However, having also considered Mr. Rykowski's comments about the CAFE model's "effective cost" metric, and having conducted side-by-side testing documented in the accompanying FRIA, the agencies are satisfied that an alternative "cost per credit" metric is also a reasonable metric to use for estimating how manufacturers might selected among available options to add specific fuel-saving technologies to specific vehicles.¹⁵⁸ Therefore, NHTSA has revised the CAFE model accordingly, as discussed below in Section VI.A.4.

Section VI.C.1 also addresses Mr. Rogers's comments on engine maps used as estimates to full vehicle simulation. In any event, because engine maps are *inputs* to full vehicle modeling and simulation, the relative merits of specific maps provide no basis to prefer one vehicle simulation modeling system over another. Similarly, Section VI.B.3 also addresses Mr. Duleep's comments preferring EPA's prior approach, using ALPHA, of effectively assuming that a manufacturer would incur no additional cost by reoptimizing every powertrain to extract the full fuel economy potential of even the smallest incremental changes to aerodynamic drag and tire rolling resistance. Mr. Duleep implies that Autonomie is flawed because the NPRM analysis did not apply Autonomie in a way that makes such assumptions. The agencies discuss powertrain sizing and calibration in Section VI.B.3, and note here that such assumptions are not inherent to

¹⁵⁸ As discussed in the FRIA, results vary with model inputs, among manufacturers, and across model years, but compared to the NPRM's "effective cost" metric, the "cost per credit" metric appears to more frequently produce less expensive solutions than more expensive solutions, at least when simulating compliance with CO₂ standards. Differences are more mixed when simulating compliance with CAFE standards, and even when simulating compliance with CO₂ standards, results simulating "perfect" trading of CO₂ compliance credits are less intuitive when the "cost per credit metric." Nevertheless, and while less expensive solutions are not necessarily "optimal" solutions (*e.g.*, if gasoline costs \$7 per gallon and electricity is free, expensive electrification could be optimal), the agencies consider it reasonable to apply the "cost per credit" metric for the analysis supporting today's rulemaking.

¹⁵⁷ U.S. DOE Benefits & Scenario Analysis publications is available at https://www.autonomie.net/publications/fuel_economy_report.html. Last accessed November 14, 2019.

Autonomie; like engine maps, these are inputs to full vehicle simulation. Therefore, neither of these comments by Mr. Rogers and Mr. Duleep lead the agencies to find reason not to use Autonomie.

None of this is to say that Autonomie and the CAFE model as developed and applied for the NPRM left no room for improvement. In the NPRM and RIA, the agencies discussed plans to continue work in a range of specific technical areas, and invited comment on all aspects of the analysis. As discussed below in Chapter VI, the agencies received extensive comment on the published model, inputs, and analysis, both in response to the NPRM and, for newly-introduced modeling capabilities (estimation of sales, scrappage, and employment effects), in response to additional peer review conducted in 2019. The agencies have carefully considered these comments, refined various specific technical aspects of the CAFE model (like the “effective cost” metric mentioned above), and have also updated inputs to both Autonomie and the CAFE model. Especially given these refinements and updates, as discussed throughout this rule, EPA maintains that for CO₂ rulemaking analysis, Autonomie and the CAFE model have advantages that warrant relying on them rather than on EPA’s ALPHA and OMEGA models. Some examples of such advantages include: A longer history of ongoing development and application for rulemaking, including by EPA; documentation and model operation stakeholders have found to be comparatively clear and enabling of independent replication of agency analyses; a mechanism to explicitly reflect the fact that manufacturers’ product decisions are likely to be informed by fuel prices; better integration of various model functions, enabling efficient sensitivity analysis; and an annual time step that makes it possible to conduct report results on both a calendar year and model year basis, to estimate accruing impacts on vehicle sales and scrappage, and to account for the fact that not every vehicle can be designed in every model year; and other advantages discussed throughout today’s notice. Therefore, recognizing that models inform but do not make regulatory decisions, EPA has elected to rely solely on the Autonomie

and CAFE models to produce today’s analysis of regulatory alternatives for CO₂ standards.

The following sections provide a brief technical overview of the CAFE model, including changes NHTSA made to the model since 2012, and differences between the current analysis, the analysis for the 2016 Draft TAR and for the 2017 Proposed Determination/2018 Final Determination, and the 2018 NPRM, before discussing inputs to the model and then diving more deeply into how the model works. For more information on the latter topic, see the CAFE model documentation, available in the docket for this rulemaking and on NHTSA’s website.

1. What assumptions have changed since the 2012 final rule?

Any analysis of regulatory actions that will be implemented several years in the future, and whose benefits and costs accrue over decades, requires a large number of assumptions. Over such time horizons, many, if not most, of the relevant assumptions in such an analysis are inevitably uncertain.¹⁵⁹ The 2012 CAFE/CO₂ rule considered regulatory alternatives for model years through MY 2025 (17 model years after the 2008 market information that formed the basis of the analysis) that accrued costs and benefits into the 2060s. Not only was the new vehicle market in 2025 unlikely to resemble the market in 2008, but so, too, were fuel prices. It is natural, then, that each successive CAFE/CO₂ analysis should update assumptions to reflect better the current state of the world and the best current estimates of future conditions.¹⁶⁰ However, beyond the issue of unreliable projections about the future, a number of agency assertions have proven similarly problematic. In fact, Securing America’s Future Energy (SAFE) stated in their comments on the NPRM:

Although the agencies argue “circumstances have changed” and “analytical methods and inputs have been updated,” a thorough analysis should provide a side-by-side comparison of the changing circumstances, methods, and inputs used to arrive at this determination . . . They represent a rapid, dramatic departure from the agencies’ previous analyses, without time for careful review and consideration.¹⁶¹

We describe in detail (below) the changes to critical assumptions,

perspectives, and modeling techniques that have created substantive differences between the current analysis and the analysis conducted in 2012 to support the final rule. To the greatest extent possible, we have calculated the impacts of these changes on the 2012 analysis.

a) The Value of Fuel Savings

The value of fuel savings associated with the preferred alternative in the 2012 final rule is primarily a consequence of two assumptions:¹⁶² The fuel price forecast and the assumed growth in fuel economy in the baseline alternative against which savings are measured. Therefore, as the value of fuel savings accounted for nearly 80 percent of the total benefits of the 2012 rule, each of these assumptions is consequential. With a lower fuel price projection and an expectation that new vehicle buyers respond to fuel prices, the 2012 rule would have shown much smaller fuel savings attributable to the more stringent standards. Projected fuel prices are considerably lower today than in 2012, the agencies now understand new vehicle buyers to be at least somewhat responsive to fuel prices, and the agencies have therefore updated corresponding model inputs to produce an analysis the agencies consider to be more realistic.

The first of these assumptions, fuel prices, was simply an artifact of the timing of the rule. Following recent periodic spikes in the national average gasoline price and continued volatility after the great recession, the fuel price forecast then produced by EIA (as part of AEO 2011) showed a steady march toward historically high, sustained gasoline prices in the United States. However, the actual series of fuel prices has skewed much lower. As it has turned out, the observed fuel price in the years between the 2012 final rule and this rule has frequently been lower than the “Low Oil Price” sensitivity case in the 2011 AEO, even when adjusted for inflation. The following graph compares fuel prices underlying the 2012 final rule to fuel prices applied in the analysis reported in today’s notice, expressing both projections in 2010 dollars. The differences are clear and significant:

¹⁵⁹ As often stated, “It’s difficult to make predictions, especially about the future.” See, e.g., <https://quoteinvestigator.com/2013/10/20/no-predict/>.

¹⁶⁰ See, e.g., 77 FR 62785 (Oct. 15, 2012) (“If EPA initiates a rulemaking [to revise standards for MYs 2022–2025], it will be a joint rulemaking with

NHTSA. . . . NHTSA’s development of its proposal in that later rulemaking will include the making of economic and technology analyses and estimates that are appropriate for those model years and based on then-current information.”).

¹⁶¹ Securing America’s Energy Future, NHTSA–2018–0067–12172, at 39.

¹⁶² The value of fuel savings is also affected by the rebound effect assumption, assumed lifetime VMT accumulation, and the simulated penetration of alternative fuel technologies. However, each of these ancillary factors is small compared to the impact of the two factors discussed in this subsection.

