, 29, 34, 36, 37). Gressel and Segel (10, 11) developed a model that suggested important factors that influence occurrence and evolution of herbicide resistance. However, their model did not include the gene flow processes of immigration and important factors influencing fitness that may improve prediction of local evolution, spread, and subsequent dynamics of the R[3] trait in a S[3] population of weeds.

Population processes that determine the relative fitness of phenotypes are survivorship (demography of seeds, seedlings, and mature plants), fecundity (pollen and seed production), and plant competition. When a herbicide is used, its selection pressure (reduced survivorship of susceptible individuals) overwhelmingly increases the relative fitness of the resistant genotype (10, 11). However, when herbicide selection pressure is removed, population dynamics are determined by differences in all processes that contribute to the fitness of each biotype.

We have developed a population model that simulates the evolution, spread, and dynamics of R and S weed biotypes (Figure 1 and Table 1). This model improves upon the biological interpretations suggested by Gressel and Segel (10, 11) and provides a refined approach for evaluating the importance of specific biological processes involved in the dynamics of herbicide resistance. The model combines plant population demographics (18, 21) and the Hardy-Weinberg equation (2, 3) to determine proportions of R and S genotypes in successive generations.

[1]Received for publication July 5, 1989, and in revised form Oct. 25, 1989.
[2]Res. Asst., Res. Assoc., and Prof., Dep. For. Sci., Oreg. State Univ., Corvallis, OR 97331.
[3]Abbreviations: R, herbicide resistant; S, herbicide susceptible.

Many herbicides inhibit a specific enzyme that can be coded for by a single gene; thus, use of the Hardy-Weinberg inheritance model is a reasonable approach. The model incorporates differential fitness (i.e., survivorship, competitive ability, and fecundity) of R and S genotypes in the presence and absence of a herbicide (selection pressure). Genotype proportions also are modified by gene flow (i.e., immigration, seed bank dynamics, inbreeding, and random genetic drift) and by mutation.

Simulations using this model predict rapid early evolution of resistance from repeated herbicide applications in the absence of an adjacent source population of the S phenotype (Figure 2). After herbicide use is suspended, the model forecasts a decline in resistance with return to populations dominated by the S type. The rate of decline in resistance depends on life-history processes, immigration processes, mechanisms of inheritance, reproductive mechanisms, and the relative fitness of the R and S phenotypes.

MODEL DEVELOPMENT

The model, like earlier herbicide resistance models (8, 10, 11), is theoretical. It was developed to generate hypotheses on the influence of demographic and inheritance processes on resistance evolution and management. The simulation model was constructed by linking eight submodels representing life-history stages (seed bank, seedling, mature plants, pollen producers, seed yield), immigration, and inheritance (Figure 1). This structure allows alternative submodels to be inserted and tested as new information on particular processes becomes available.

The current model assumes for mathematical simplicity that the weed is a single-cohort (one germination time) annual, that all parameters are held constant over time unless indicated otherwise (Table 1), and that herbicide resistance is associated with a single gene locus. Thus, it is assumed that herbicide resistance is determined by a single pair of alleles, where **a** denotes the recessive allele and **A** the dominant allele. The computer model allows the user to select (Figure 3) if the genotype **aa**, the homozygous recessive, results in the R phenotype and **AA** and **As** represent S phenotype plants or if **aa** results in the S phenotype and **AA** and **Aa** are R. Throughout this paper the **aa** genotype was assumed to confer resistance. The model will allow for different inheritance patterns by inserting a different inheritance submodel. A separate description of each submodel follows.

Seed bank submodel. The number of R and S weed seed in the seedbank was assumed to be a function of seed mortality and germination rates for each phenotype. This amount is supplemented by the number of seed entering the seedbank from the treated population and seed immigration.