Figure IV-2 – Gasoline Price Projections (in 2010 \$/gal.) from 2012 and Current Analyses

The discrepancy in fuel prices is important to the discussion of differences between the current rule and the 2012 final rule, because that discrepancy leads in turn to differences in analytical outputs and thus to differences in what the agencies consider in assessing what levels of standards are reasonable, appropriate, and/or maximum feasible. As an example, the agencies discuss in Sections VI.D.3 Simulating Environmental Impacts of Regulatory Alternatives and VIII.A.3 EPA's Conclusion that the Final CO₂ Standards are Appropriate and Reasonable that fuel price projections from the 2012 rule were one assumption, among others, that could have led to overestimates of the health benefits that resulted from reducing criteria pollutant emissions. Yet the agencies caution readers not to interpret this discrepancy as a reflection of negligence on the part of the agencies, or on the part of EIA. Long-term predictions are challenging and the fuel price projections in the 2012 rule were within the range of conventional wisdom *at the time*. However, it does suggest that fuel economy and tailpipe CO₂ regulations set almost two decades into the future are vulnerable to

surprises, in some ways, and reinforces the value of being able to adjust course when critical assumptions are proven inaccurate. This value was codified in regulation when EPA bound itself to the mid-term evaluation process as part of the 2012 final rule.¹⁶³

To illustrate this point clearly, substituting the current (and observed) fuel price forecast for the forecast used in the 2012 final rule creates a significant difference in the value of fuel savings. Even under identical discounting methods (see Section 2, below), and otherwise identical inputs in the 2012 version of the CAFE Model, the current (and historical) fuel price forecast reduces the value of fuel savings by *\$150 billion*—from \$525 billion to \$375 billion (in 2009 dollars).

The second assumption employed in the 2012 (as well as the 2010) final rule, that new vehicle fuel economy never improves unless manufacturers are required to increase fuel economy in the new vehicle market by increasingly stringent regulations, is more problematic. Despite the extensive set of recent academic studies showing, as discussed in Section VI.D.1.a)(2), that consumers value at least *some* portion,

and in some studies nearly *all*, of the potential fuel savings from higher levels of fuel economy at the time they purchase vehicles, the agencies assumed in past rulemakings that buyers of new vehicles would never purchase, and manufacturers would never supply, vehicles with higher fuel economy than those in the baseline (MY 2016 in the 2012 analysis), regardless of technology cost or prevailing fuel prices in future model years. In calendar year 2025, the 2012 final rule assumed gasoline would cost nearly \$4.50/gallon in today's dollars, and continue to rise in subsequent years. Even recognizing that higher levels of fuel economy would be achieved under the aural/existing standards than without them, the assertion that fuel economy and CO₂ emissions would not improve beyond 2016 levels in the presence of nearly \$5/gallon gasoline is not supportable. This is highlighted by the observed increased consumer demand for higher-fuel-economy vehicles during the gas price spike of 2008, when average U.S. prices briefly broke \$4/gallon. In the 2012 final rule, this assumption—that fuel economy and emissions would never improve absent regulation—created a persistent gap in fuel economy between

¹⁶³ See 40 CFR 86–1818–12(h).

the baseline and augural standards that grew to 13 mpg (at the industry average, across all vehicles) by MY 2025. In the 2016 Draft TAR, NHTSA's analysis included the assumption that manufacturers would deploy, and consumers would demand, any technology that recovered its own cost in the first year of ownership through avoided fuel costs. However, in both the Draft TAR and the Proposed and Final Determination documents, EPA's analysis assumed that the fuel economy levels achieved to reach compliance with MY 2021 standards would persist indefinitely, regardless of fuel prices or technology costs.

By substituting the conservative assumption that consumers are willing to purchase fuel economy improvements that pay for themselves with avoided fuel expenditures over the first 2.5 years¹⁶⁴ (identical to the assumption in this final rule's central analysis) the gap in industry average fuel economy between the baseline and augural scenarios narrows from 13 mpg in 2025 to 6 mpg in 2025. As a corollary, acknowledging that fuel economy would continue to improve in the baseline under the fuel price forecast used in the final rule erodes the value of fuel savings attributable to the preferred alternative. While each gallon is still worth as much as was assumed in 2012, fewer gallons are consumed in the baseline due to higher fuel economy levels in new vehicles. In particular, the

number of gallons saved by the preferred alternative selected in 2012 drops from about 180 billion to 50 billion once we acknowledge the existence of even a moderate market for fuel economy.¹⁶⁵ The value of fuel savings is similarly eroded, as higher fuel prices lead to correspondingly higher demand for fuel economy even in the baseline—reducing the value of fuel savings from \$525 billion to \$190 billion.

The magnitude of the fuel economy improvement in the baseline is a consequence of both the fuel prices assumed in the 2012 rule (already discussed as being higher than both subsequent observed prices and current projections) and the assumed technology costs. In 2012, a number of technologies were assumed to have negative incremental costs—meaning that applying those technologies to existing vehicles would both improve their fuel economy and reduce the cost to produce them. Asserting that the baseline would experience no improvement in fuel economy without regulation is equivalent to asserting that manufacturers, despite their status as profit maximizing entities, would not apply these cost-saving technologies unless forced to do so by regulation. While this issue is discussed in greater detail in Section VI.B the combination of inexpensive (or free) technology and high fuel prices created a logically inconsistent perspective in the 2012 rule—where consumers never demanded additional fuel economy, despite high fuel costs, and manufacturers never supplied

additional fuel economy, despite the availability of inexpensive (or cost saving) technology to do so.

Many commenters on earlier rules supported the assumption that fuel economy would not improve at all in the absence of standards. In fact, some commenters still support this position. For example, EDF commented to the NPRM that, “NHTSA set the Volpe model to project that, with CAFE standards remaining flat at MY 2020 levels through MY 2026, automakers would over-comply with the MY 2020 standards by 9 grams/mile of CO₂ for cars and 15 g/mi of CO₂ for light trucks during the 2029–2032 timeframe, plus 1%/year improvements beyond MY 2032. This assumption unreasonably obscures the impacts of the rollback and is not reflective of historical compliance performance.”¹⁶⁶

EDF is mistaken in two different ways: (1) By acknowledging the existence of a well-documented market for fuel economy, rather than erroneously inflating the benefits associated with increasing standards, this assumption serves to isolate the benefits actually attributable to each regulatory alternative, and (2) it is, indeed, reflective of historical compliance performance. While the agencies rely on the academic literature (and comments from companies that build and sell automobiles) to defend the assertion that a market for fuel economy exists, the industry's historical CAFE compliance performance is a matter of public record.¹⁶⁷ As shown in Figure IV–3, Figure IV–4, and Figure IV–5 for more than a decade, the industry average CAFE has exceeded the standard for each regulatory class—by several mpg during periods of high fuel prices.

BILLING CODE 4910–59–P

¹⁶⁴ Greene, D.L. and Welch, J.G., “Impacts of fuel economy improvements on the distribution of income in the U.S.,” Energy Policy, Volume 122, November 2018, pp. 528–41 (“Four nationwide random sample surveys conducted between May 2004 and January 2013 produced payback period estimates of approximately three years, consistent with the manufacturers’ perceptions.”) (The 2018 article succeeds Greene and Welch’s 2017 publication titled “The Impact of Increased Fuel Economy for Light-Duty Vehicles on the Distribution of Income in the U.S.: A Retrospective and Prospective Analysis,” Howard H. Baker Jr. Center for Public Policy, March 2017, which Consumers Union, CFA, and ACEEE comments include as Attachment 4, Docket NHTSA–2018–0067–11731).

¹⁶⁵ Readers should note that this is not an estimate of the total amount of fuel that will be consumed or not consumed by the fleet as a whole, but simply the amount of fuel that will be consumed or not consumed *as a direct result of the regulation*. As illustrated in Section VII, light-duty vehicles in the U.S. would continue to consume considerable quantities of fuel and emit considerable quantities of CO₂ even under the baseline/augural standards, and agencies’ analysis shows that the standards finalized today will likely increase fuel consumption and CO₂ emissions by a small amount.

Figure IV-5 – Historical CAFE Compliance, Light Trucks

BILLING CODE 4910-59-C

While this rulemaking has shown the impact of deviations from the 2012 rule assumptions individually, these two assumptions affect the value of fuel savings jointly. Replacing the fuel price forecast with the observed historical and current projected prices, and including any technology that pays for itself in the first 2.5 years of ownership through avoided fuel expenditures, reduces the value of fuel savings from \$525 billion in the 2012 rule to \$140 billion, all else

equal. Interestingly, this reduction in the value of fuel savings is smaller than the result when assuming only that the desired payback period is nonzero. While it may seem counterintuitive, it is entirely consistent.

The number of gallons saved under the preferred alternative is actually higher when modifying both assumptions, compared to only modifying the payback period. Updating both assumptions leads to about 100

billion gallons saved by the preferred alternative in 2012, compared to only 50 billion from changing only the payback period, and 180 billion in the 2012 analysis. This occurs because the fuel economy in the baseline is lower when updating both the fuel price and the payback period—the gap between the augural standards and the baseline grows to 9 mpg, rather than only 6 mpg when updating only the payback period. Despite the existence of inexpensive

technology in both cases, with lower fuel prices there are fewer opportunities to apply technology that will pay back quickly. As a consequence, the number of gallons saved by the preferred alternative in 2012 increases—but each gallon saved is worth less because the price of fuel is lower.

b) Technology Cost

While the methods used to identify cost-effective technologies to improve fuel economy in new vehicles have continuously evolved since 2012 (as discussed further in Section IV.B.1), as have the estimated cost of individual technologies, the inclusion of a market response in all scenarios (including the baseline) has changed the total technology cost associated with a given alternative. As also discussed in Section VI.B, acknowledging the existence of a market for fuel economy leads to continued application of the most cost-effective technologies in the baseline—and in other less stringent alternatives—up to the point at which there are no remaining technologies whose cost is fully offset by the value of fuel saved in the first 30 months of ownership. The application of this market-driven technology has implications for fuel economy levels under lower stringencies (as discussed earlier), but also for the incremental technology cost associated with more stringent alternatives. As lower stringency alternatives (including the 2012 baseline) accrue more technology, the incremental cost of more stringent alternatives decreases.

By including a modest market for fuel economy, and preserving all other assumptions from the 2012 final rule, the incremental cost of technology attributable to the preferred alternative decreases from about \$140 billion to about \$72 billion. This significant reduction in technology cost is somewhat diminished by the associated reduction in the value of fuel savings (a decrease of \$385 billion) when acknowledging the existence of a market for fuel economy. Another consequence of these changes is that the incremental cost of fuel economy technology is responsive to fuel price, as it should be. Under higher prices (as were assumed in 2012), consumers demand higher fuel economy in the new vehicle market. Under lower prices (as have occurred since the 2012 rule) consumers demand less fuel economy than would have been consistent with the fuel price assumptions in 2012.¹⁶⁸ Including a

market response in the analysis ensures that, in each case, the cost of fuel economy technology within an alternative is consistent with those assumptions. Using the same fuel price forecast that supports this rule, and the same estimate of market demand for fuel economy, the incremental cost of technology in the preferred alternative would rise back up to about \$110 billion.

c) The Social Cost of Carbon (SCC) Emissions

As discussed extensively in the NPRM, the agencies' perspective regarding the social cost of carbon has narrowed in focus. While the 2012 final rule considered the net present value of global damages resulting from carbon emitted by vehicles sold in the U.S. between MY 2009 and MY 2025, the NPRM (and this final rule) consider only those damages that occur to the United States and U.S. territories. As a result of this change in perspective, the value of estimated damages per-ton of carbon is correspondingly smaller. Had the 2012 final rule utilized the same perspective on the social cost of carbon, the benefits associated with the preferred alternative would have been about \$11 billion, rather than \$53 billion. However, the savings associated with carbon damages are a consequence of both the assumed cost per-ton of damages and the number of gallons of fuel saved. As discussed above, the gallons saved in the 2012 final rule were likely inflated as a result of both fuel price forecasts and the assumption that no market exists for fuel economy improvements. Correcting the estimate of gallons saved from the preferred alternative in the 2012 rule and considering only the domestic social cost of carbon further reduces the savings in carbon damages to \$6 billion.

d) Safety Neutrality

In the 2012 final rule, the agencies showed a “safety neutral” compliance solution; that is, a compliance solution that produced no net increase in on-road fatalities for MYs 2017–2025 vehicles as a result of technology changes associated with the preferred alternative. In practice, safety neutrality was achieved by expressly limiting the availability of mass reduction technology to only those vehicles whose usage causes fewer fatalities with decreased mass. This result was discussed as one possible solution, where manufacturers chose technology

solutions that limited the amount of mass reduction applied, and concentrated the application on vehicles that improve the safety of other vehicles on the roads (primarily by reducing the mass differential in collisions). However, it implicitly assumed that each and every manufacturer would leave cost-effective technologies unused on entire market segments of vehicles in order to preserve a safety neutral outcome at the fleet level for a given model year (or set of model years) whose useful lives stretched out as far as the 2060s. Removing these restrictions tells a different story.

When mass reduction technology, determined in the model to be a cost-effective solution (particularly in later model years, when more advanced levels of mass reduction were expected to be possible), is unrestricted in its application, the 2012 version of the CAFE Model chooses to apply it to vehicles in all segments. This has a small effect on technology costs, increasing compliance costs in the earliest years of the program by a couple billion dollars, and reducing compliance costs for MYs 2022–2025 by a couple billion dollars. However, the impact on safety outcomes is more pronounced.

Also starting with the model and inputs used for the 2012 final rule (and, as an example, focusing on that rule's 2008-based market forecast), removing the restrictions on the application of mass reduction technology results in an additional 3,400 fatalities over the full lives of MYs 2009–2025 vehicles in the baseline,¹⁶⁹ and another 6,900 fatalities over those same vehicle lives under the preferred alternative. The result, a net increase of 3,500 fatalities under the preferred alternative relative to the baseline, also produces a net social cost of \$18 billion. The agencies' current treatment of both mass reduction technology, which can greatly improve the effectiveness of certain technology packages by reducing road load, and estimated fatalities and now account for both general exposure (omitted in the 2012 final rule modeling) and fatality risk by age of the vehicle, further changes the story around mass reduction technology application for compliance and its relationship to on-road safety.

2. What methods have changed since the 2012 final rule?

Simulating how manufacturers might respond to CAFE/CO₂ standards

¹⁶⁸ This is why dozens of studies examining the ability of fuel taxes (and carbon taxes, which produce the same result for transportation fuels) to

reduce CO₂ emissions have found cost-effective opportunities available for those pricing mechanisms.

¹⁶⁹ Relative to the continuation of vehicle mass from the 2008 model year carried forward into the future.

requires information about existing products being offered for sale, as well as information about the costs and effectiveness of technologies that could be applied to those vehicles to bring the fleets in which they reside into compliance with a given set of standards. Following extensive additional work and consideration since the 2012 analysis, both agencies now use the CAFE Model to simulate these compliance decisions. This has several practical implications which are discussed in greater detail in Section VI.A. Briefly, this change represents a shift toward including a number of real-world production constraints—such as component sharing across a manufacturer's portfolio—and product cadence, where only a subset of vehicles in a given model year are redesigned (and thus eligible to receive fuel economy technology). Furthermore, the year-by-year accounting ensures a continuous evolution of a manufacturer's product portfolio that begins with the market data of an initial model year (model year 2017, in this analysis) and continues through the last year for which compliance is simulated. Finally, the modeling approach has migrated from one that relied on the simple product of single values to estimate technology effectiveness to a model that relies on full vehicle simulation to determine the effectiveness of any combination of fuel economy technologies. The combination of these changes has greatly improved the realism of simulated vehicle fuel economy for combinations of technologies across vehicle systems and classes.

In addition to these changes to the portions of the analysis that represent the supply of fuel economy (by manufacturer, fleet, and model year) in the new vehicle market, this analysis contains changes to the representation of consumer demand for fuel economy. One such measure was discussed above—the notion that consumers will demand some amount of fuel economy improvement over time, consistent with technology costs and fuel prices. However, another deviation from the 2012 final rule analysis reflects overall demand for new vehicles. Across ten alternatives, ranging from the baseline (freezing future standards at 2016 levels) to scenarios that increased stringency by seven percent per year, from 2017 through 2025, the 2012 analysis showed no response in new vehicle sales, down to the individual model level. This implied that, regardless of changes to vehicle cost or attributes driven by stringency increases, no fewer (or

possibly more) units of any single model would be sold in any year, in any alternative. Essentially, that analysis asserted that the new vehicle market does not respond, in any way, to average new vehicle prices across the alternatives—regardless of whether the incremental cost is \$1,600/vehicle (as it was estimated to be under the preferred alternative) or nearly \$4,000/vehicle (as it was in under the 7 percent alternative). Both the NPRM and this final rule, while not employing pricing models or full consumer choice models to address differentiated demand within brands or manufacturer portfolios, have incorporated a modeled sales response that seeks to quantify what was not quantified in previous rulemakings.