The number of R and S seed in the seedbank before germination (RSB and SSB, respectively) is expressed as

$$RSB = RSB_{t-1} + Ryld_{t-1} + RISD_{t;\ -\ Rm}(RSB_{t-1}) \quad [2.1]$$

$$SSB = SSB_{t-1} + Syld_{t-1} + SISD_t - S_m(SSB_{t-1}) \quad [2.2]$$

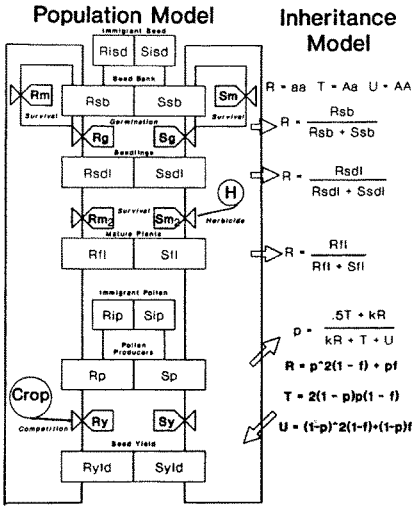

Figure 1. A representation of the model that follows life-history sages of resistant and susceptible biotypes and incorporates the influences of fitness processes and gene flow. Open arrows indicate the flow of information between the population model and the inheritance model. State variables are named above each box and processes are indicated in italics. Abbreviations are explained in the text and Table 1.

Table 1. Definitions used in the development of the herbicide resistance model (see Figure 1).

Parameter	Definition and default values	Equation number
t	Current generation	
Immigration parameters		
a_{sd}	The number of pollen-produced per unit area by the source population. a_{sd} = TOT = model input value (Figure 5).	1.1
a_p	The number of pollen-producing plants per unit area representing the total amount of pollen produced by the source population. $a_p = a_{sd}/10$. 5.1	
x′	The distance from the center of the source population to the center of the treated population.	1.1 & 5.1
c_s	The radius of the total source area (Figure 4).	1.1 & 5.1
c_o	The radius of the interior source population that is equal to the treated population radius (0.5) (Figure 4).	1.1 & 5.1
c	The square root of the scaling factor $[c = (c_s^2/c_o^2)^{\frac{1}{2}}]$ (Figure 4).	
bp	The steepness of the diffusion gradient for pollen (1.7).	5.1
bsd	The steepness of the diffusion gradient for seed (7.4).	1.1
Demographic parameters		
RSB	The number of R seed in the seed bank before germination.	2.1
SSb	The number of S seed in the seed bank before germination.	2.2
R_m	The proportion of R seed that die over 1 generation in the seed bank (0.7).	2.1
S_m	The proportion of S seed that die over 1 generation in the seed bank (0.7).	2.2
ISD	The total number of seed added to the seed bank through immigration over 1 generation.	1.1
RISD	The number of immigrant seed that is R-phenotype.	2.1
SISD	The number of immigrant seed that is S-phenotype.	2.2
R_g	The proportion of R seed that germinate over 1 generation (0.3).	2.3
S_g	The proportion of S seed that germinate over 1 generation (0.3).	2.4
RSDL	The number of R seedlings produced from seed germinating in the seed bank.	3.1
SSDL	The number of S seedlings produced from seed germinating in the seed bank.	3.2
R_{m2}	The proportion of R seedlings that die over 1 generation (0.75).	3.3
S_{m2}	The proportion of S seedlings that die over 1 generation (0.75).	3.4
RFL	The number of R mature (flowering) plants.	4.1
SFL	The number of S mature (flowering) plants.	4.2
h	Herbicide efficacy on seedlings (95%).	4.2
IP	The total number of pollen-producing plants represented by immigrant pollen.	5.1
RP	The number of R pollen-producing plants represented by immigrant pollen.,	6.1
SP	The number of S pollen-producing plants represented by immigrant pollen.	6.2
TM	The total number of mating plants.	7.7
TMr	The number of mating plants that will produce R seed.	7.8
TMs	The number of mating plants that will produce S seed.	7.9
RY	The number of R seed produced per R plant.	8.1
SY	The number of S seed produced per S plant.	8.2
Ryld	The R seed yield per unit area.	8.3
Syld	The S seed yield per unit area.	8.4
Tyld	The seed yield per unit area with genotype Aa.	2.7
Inheritance parameters		
Rsb	The proportion of the seed bank that is R-phenotype.	2.5
Tsb	The proportion of the seed bank that is Aa genotype.	2.7
Usb	The proportion of the seed bank that is Aa genotype.	2.8
Ssb	The proportion of the seed bank that is S-phenotype.	2.6
Rsdl	The proportion of seedlings that are R-phenotype.	3.5
Tsdl	The proportion of seedlings that are Aa genotype.	3.7
Usdl	The proportion of seedlings that are AA genotype.	3.8
Ssdl	The proportion of seedlings that are S-phenotype.	3.6

(continued)

Table 1. (continued) Definitions used in the development of the herbicide resistance model (see Figure 1).