An important accounting method has also changed since the 2012 final rule was published. At the time of that rule, the agencies used an approach to discounting that combined attributes of a private perspective and a social perspective in their respective benefit cost analyses. This approach was logically inconsistent, and further reinforced some of the exaggerated estimates of fuel savings, social benefits (from reduced externalities), and technology costs described above. The old method discounted the value of all incremental quantities, whether categorized as benefits or costs, to the model year of the vehicle to which they accrued. This approach is largely acceptable for use in a private benefit cost analysis, where the costs and benefits accrue to the buyer of a new vehicle (in the case of this policy) who weighs their discounted present values at the time of purchase. However, the private perspective would not include any costs or benefits that are external to the buyer (e.g., congestion or the social cost of carbon emissions). For an analysis that compares benefits and costs from the social perspective, attempting to estimate the relative value of a policy to all of society rather than just buyers of new vehicles, this approach is more problematic.

The discounting approach in the 2012 final rule was particularly distortionary for a few reasons. The fact that benefits and costs occurred over long time periods in the 2012 rule, and the standards isolated the most aggressive stringency increases in the latter years of the program, served to allow benefits that occurred in 2025 (for example) to enter the accounting without being discounted, provided that they accrued to the affected vehicles during their first year of ownership. In a setting where numerous inputs (e.g., fuel price and social cost of carbon) increase over time, benefits were able to grow faster than

the discount rate in some cases—essentially making them infinite. The interpretation of discounting for externalities was equally problematic. For example, the discounting approach in the 2012 final rule would have counted a ton of CO₂ not emitted in CY 2025 in multiple ways, despite the fact that the social cost of carbon emissions was inherently tied to the calendar year in which the emissions occurred. Were the ton avoided by a MY 2020 vehicle, which would have been five years old in CY 2025, the value of that ton would have been the social cost of carbon times 0.86, but would have been undiscounted if that same ton had been saved by a MY 2025 vehicle in its initial year of usage.

This approach was initially updated in the 2016 Draft TAR to be consistent with common economic practice for benefit-cost analysis, and this analysis continues that approach. In the social perspective, all benefits and costs are discounted back to the decision year based on the calendar year in which they occur. Had the agencies utilized such an approach in the 2012 final rule, net benefits would have been reduced by about 20 percent, from \$465 billion to \$374 billion—not accounting for any of the other adjustments discussed above.

3. How have conditions changed since the 2012 final rule was published?

The 2012 final rule relied on market and compliance information from model year 2008 to establish standards for model years 2017–2025. However, in the intervening years, both the market and the industry's compliance positions have evolved. The industry has undergone a significant degree of change since the MY 2008 fleet on which the 2012FR was based. Entire brands (Pontiac, Oldsmobile, Saturn, Hummer, Mercury, etc.) and companies (Saab, Suzuki, Lotus) have exited the U.S. market, while others (most notably Tesla) have emerged. Several dozen nameplates have been retired and dozens of other created in that time. Overall, the industry has offered a diverse set of vehicle models that have generally higher fuel economy than the prior generation, and an ever-increasing set of alternative fuel powertrains.

As Table IV–1 shows, alternative powertrains have steadily increased under CAFE/CO₂ regulations. Under the standards between 2011 and 2018, the number of electric vehicle offerings in the market has increased from 1 model to 57 models (inclusive of all plug-in vehicles that are rated for use on the highway), and hybrids (like the Toyota Prius) have increased from 20 models to

43 models based on data from DOE's Alternative Fuels Data Center. Fuel efficient diesel vehicles have similarly been on the rise in that period, more than doubling the number of offerings. Flexible fuel vehicles (FFVs), capable of

operating on both gasoline and E85 remain readily available in the market, but have been excluded from the table due to both their lower fuel economy and demonstrated consumer reluctance to operate FFVs on E85. They have

historically been used to improve a manufacturer's compliance position, rather than other alternative fuel systems that reduce fuel consumption and save buyers money.

Table IV-1 – Alternative Fuel and Diesel Vehicle Offerings

| Model Year | Diesel | Electric | Hybrid | Hydrogen | Total |
|------------|--------|----------|--------|----------|-------|
| 2008 | 6 | 1 | 16 | 0 | 23 |
| 2009 | 12 | 1 | 19 | 0 | 32 |
| 2010 | 14 | 1 | 20 | 0 | 35 |
| 2011 | 16 | 2 | 29 | 0 | 47 |
| 2012 | 17 | 6 | 31 | 0 | 55 |

*EVs include plug-in HEVs, but do not include Neighborhood Electric Vehicles, Low Speed Electric Vehicles, or two-wheeled electric vehicles. Only full-sized vehicles sold in the U.S. and capable of 60mph are listed.

Not only have alternative powertrain options proliferated since the 2012 FR, the average fuel economy of new vehicles within each body style has increased. However, the more dramatic effect may lie in the *range* of fuel economies available within each body style. Figure IV–6 shows the distribution of new vehicle fuel economy (in miles per gallon equivalent) by body style for MYs 2008, 2016, and 2020 (simulated). Each box represents the 25th and 75th percentiles, where 25 and 75 percent of new models offered are less fuel efficient than that level. Not only has the median fuel economy improved (the median shows the point at which 50

percent of new models are less efficient) under the CAFE/CO₂ programs, but the range of available fuel economies (determined by the length of the boxes and their whiskers) has increased as well. For example, the 25th percentile of pickup truck fuel economy in 2020 is expected to be significantly more efficient than 75 percent of the pickups offered in 2008. In MY 2008, there were only a few SUVs offered with rated fuel economies above 34MPG. By MY 2020 almost half of the SUVs offered will have higher fuel economy ratings—with almost 20 percent of offerings exceeding 40MPG.

The improvement in passenger car styles has been no less dramatic. As with the other styles, the range of

available fuel economies has increased under the CAFE/CO₂ programs and the distribution of available fuel economies skewed higher—with 40 percent of MY 2020 models exceeding 40MPG. The attribute-based standards are designed to encourage manufacturers to improve vehicle fuel economy across their portfolios, and they have clearly done so. Not only have the higher ends of the distributions increased, the lower ends in all body styles have improved as well, where the least fuel efficient 25 percent of vehicles offered in MY 2016 (and simulated in 2020) are more fuel efficient than the most efficient 25 percent of vehicles offered in MY 2008.

Figure IV-6 – Fuel Economy Distribution¹⁷⁰ of New Vehicle Market by Body Style

BILLING CODE 4910-59-C

Some commenters have argued that consumers will be harmed by any set of standards lower than the baseline (augural) standards because buyers of new vehicles will be forced to spend more on fuel than they would have under the augural standards. However, as Figure IV-6 shows, the range of fuel economies available in the new market is already sufficient to suit the needs of buyers who desire greater fuel economy

rather than interior volume or some other attributes. Full size pickup trucks are now available with smaller turbocharged engines paired with 8 and 10-speed transmissions and some mild electrification. Buyers looking to transport a large family can choose to purchase a plug-in hybrid minivan. There were 57 electric models available in 2018, and hybrid powertrains are no longer limited to compact cars (as they once were). Buyers can choose hybrid SUVs with all-wheel and four-wheel drive. While these kinds of highly

efficient options were largely absent from some body styles in MY 2008, this is no longer the case. Given that high-MPG vehicles are widely available, consumers must also value other vehicle attributes (*e.g.*, acceleration and load-carrying capacity) that can also be improved with the same technologies that can be used to improve fuel economy.

Manufacturers have accomplished a portfolio-wide improvement by improving the combustion efficiency of engines (through direct injection and

¹⁷⁰ Circles represent specific outlying vehicle models.

turbocharging), migrating from four and five speed transmissions to 8 and 10 speed transmissions, and electrifying to varying degrees. All of this has increased both production costs and fuel efficiency during a period of economic expansion and low energy prices. While the vehicles offered for sale have increased significantly in efficiency between MY 2008 and MY 2020, the sales-weighted average fuel economy has achieved less improvement. Despite stringency

increases of about five percent (year-over-year) between 2012 and 2016, the sales-weighted average fuel economy increased marginally. Figure IV-7 shows an initial increase in average new vehicle fuel economy (the heavy solid line, shown in mpg as indicated on the left y axis), followed by relative stagnation as fuel prices (the light dashed lines, shown in dollars per gallon as indicated on the right y axis) fell and remained low.¹⁷¹ It is worth noting that average new vehicle fuel

economy observed a brief spike during the year that the Tesla Model 3 was introduced (as a consequence of strong initial sales volumes, as pre-orders were satisfied, and fuel economy ratings that are significantly higher than the industry average), and settled around 27.5 MPG in Fall 2019. Average fuel economy receded further over the next several months to 26.6 MPG in February 2020.¹⁷²

Figure IV-7 – Ward's Automotive Fuel Economy Index, April 2013 – April 2017

In their NPRM comments, manufacturers expressed concern that CAFE standards had already increased to the point where the price increases necessary to recoup manufacturers' increased costs for providing further increases in fuel economy outweigh the value of fuel savings.¹⁷³ The agencies do not agree that this point has already been reached by previous stringency increases, but acknowledge the reality of diminishing marginal returns to improvements in fuel economy. A driver with a 40MPG vehicle uses about 300 gallons of fuel per year. Increasing the fuel economy of that vehicle to 50MPG, a 25 percent increase, would likely be over \$1000 in additional technology cost. However, that driver would only save 25 percent of their annual fuel consumption, or 75 gallons

out of 300 gallons. Even at \$3/gallon, higher than the current national average, that represents \$225 per year in fuel savings. That means that the buyer's \$1000 investment in additional fuel economy pays back in just under 4.5 years (undiscounted). The agencies' respective programs have created greater access to high MPG vehicles in all classes and encouraged the proliferation of alternative fuels and powertrains. But if the value of the fuel savings is insufficient to motivate buyers to invest in ever greater levels of fuel economy, manufacturers will face challenges in the market.

While Figure IV-3 through Figure IV-5 illustrate the trends in historical CAFE compliance for the entire industry, the figures contain another relevant fact. After several consecutive years of

increasing standards, the achieved and required levels converge. When the standards began increasing again for passenger cars in 2011, the prior year had industry CAFE levels 5.6 mpg and 7.7 mpg in excess of their standards for domestic cars and imported cars, respectively. Yet, by 2016, the consecutive year-over-year increases had eroded the levels of over-compliance. Light trucks similarly exceeded their standard prior to increasing standards, which began in 2005. Yet, by 2011, after several consecutive years of stringency increases, the industry light-truck average CAFE was merely compliant with the rising standard.

This is largely due to the fact that stringency requirements have increased at a faster rate than achieved fuel

¹⁷³ NHTSA-2018-0067-12064-25.

¹⁷⁴ NHTSA-2018-0067-12073-2.

economy levels for several years. The attribute-based standards took effect in 2011 for all regulatory classes, although light truck CAFE standards had been increasing since 2005. Since 2004, light truck stringency has increased an average of 2.7 percent per year, while light truck's compliance fuel economy has increased by an average of 1.7 percent over the same period.¹⁷⁵ For the passenger classes, a similar story unfolds over a shorter period of time. Year over year stringency increases have averaged 4.7 percent per year for domestic cars (though increases in the first two years were about 8 percent—with lower subsequent increases), but achieved fuel economy increases averaged only 2.2 percent per year over the same period. Imported passenger

cars were similar to domestic cars, with average annual stringency increases of 4.4 percent but achieved fuel economy levels increasing an average of only 1.4 percent per year from 2011 through 2017. Given that each successive percent increase in stringency is harder to achieve than the previous one, long-term discrepancies between required and achieved year-over-year increases cannot be offset indefinitely with existing credit banks, as they have been so far.

With the fuel price increases fresh in the minds of consumers, and the great recession only recently passed, the CAFE stringency increases that began in 2011 (and subsequent CAFE/CO₂ stringency increases after EPA's program was first enforced in MY 2012)

had something of a head start. As Figure IV-3 through Figure IV-5 illustrate, the standards were not binding in MY 2011—even manufacturers that had historically paid civil penalties were earning credits for overcompliance. It took two years of stringency increase to catch up to the CAFE levels already present in MY 2011. However, seven consecutive years of increases for passenger cars and a decade of increases for light trucks has changed the credit situation. Figure IV-8 shows CAFE credit performance for regulated fleets—the solid line represents the number of fleets generating shortfalls and the dashed line represents the number of fleets earning credits in each model year.

Figure IV-8 – Industry CAFE Credit Performance Over Time

Fewer than half as many fleets earned surplus credits for over-compliance in MY 2017 compared to MY 2011—and this trend is persistent. The story varies from one manufacturer to another, but it seems sufficient to state the obvious—when the agencies conducted the analysis to establish standards through MY 2025 back in 2012, most (if not all) manufacturers had healthy credit positions. That is no longer the case,

and each successive increase requires many fleets to not only achieve the new level from the resulting increase, but to resolve deficits from the prior year as well. The large sums of credits, which last five years under both programs, have allowed most manufacturers to resolve shortfalls. But the light truck fleet, in particular, has a dwindling supply of credits available for purchase or trade. The CO₂ program has a

provision that allows credits earned during the early years of over-compliance to be applied through MY 2021. This has reduced the compliance burden in the last several years, as intended, but will not mitigate the compliance challenges some OEMs would face if the baseline standards remained in place and energy prices persisted at current levels.

BILLING CODE 4910-59-P

¹⁷⁵ Both the standards and these calculations are defined in consumption space—gallons per mile—

which also translates directly into CO₂ based on the carbon content of the fuel consumed.

BILLING CODE 4910-59-C

Table IV-2 shows the credits earned by each manufacturer over time.¹⁷⁶ As the table shows, when the agencies

considered future standards in 2012, most manufacturers were earning credits in at least one fleet. However, the bold values show years with deficits

and even some manufacturers who started out in strong positions, such as Ford's passenger car fleet, have seen growing deficits in recent years. While

¹⁷⁶ MY 2017 values represent estimated earned credits based on MY 2017 final compliance data.

the initial banks for early-action years eases the burden of CO₂ compliance for many OEMs, the year-to-year

compliance story is similar to CAFE, see Table IV-3.

Table IV-3 – CO₂ Credits (MMT) Earned by Manufacturer and Model Year

| VW | 6.4 | (0.4) | 0.0 | 0.1 | (0.4) | (1.9) | (4.1) |

Credit position and shortfall rates clearly illustrate manufacturers' fleet performance relative to the standards. Recognizing that manufacturers plan compliance over several model years at any given time, sporadic shortfalls may not be evidence of undue difficulty, but sustained, widespread, growing shortfalls should probably be viewed as evidence that standards previously believed to be manageable might no longer be so. While NHTSA is prohibited by statute from considering availability of credits (and thus, size of credit banks) in determining maximum feasible standards, it does consider shortfalls as part of its determination. EPA has no such prohibition under the CAA and is free to consider both credits and shortfalls.

These increasing credit shortfalls are occurring at a time that the industry is deploying more technology than the agencies anticipated when establishing future standards in 2012. The agencies' projections of transmission technologies were mixed. While the agencies expected the deployment of 8-speed

transmissions to about 25 percent of the market by MY 2018, transmissions with eight or more gears account for almost 30 percent of the market. However, the agencies projected no CVT transmissions in future model years, instead projecting high penetration of DCTs. However, CVTs currently make up more than 20 percent of new transmissions. The tradeoff between advanced engines and electrification was also underestimated. While the agencies projected penetration rates of turbocharged engines that are higher than we've observed in the market (45 percent compared to 30 percent), the estimated penetration of electric technologies was significantly lower. The agencies projected a couple percent of strong hybrids—which we've seen—but virtually no PHEVs or EVs. While the volumes of those vehicles are still only a couple percent of the new vehicle market, they are heavily credited under both programs and can significantly improve compliance positions even at smaller volumes. Even lower-level electrification technologies, like stop-

start systems, are significantly more prevalent than we anticipated (stop-start systems were projected to be in about 2 percent of the market, compared to over 20 percent in the 2018 fleet). Despite technology deployment that is comparable to 2012 projections, and occasionally more aggressive, passenger car and light truck fleets have slightly lower fuel economy than projected. As fleet volumes have shifted along the footprint curve, the standards have decreased as well (relative to the expectation in 2012), but less so. While compliance deficits have been modest, they have been accompanied by record sales for several years. This has not only depleted existing credit banks, but created significant shortfalls that may be more difficult to overcome if sales recede from record levels.