Parameter	Definition and default values	Equation number
Inheritance parameters		
Rfl	The proportion of mature (flowering) plants that are R-phenotype.	4.3
Tfl	The proportion of mature (flowering) plants that are Aa genotype.	4.5
Ufl	The proportion of mature (flowering) plants that are AA genotype.	4.6
Sfl	The proportion of mature (flowering) plants that are S-phenotype.	4.4
Rof	The proportion of R pollen-producing plants in the outside (source for immigration) population.	1.2
Sof	The proportion of S pollen-producing plants in the outside (source for immigration) population.	1.3
Tof	The proportion of pollen-producing plants with Aa genotype in the outside (source for immigration) population.	2.7
Rp	The proportion of R pollen-producing plants in the treated population.	6.3
Sp	The proportion of S pollen-producing plants in the treated population.	6.4
Tp	The proportion of pollen-producing plants with Aa genotype in the treated population.	6.5
Up	The proportion of pollen-producing plants with AA genotype in the treated population.	6.6
p	The probability of an individual's donating the a allele in a mating.	7.1
kr	The fitness of the R pollen relative to the S pollen (0.9).	7.1
f	The inbreeding coefficient.	7.5
m	The forward mutation rate to resistance (10^{-6}).	7.5
Ne	The effective size of the population (related to the number of reproducing adults).	7.6
R	The proportion of the total matings that will produce R seed.	7.2
T	The proportion of the total matings that will produce seed with Aa genotype.	7.3
U	The proportion of the total matings that will produce seed with AA genotype.	7.4
S	The proportion of the total matings that will produce S seed.	7.4
RY_{max}	The maximum yield per R plant (900 seeds/plant).	8.1
SY_{max}	The maximum yield per S plant (1000 seeds/plant).	8.2
a_r	The area required to produce RY_{maxi} (1).	8.1
a_s	The area required to produce SY_{maxi} (1).	8.2
z_{sr}	The influence of S plant density on the seed yield of R plants (1).	8.1
z_{rs}	The influence of R plant density on the seed yield of S plants (1).	8.2
z_{ir}	The influence of another weed or crop plant (i) density on the seed yield of R plants (1.2).	8.1
z_{is}	The influence of another weed or crop plant density on the seed yield of S plants (1.1).	8.2
N_i	The density of the other weed or crop (200 plants/m^2).	8.1 & 8.2
br	The coefficient which determines the form of the relationship between RY_t and the total density (0.8).	8.1
bs	The coefficient which determines the form of the relationship between SY_t and the total density (0.8).	8.2

where $Ryld_{t-1}$ is the number of R seed produced per unit area by the previous generation and $Syld_{t-1}$ is the number of S seed produced per unit area by the previous generation in the treated population. The mortality rates for R and S seed are R_m and S_m, respectively.

Seed immigration submodel. Immigration of genes has two points of origin: seed and pollen from outside the treated population. The immigration of seed from an outside population is treated as an influx into the seedbank. Pollen immigration enters the model in the pollen producer submodel. The proportions of genotypes immigrating from a source are assumed to be the same as the proportions in the source (outside field) population. Emigration was not included in the model.

Seed immigration is a function of dispersal which involves several variables: a) heights and distance of the seed source, b) concentration at the seed source, c) dispersibility of the seed (e.g., weight, possession of wings, plumes, etc.) and d) activity of distributing agents (e.g., wind direction and velocity) (12). These variables are generally species specific and require specific models. In the current model, seed immigration is based on a diffusion gradient model used to predict a plant disease gradient (24) and pollen dispersal (6).

$$ISD_t = (a_{sd} (x' + c_o)^{-bsd}) (c_s^2 / c_o^2) \quad [1.1]$$

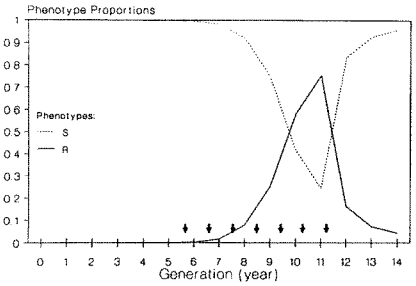

Figure 2. Model simulations describing the evolution of resistance when the herbicide is used in the system and the subsequent dynamics of resistance in the weed population after the herbicide has been removed. The solid arrows indicate the years of continuous herbicide use.

```
Mechanisms of Resistance Inheritance:
--------------------------------------

 1. Resistance is a recessive trait.

 2. Resistance is a dominant trait.

--------------------------------------

        Reproductive mechanism:
        ------------------------------------------------

         1. Outcrossing with 7 % selfing.

         2. Selfing with 7 % outcrossing.

        ------------------------------------------------

        Choose a number?
```

Figure 3. The first input screen for RSIM (the interactive computer program version of the model) used for selecting the mechanism of resistance inheritance and the reproductive mechanism for a weed species of interest.

$$RISD_t = ISD_t(Rof) \qquad [1.2]$$

$$SISD_t = ISD_t(Sof) \qquad [1.3]$$

ISD is the total number of immigrant seed per unit area entering the treated population seedbank from outside populations (Figure 4). The parameter a_{sd} is the number of seed produced per unit area at $1–c_o$ units of distance from the center of the source, which is equivalent to the total number of seed produced by the source when it is equal in size to the treated population. Since the source was assumed to be equal in size to the treated population, it was also assumed that the source would produce the same amount of seed as the treated population.

The x′ parameter is the distance (in treated population diameters) from the center of the source population to the center of the treated (receptor) population, and c_o is a truncation factor which approximates the radius of a source population (23) in the center of the total source that is equal in size to the treated population (Figure 4). Setting all measures relative to the size of the treated population allows for assessment of immigration at all scales. The parameter bsd is the slope of a linear regression of log(Isd) on $\log(x' + c_o)$. To accommodate immigrant sources larger or smaller than the treated population, a scaling factor (c^2/ c_o^2) was added to the immigration equation, where c_s is the total source (a set of source populations) area radius in units of treated population diameters.

The number of R and S seed reaching the treated population as a result of immigration are RISD and SISD, respectively. The proportions of each genotype in the outside (source) population are Rof (genotype **aa**), Tof (genotype **Aa**), and Uof (genotype **AA**). The proportion of the susceptible phenotype in the source population is Sof = Tof + Uof.

After germination the numbers of R and S seeds that remain in the seedbank until the next generation are

$$RSB_t = RSB - R_g(RSB) \qquad [2.3]$$

$$SSB_t = SSB - S_g(SSB) \qquad [2.4]$$

where R_g and S_g are germination rates for R and S seed.

The proportion of each genotype (Rsb = **aa**, Tsb = **Aa**, Usb = **AA**) in the seed bank at time t is calculated by

$$Rsb_t = \frac{RSB}{RSB + SSB} \qquad [2.5]$$

$$Ssb_t = \frac{SSB}{RSB + SSB} \qquad [2.6]$$

$$Tsb_t = \frac{Tsb_{t-1}\,(RSB_{t-1} + SSB_{t-1}) + Tyld_{t-1} + ISD_t\,(Tof)}{RSB + SSB} \qquad [2.7]$$

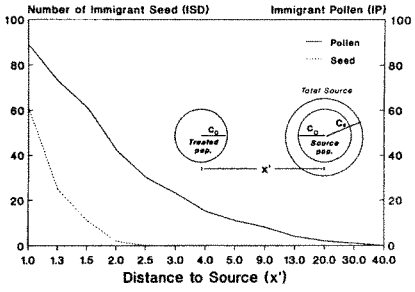

Figure 4. Pollen and seed dispersal as a function of distance (in units of treated population diameter) to a source population.

$$Usb_t = Ssb_t - Tsb_t \quad (2.8)$$

Rsb_t, Ssb_t, and Usb_t are the proportions of R phenotype (**aa** genotype), S phenotype, **Aa** genotype, and **AA** genotype, respectively, in the seedbank of the current generation. Tsb_{t-1} is the proportion of the heterozygous (**Aa**) genotype in the seedbank during the previous generation; $Tyld_{t-1}$ is the number of seed produced per unit area by the treated population in the previous generation that were the heterozygous (**Aa**) genotype.