V. Regulatory Alternatives Considered

Agencies typically consider regulatory alternatives in proposals as a way of evaluating the comparative effects of different potential ways of accomplishing their desired goal. NEPA

requires agencies (in this case, NHTSA, but not EPA) to compare the potential environmental impacts of their proposed actions to those of a reasonable range of alternatives. Executive Orders 12866 and 13563 and OMB Circular A-4 also encourage agencies to evaluate regulatory alternatives in their rulemaking analyses. Alternatives analysis begins with a “no-action” alternative, typically described as what would occur in the absence of any regulatory action. This final rule, like the proposal, includes a no-action alternative, described below, as well as seven “action alternatives.” The final standards may, in places, be referred to as the “preferred alternative,” which is NEPA parlance, but NHTSA and EPA intend “final standards” and “preferred alternative” to be used interchangeably for purposes of this rulemaking.

In the proposal, NHTSA and EPA defined the different regulatory alternatives (other than the no-action alternative) in terms of percent-increases in CAFE and CO₂ stringency from year to year. Percent increases in stringency referred to changes in the standards year over year—as in, standards that become 1 percent more stringent each year. Readers should recognize that those year-over-year changes in stringency are *not* measured in terms of mile per gallon or CO₂ gram per mile differences (as in, 1 percent more stringent than 30 miles per gallon in one year equals 30.3 miles per gallon in the following year), but in terms of shifts in the *footprint functions* that form the basis for the *actual* CAFE and CO₂ standards (as in, on a gallon or gram per mile basis, the CAFE and CO₂ standards change by a given percentage from one model year to the next). Under some alternatives, the rate of change was the same for both passenger cars and light trucks; under others, the rate of change differed. Like the no-action alternative, all of the alternatives considered in the proposal were more stringent than the preferred alternative.

Alternatives considered in the proposal also varied in other significant ways. Alternatives 3 and 7 in the proposal involved a gradual discontinuation of CAFE and average CO₂ adjustments reflecting the use of technologies that improve air conditioner efficiency or otherwise improve fuel economy under conditions not represented by long-standing fuel economy test procedures (off-cycle adjustments, described in further detail in Section IX, although the proposal itself would have retained these flexibilities. Commenters responding to the request for comment on phasing out

these flexibilities generally supported maintaining the existing program, as proposed. Some commenters suggested changes to the existing program that were not discussed in the NPRM. Such changes would be beyond the scope of this rulemaking and were not considered. Section IX contains a more thorough summary of these comments and the issues they raise, as well as the agencies’ responses. Consistent with the decision to retain these flexibilities in the final rule, alternatives reflecting their phase-out have not been considered in this final rule.

Additionally, in the NPRM for this rule, EPA proposed to exclude the option for manufacturers partially to comply with tailpipe CO₂ standards by generating CO₂-equivalent emission adjustments associated with air conditioning refrigerants and leakage after MY 2020. This approach was proposed in the interest of improved harmonization between the CAFE and tailpipe CO₂ emissions programs because this optional flexibility cannot be available in the CAFE program.¹⁷⁷ Alternatives 1 through 8 excluded this option. EPA requested comment “on whether to proceed with [the] proposal to discontinue accounting for A/C leakage, methane emissions, and nitrous oxide emissions as part of the CO₂ emissions standards to provide for

¹⁷⁷ For the CAFE program, carbon-based tailpipe emissions (including CO₂, HC, and CO) are measured, and fuel economy is calculated using a carbon balance equation. EPA also uses carbon-based emissions (CO₂, HC, and CO, the same as for CAFE) to calculate tailpipe CO₂ for use in determining compliance with its standards. In addition, under the no-action alternative for the proposal and under all alternatives in the final rule, in determining compliance, EPA includes on a CO₂ equivalent basis (using Global Warming Potential (GWP) adjustment) A/C refrigerant leakage credits, at the manufacturer’s option, and nitrous oxide and methane emissions. EPA also has separate emissions standards for methane and nitrous oxides. The CAFE program does not include or account for A/C refrigerant leakage, nitrous oxide and methane emissions because they do not impact fuel economy. Under Alternatives 1–8 in the proposal, the standards were closely aligned for gasoline powered vehicles because compliance with the fleet average standard for such vehicles is based on tailpipe CO₂, HC, and CO for both programs and not emissions unrelated to fuel economy, although diesel and alternative fuel vehicles would have continued to be treated differently between the CAFE and CO₂ programs. While such an approach would have significantly improved harmonization between the programs, standards would not have been fully aligned because of the small fraction of the fleet that uses diesel and alternative fuels (as described in the proposal, such vehicles made up approximately four percent of the MY 2016 fleet), as well as differences involving EPCA/EISA provisions EPA has not adopted, such as minimum standards for domestic passenger cars and limits on credit transfers between regulated fleets. The proposal to eliminate flexibilities associated with A/C refrigerants and leakage was not adopted for this final rule, and the reasons for and implications of that decision are discussed further below.

better harmony with the CAFE program, or whether to continue to consider these factors toward compliance and retain that as a feature that differs between the programs.”¹⁷⁸ EPA stated that if EPA were to proceed with excluding A/C refrigerant credits as proposed, “EPA would consider whether it is appropriate to initiate a new rulemaking to regulate these programs independently”¹⁷⁹ EPA also stated that “[i]f the agency decides to retain the A/C leakage . . . provisions for CO₂ compliance, it would likely reinsert the current A/C leakage offset and increase the stringency levels for CO₂ compliance by the offset amounts described above (*i.e.*, 13.8 g/mi equivalent for passenger cars and 17.2 g/mi equivalent for light trucks). EPA received comments from a wide range of stakeholders, most of whom opposed the elimination of these flexibility provisions.

Specifically, the two major trade organizations of auto manufacturers, as well as some individual automakers, supported retaining these provisions. Global Automakers commented that “[a]ir conditioning refrigerant leakage . . . should be included for compliance with the EPA standards for all MYs, even if it means a divergence from the NHTSA standards.”¹⁸⁰ Global provides several detailed reasons for their comments, including that the existing provisions are “. . . important to maintaining regulatory flexibility through real [CO₂] emission reductions and would prevent the potential for additional bifurcated, separate programs at the state level.”¹⁸¹ The Alliance similarly commented that it “supports continuation of the full air conditioning refrigerant leakage credits under the [CO₂] standards.”¹⁸² Some individual

¹⁷⁸ 83 FR at 43193 (Aug. 24, 2018).

¹⁷⁹ *Id.* at 43194.

¹⁸⁰ Global, NHTSA–2018–0067–12032, Appendix A at A–5.

¹⁸¹ *Id.* Global also stated that excluding A/C leakage credits would “. . . greatly limit the ability [of manufacturers] to select the most cost-effective approach for technology improvements and result in a costlier, separate set of regulations that actually relate to the overall GHG standards.” Global also expressed concern that issuing separate regulations for A/C leakage could take too long and create a gap in which States might act to separately regulate or even ban refrigerants, and supported continued inclusion of A/C leakage and refrigerant regulation in EPA’s GHG program to avoid risk of an ensuing patchwork. Global argued that manufacturers had already invested to meet the existing program, and that “the proposed phase-out also creates another risk that manufacturers will have stranded capital in technologies that are not fully amortized.” Global Automakers, EPA–HQ–OAR–2018–0283–5704, Attachment A, at A.43–44.

¹⁸² Alliance, NHTSA–2018–0067–12073, Full Comment Set, at 12. Alliance also expressed

manufacturers, including General Motors,¹⁸³ Fiat Chrysler,¹⁸⁴ and BMW,¹⁸⁵ also commented in support of maintaining the current A/C refrigerant and leakage credits.