Seedling submodel. The number of R and S seedlings (RSDL and SSDL, respectively) in the treated population at time t is calculated as follows:

$$RSDL = R_g(RSB) \quad [3.1]$$

$$SSDL = S_g(SSB) \quad [3.2]$$

where R_g and S_g are germination rates for R and S seed, respectively.

The number of seedlings of R and S phenotype that survive to become flowering plants is regulated by seedling mortality rates for the R (R_{m2}) and S (S_{m2}) phenotypes:

$$RSDL_t = RSDL(R_{m2}) \quad [3.3]$$

$$SSDL_t = SSDL(S_{m2}) \quad [3.4]$$

The proportion of seedlings of each genotype at time t are then calculated by

$$Rsdl_t = \frac{RSDL_t}{RSDL_t + SSDL_t} \quad [3.5]$$

$$Ssdl_t = \frac{SSDL_t}{RSDL_t + SSDL_t} \quad [3.6]$$

$$Tsdl_t = \frac{Tsb_t\ (Ssdl_t)}{Ssb_t} \quad [3.7]$$

$$Usdl_t = Ssdl_t - Tsdl_t \quad [3.8]$$

The parameters are defined in Table 1.

The current model includes the influence of the herbicide at the transition from the seedling to mature plant life-history stage. The effect of the herbicide on the weed population is based on its efficacy in S populations. The herbicide efficacy (h) is equivalent to the percent control relative to an untreated control plot of a S population.

Mature plant submodel. The number of R and S mature individuals in the population (RFL and SFL, respectively) at time t is equal to the number of seedlings in the population after accounting for the effect of the herbicide and R and S seedling mortality.

$$RFL_t = RSDL_t \quad [4.1]$$

$$SFL_t = SSDL_t - h(SSDL_t) \quad [4.2]$$

The proportions of each genotype at the mature stage are calculated as follows:

$$Rfl_t = \frac{RFL_t}{RFL_t + SFL_t} \quad [4.3]$$

$$Sfl_t = \frac{SFL_t}{RFL_t + SFL_t} \quad [4.4]$$

$$Tfl_t = \frac{Tsdl_t\ (Sfl_t)}{Ssdl_t} \quad [4.5]$$

$$Ufl_t = Sfl_t - Tfl_t \quad [4.6]$$

The parameters are defined in Table 1.

Pollen immigration submodel. The same equation that is used for seed immigration (Equation 1.1) is used for predicting pollen immigration but with different coefficients (a_p and bp). The immigration submodel has been adapted to predict the total number of pollen-producing plants (IP) represented by pollen reaching the treated population (Figure 4). It, therefore, is assumed that all the plants in the source population produce the same amount of pollen and that the proportions of immigrating R and S pollen are the same as the phenotype proportions of individual plants in the outside source population.

$$IP_t = (a_p\ (x' + c_o\ )^{-bp}\ )\ (c^2\ /\ c_o^2\ ) \qquad [5.1]$$

The a_p parameter is the number of pollen-producing plants per unit area at $1–c_o$ units of distance from the source population. This value is equivalent to the total number of pollen producers in the source population which is assumed to be the number of seed produced in the source population divided by a constant. The number of seed produced in the source is assumed to be equal to that produced in the treated population of the same size. The bp parameter is the slope of a linear regression of log(Ip) on $\log(x' + c_o)$. This parameter controls the steepness of the diffusion gradient which is a function of the pollen grain mass and shape as well as air flow properties. The other parameters are described in the seed immigration submodel (Equation 1.1) and in Table 1.

Pollen producer submodel. The total number of pollen producers for the treated population that are R (RP) and S (SP) at time t are calculated as

$$RP_t = Rfl_t(RFL_t + SFL_t - IP_t) + Rof(IP_t) \qquad [6.1]$$

$$SP_t = Sfl_t(RFL_t + SFL_t - IP_t) + Sof(IP_t) \qquad [6.2]$$

The proportions of pollen producers represented by each genotype are

$$Rp_t = \frac{RP_t}{RP_t + SP_t} \qquad [6.3]$$

$$Sp_t = \frac{SP_t}{RP_t + SP_t} \qquad [6.4]$$

$$Tp_t = \frac{Tfl_t\ (RP_t + SP_t\ ) - IP_t\ ) + Tof(Ip_t\ )}{RP_t + SP_t} \qquad [6.5]$$

$$Up_t = SP_t - Tp_t \qquad [6.6]$$

The parameters are defined in Table 1.

Inheritance submodel. The probability (p) of an individual's donating the **a** allele in a mating is based on the proportions of each genotype at the pollen production stage. The fitness of the R pollen relative to the S pollen (k_r) is included in the equation.

$$p = \frac{0.5\ Tp_t\ + k_r\ R_{pt}}{k_r\ R_{pt} + T_{pt} + U_{pt}} \qquad [7.1]$$

The basic Hardy-Weinberg model is based on the assumption that populations are infinitely large and mating is random (panmictic). In populations of defined size or breeding behavior that are not random, there is a potential for inbreeding. The Hardy-Weinberg equation may be modified by inclusion of an inbreeding coefficient (32, 38). The following equations result:

$$R_{t+1} = p^2(1–f) + p(f) \qquad [7.2]$$

$$T_{t+1} = 2(1–p)(p)(1–f) \qquad [7.3]$$

$$U_{t+1} = (1–p)^2(1–f) + (1–p)(f) \qquad [7.4]$$

$$S_{t+1} = T_{t+1} + U_{t+1}$$

$$f = \frac{1–2\ m}{4\ N_e\ m–2m+1} \qquad [7.5]$$

In this equation m is the mutation rate which is fixed in the current model at 10^{-6}, which is in the range suggested by Georghiou and Taylor (7). N_e is the effective size of the population which is related to the number of reproducing adults and is calculated as follows when there are differences in the number of male (N_{em}) and female (N_{ef}) adults:

$$N_e = \frac{1}{0.25(1/\ N_{ef} + 1/N_{em}\ )} \qquad [7.6]$$

It is assumed that the male part of a plant population (pollen grains) far exceeds the number of female ovules. Therefore, N_{em} approaches 0 and N_{ef} is approximated by the number of seed produced per unit area by the treated population. The unit area thus defines the finite population size.

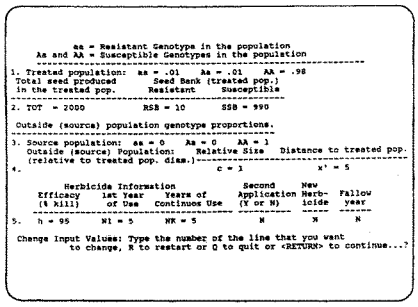
The proportions of each genotype proceeding into the next generation have been determined above. To calculate the number of seed representing each genotype, the number of total plants involved in mating first must be calculated; then the number of those matings that will represent production of each phenotype (R and S) is determined.

$$TM_t = RFL_t + SFL_t \quad [7.7]$$

$$TMr_t = R_{t+1}(TM_t) \quad [7.8]$$

$$TMs_t = S_{t+1}(TM_t) \quad [7.9]$$

TM_t is the total number of mating plants in the current generation. TMr_t and TMs_t are the number of mating plants that will produce seed with the R and S phenotypes, respectively.



Seed yield submodel. A competition model proposed by Firbank and Watkinson (5) was adapted to predict the seed yield for individual R and S plants. Separate equations for the R and S phenotypes account for differential competitive abilities. The influence of a crop and other weed species can be included in the model in addition to intra- and inter-phenotype competition.

$$RY_t = RY_{max}[1 + a_r(RFL_t + z_{sr}SFL_t + z_{ir}N_i)]^{-br} \quad [8.1]$$

$$SY_t = SY_{max}[1 + a_s(SFL_t + z_{rs}RFL_t + z_{is}N_i)]^{-bs} \quad [8.2]$$

RY_{max} and SY_{max} are the maximum yield per plant that can be attained by the R and S phenotypes, respectively. The areas required to attain R_{max} and SY_{max} are a_r and a_s, respectively. The inter-phenotype competition coefficient which expresses the influence of the S phenotype density on the R phenotype is z_{sr}. The inter-phenotype competition coefficient that expresses the influence of the R phenotype density on the S phenotype is z_{rs}. The inter-specific competition coefficients that express the influence of the crop or other dominant weed density on the R phenotype and the S phenotype are z_{ir} and z_{is}, respectively. N_i is the density of the crop or other dominant species in the system, and br and bs are the coefficients which determine the forms of the relationship between RY_t and SY_t and the total density, respectively.