Auto manufacturing suppliers who addressed A/C refrigerant and leakage credits also generally supported retaining the existing provisions. MEMA commented that “It is essential for supplier investment and jobs, and continuous innovation and improvements in the technologies that the credit programs continue and expand to broaden the compliance pathways. MEMA urges the agencies to continue the current credit and incentives programs”¹⁸⁶ DENSO also supported maintaining the current provisions.¹⁸⁷ However, BorgWarner supported the proposed removal of A/C refrigerant credits “for harmonization reasons,” while encouraging EPA to regulate A/C refrigerants and leakage separately from the CO₂ standards.¹⁸⁸

The two producers of a lower GWP refrigerant, Chemours and Honeywell,

commented extensively in support of continuing to allow A/C refrigerant and leakage credits for CO₂ compliance, making both economic and legal arguments. Both Chemours and Honeywell stated that A/C refrigerant and leakage credits were a highly cost-effective way for OEMs to comply with the CO₂ standards,¹⁸⁹ with Chemours suggesting that OEM compliance strategies are based on the assumption that these credits will be available for CO₂ compliance¹⁹⁰ and that any increase in stringency above the proposal effectively necessitates that the credits remain part of the program.¹⁹¹ Honeywell stated that all OEMs (and a variety of other parties) supported retaining the credits for CO₂ compliance,¹⁹² and Chemours, Honeywell, and CBD *et al.* all noted that OEMs are already using the credits for low GWP refrigerants in more than 50 percent of the MY 2018 vehicles produced for sale in the U.S.¹⁹³ The American Chemistry Council also stated that the “auto industry widely supports the credits, and U.S. chemical manufacturers are at a loss as to why EPA would propose to eliminate such a successful flexible compliance program.”¹⁹⁴ In response to NPRM statements expressing concern that the A/C refrigerant and leakage credits could be market distorting, both Chemours and Honeywell disagreed,¹⁹⁵ arguing that the credits were simply a highly cost-effective means of complying with the CO₂ standards,¹⁹⁶ and that removal of the credits at this point would, itself, distort the market for refrigerants. Honeywell argued that eliminating the A/C credit program from CO₂ compliance would put the U.S. at a competitive disadvantage with other countries, and would risk U.S. jobs.¹⁹⁷

Regarding the NPRM’s statements that removing the A/C refrigerant and leakage credits from CO₂ compliance would promote harmonization with the CAFE program, these commenters

argued that harmonization was not a valid basis for that aspect of the proposal. Chemours, Honeywell, and CBD *et al.* all argued that Section 202(a) creates no obligation to harmonize the [CO₂] program with the CAFE program.¹⁹⁸ Chemours further argued that to the extent disharmonization between the programs existed, it should be addressed via stringency changes (*i.e.*, reducing CAFE stringency relative to CO₂ stringency) rather than “dropping low-cost compliance options.”¹⁹⁹

These commenters also expressed concern that the proposal constituted an EPA decision not to regulate HFC emissions from motor vehicles at all. Commenters argued that the NPRM provided no legal analysis or reasoned explanation for stopping regulation of HFCs,²⁰⁰ and that *Massachusetts v. EPA* requires any final rule to regulate all greenhouse gases from motor vehicles and not CO₂ alone,²⁰¹ suggesting that there was a high likelihood of a lapse in regulation because EPA had not yet proposed a new way of regulating HFC emissions.²⁰² Because the NPRM provided no specific information about how EPA might regulate non-CO₂ emissions separately, commenters argued that the lack of clarity was inherently disruptive to OEMs.²⁰³ CBD *et al.* argued that any lapse in regulation is “illegal on its face” and that even creating a separate standard for HFC emissions would be “illegal” because it “would increase costs to manufacturers and result in environmental detriment by removing any incentive to use the most aggressive approaches to curtail emissions of these highly potent GHGs.”²⁰⁴

Environmental organizations,²⁰⁵ other NGOs, academic institutions, consumer organizations, and state governments²⁰⁶ also commented in support of continuing the existing provisions.

EPA has considered its proposed approach to A/C refrigerant and leakage

concern about stranded capital and risk of patchwork of state regulation if MAC direct credits were not retained in the Federal GHG program. *Id.* at 80–81.

¹⁸³ General Motors, NHTSA–2018–0067–11858, Appendix 4, at 1 (“General Motors supports the extensive comments from the Alliance of Automobile Manufacturers regarding flexibility mechanisms, and incorporates them by reference. In particular, the Alliance cites the widening gap between the regulatory standards and actual industry-wide new vehicle average fuel economy that has become evident since 2016, despite the growing use of improvement ‘credits’ from various flexibility mechanisms, such as off-cycle technology credits, mobile air conditioner efficiency credits, mobile air conditioner refrigerant leak reduction credits and credits from electrified vehicles.”)

¹⁸⁴ FCA, NHTSA–2018–0067–11943, at 8. FCA also expressed concern about patchwork in the absence of a federal rule. *Id.*

¹⁸⁵ BMW, EPA–HQ–OAR–2018–4204, at 3. BMW stated that “Today’s rules allow flexibilities to be used by the motor vehicle manufacturers for fuel saving technologies and efficiency gains which are not covered in the applicable test procedures. To enhance the future use of these technologies and to reward motor vehicle manufacturer’s investments taken for future innovations, the agencies should consider the continuation of current flexibilities for the model years 2021 to 2026.”

credits in light of these comments. EPA believes that maintaining this element of its program is consistent with EPA's authority under Section 202(a) to establish standards for reducing emissions from LDVs. Thus, maintaining the optional HFC credit program is appropriate. In addition, EPA recognizes the value of regulatory flexibility and compliance options, and has concluded that the advantages from retaining the existing A/C refrigerant/leakage credit program and associated offset between the CO₂ and CAFE standards—in terms of providing for a more-comprehensive regulation of emissions from light-duty vehicles—outweigh the disadvantages resulting from the lack of harmonization.

Regarding the comment from BorgWarner about how having a separate A/C refrigerant and leakage regulation would allow for better harmonization between the programs, the agencies accept this to be an accurate statement, but believe the benefits of continued refrigerant regulation as an option for CO₂ compliance outweigh the problems associated with lack of harmonization with the CAFE program.

For these reasons, EPA is not finalizing the proposed provisions, and is making no changes in the A/C refrigerant and leakage-related provisions of the current program. In light of this conclusion, EPA does not need to address the legal arguments made by CBD *et al.* and CARB about regulating refrigerant-related emissions separately, or potential lapses in regulation of refrigerant emissions while such a program could be developed.

As with A/C refrigerant and leakage credits, EPA proposed to exclude nitrous oxide and methane from average performance calculations after model year 2020, thereby removing these optional program flexibilities. Alternatives 1 through 8 excluded this option. EPA sought comment on whether to remove those aspects of the program that allow a manufacturer to use nitrous oxide and methane emissions reductions for compliance with its CO₂ average fleet standards because such a flexibility is not allowed in the NHTSA CAFE program, or whether to retain the flexibilities as a feature that differs between the programs. Further, EPA sought comment on whether to change the existing methane and nitrous oxide standards. Specifically, EPA requested information from the public on whether the existing standards are appropriate, or whether they should be revised to be less stringent or more stringent based on any updated data.

The Alliance in its comments may have misunderstood EPA's proposal to mean that EPA was proposing to eliminate regulation of methane and nitrous oxide emissions altogether. The Alliance commented in support of such a proposal as they understood it, to eliminate the standards to provide better harmony between the two compliance programs.²⁰⁷ The Alliance commented that “[n]ot only is emission of these two substances from vehicles a relatively minor contribution to GHG emissions, the Alliance has continuing concern regarding measurement and testing technologies for nitrous oxide.”²⁰⁸ The Alliance commented further that if “EPA decides instead to continue to regulate methane and nitrous oxide, the Alliance recommends that EPA re-assess whether the levels of the standards remain appropriate and to retain the current compliance flexibilities. Furthermore, in this scenario, the Alliance also recommends that methane and nitrous oxide standards be assessed as a fleet average and as the average of FTP and HFET test cycles.”²⁰⁹ Several individual manufacturers submitted similar comments, including Ford,²¹⁰ FCA,²¹¹ Volvo,²¹² and Mazda.²¹³ Ford also commented that it does not support the proposal to maintain the existing N₂O/CH₄ standards while removing the program flexibilities.²¹⁴

The Alliance further commented that “data from the 2016 EPA report on light-duty vehicle emissions supports the position that CH₄ and N₂O have minimal impact on total GHG emissions, reporting only 0.045 percent in exceedance of the standard. This new information makes it apparent that CH₄ and N₂O contribute a *de minimis*

amount to GHG emissions. Additionally, gasoline CH₄ and N₂O performance is within the current standards. Finally, the main producers of CH₄ and N₂O emissions are flex fuel (E85) and diesel vehicles, and these vehicles have been declining in sales as compared to gasoline-fueled vehicles.”²¹⁵ The Alliance also commented that CH₄ and N₂O have minimal opportunities to be catalytically treated, as N₂O is generated in the catalyst and CH₄ has a low conversion efficiency compared to other emissions. EPA did not intend that additional hardware should be required to comply with the CH₄ or N₂O standards on any vehicle.”²¹⁶

Global Automakers commented in support of continuing inclusion of nitrous oxide and methane emissions standards for all MYs, even if it means a divergence from the NHTSA standards for these program elements in the regulations, “because they are complementary to EPA's program, and are better managed through a coordinated federal policy. They are also important to maintaining regulatory flexibility through real [CO₂] emission reductions and would prevent the potential for additional bifurcated, separate programs at the state level.”²¹⁷ Global Automakers recommended that they remain in place per the existing program but continued to support that the N₂O testing is not necessary. Global Automakers commented that it “strongly recommends reducing the need for N₂O testing or eliminating these test requirements in their entirety. It should be sufficient to allow manufacturers to attest to compliance with the N₂O capped standards based upon good engineering judgment, development testing, and correlation to NO_x emissions. EPA could, however, maintain the option to request testing to be performed for new technologies only, which could have unknown impacts on N₂O emissions.”²¹⁸ Hyundai²¹⁹ and Kia²²⁰ submitted similar comments.

Others commented in support of retaining the existing program. MECA commented that it supports the existing standards for methane and nitrous oxide because catalyst technologies provided by MECA members that reduce these climate forcing gases are readily

available and cost-effective.²²¹ MECA also commented that the ability to trade reductions in these pollutants in exchange for CO₂ gives vehicle manufacturers the flexibilities they need to comply with the emission limits by the most cost-effective means.²²² CBD *et al.* commented that the alternative compliance mechanisms currently available in the program exist to provide cost-effective options for compliance, and were considered by manufacturers to be a necessary element of the program for certain types of vehicles.²²³ CBD *et al.* further argued that “[e]liminating these flexibilities consequently imposes costs on manufacturers without discernible environmental benefits,” and suggested that harmonization with the CAFE program was not a relevant decision factor for EPA.²²⁴ Several other parties commented generally in support of retaining the existing program for A/C leakage credits, discussed above, and N₂O and CH₄ standards.²²⁵

After considering these comments, EPA is retaining the regulatory provisions related to the N₂O and CH₄ standards with no changes, specifically including the existing flexibilities that accompany those standards. EPA is not adopting its proposal to exclude nitrous oxide and methane emissions from average performance calculations after model year 2020 or any other changes to the program. The standards continue to serve their intended purpose of capping emissions of those pollutants and providing for more-comprehensive regulation of emissions from light-duty vehicles. The standards were intended to prevent future emissions increases, and these standards were generally not expected to result in the application of new technologies or significant costs for manufacturers using current vehicle designs.²²⁶ The program flexibilities are working as intended and all manufacturers are successfully complying with the standards. Most vehicle models are well below the standards and for those that are above the standards, manufacturers have used the flexibilities to offset exceedances with CO₂ improvements to demonstrate compliance. EPA did not receive any data in response to its request for comments supporting potential alternative levels of stringency.

While the Alliance and several individual manufacturers recommended

eliminating the standards altogether, EPA did not propose to eliminate the standards, but to eliminate the optional flexibilities, and solicited comment on adjusting the standards to be more or less stringent. Thus, EPA does not believe it would be appropriate to eliminate completely the standards in this final rule without providing an opportunity for comment on that idea. Furthermore, as noted above, EPA believes the standards are continuing to serve their intended purpose of capping emissions and remain appropriate. Manufacturers have been subject to the standards for several years, and the Alliance acknowledges in their comments that the exceedance of the standards, which is offset by manufacturers using compliance flexibilities, is very small and that most vehicles meet the standards. Regarding the Alliance comments that the standards should be based on a fleet average approach, EPA notes that the purpose of the standards is to cap emissions, not to achieve fleet-wide reductions.²²⁷ The fleet average emissions for N₂O and CH₄ are well below the numerical level of the cap standards and therefore the existing cap standards would not be an appropriate fleet average standard. Adopting a fleet average approach using the same numerical level as the established cap standards would not achieve the intended goal of capping emissions at current levels. If technologies lead to exceedances of the caps, automakers have the opportunity to apply appropriate flexibilities under the current program to achieve GHG emission neutrality. EPA is not aware of any manufacturer that has been prevented from bringing a technology to the marketplace because of the current cap levels or approach. EPA believes it would need to consider all options further, with an opportunity for public comment, before adopting such a significant change to the program.

As explained above, the agencies have changed the alternatives considered for the final rule, partly in response to comments. The basic form of the standards represented by the

alternatives—footprint-based, defined by particular mathematical functions—remains the same and as described in the NPRM. For the EPA program, EPA has chosen in this final rule to retain the existing program for regulation of A/C refrigerant leakage, nitrous oxide, and methane emissions as part of the CO₂ standard. This allows manufacturers to continue to rely on this flexibility which they describe as extremely important for compliance, although it results in continued differences between EPA’s and NHTSA’s programs. This approach also avoids the possibility of gaps in the regulation of HFCs, CH₄, and N₂O while EPA developed a different way of regulating the non-CO₂ emissions as part of or concurrent with the NPRM, and thereby allows EPA to continue to regulate GHE emissions from light-duty vehicles on a more-comprehensive basis. Thus, all alternatives considered in this final rule reflect inclusion of CH₄, N₂O, and HFC in EPA’s overall “CO₂” (more accurately, CO₂-equivalent, or CO₂e) requirements. Besides this change, the alternatives considered for the final rule differ from the NPRM in two additional ways: First, alternatives reflecting the phase-out of the A/C efficiency and off-cycle programs have been dropped in response to certain comments and in recognition of the potential real-world benefits of those programs. And second, the preferred alternative for this final rule reflects a 1.5 percent year-over-year increase for both passenger cars and light trucks. These changes will be discussed further below, following a brief discussion of the form of the standards.

A. Form of the Standards

As in the CAFE and CO₂ rulemakings in 2010 and 2012, NHTSA and EPA proposed in the NPRM to set attribute-based CAFE and CO₂ standards defined by a mathematical function of vehicle footprint, which has observable correlation with fuel economy and vehicle emissions. EPCA, as amended by EISA, expressly requires that CAFE standards for passenger cars and light trucks be based on one or more vehicle attributes related to fuel economy and be expressed in the form of a mathematical function.²²⁸ While the CAA includes no specific requirements regarding CO₂ regulation, EPA has chosen to adopt attribute-based CO₂ standards consistent with NHTSA’s EPCA/EISA requirements in the interest of harmonization and simplifying compliance. Such an approach is permissible under section 202(a) of the

²²⁶ 77 FR 62624, at 62799 (Oct 15, 2012).

²²⁷ Relatedly, the Alliance and Global Automakers raised concerns in their comments regarding N₂O measurement and testing burden. EPA did not propose any changes in testing requirements and at this time EPA is not adopting any changes. Manufacturers have been measuring N₂O emissions and have successfully certified vehicles to the N₂O standards for several years and EPA does not believe N₂O measurement is an issue needing regulatory change. EPA continues to believe direct measurement is the best way for manufacturers to demonstrate compliance with the N₂O standards and is more appropriate than an engineering statement without direct measurement.

²²⁸ 49 U.S.C. 32902(a)(3)(A).

CAA, and EPA has used the attribute-based approach in issuing standards under analogous provisions of the CAA. Thus, both the proposed and final standards take the form of fuel economy and CO₂ targets expressed as functions of vehicle footprint (the product of vehicle wheelbase and average track width). Section V.A.2 below discusses the agencies' continued reliance on footprint as the relevant attribute.

Under the footprint-based standards, the function defines a CO₂ or fuel economy performance target for each unique footprint combination within a car or truck model type. Using the functions, each manufacturer thus will have a CAFE and CO₂ average standard for each year that is almost certainly

unique to each of its fleets,²²⁹ based upon the footprints and production volumes of the vehicle models produced by that manufacturer. A manufacturer will have separate footprint-based standards for cars and for trucks. The functions are mostly sloped, so that generally, larger vehicles (*i.e.*, vehicles with larger footprints) will be subject to lower CAFE mpg targets and higher CO₂ grams/mile targets than smaller vehicles. This is because, generally speaking, smaller vehicles are more capable of achieving higher levels of fuel economy/lower levels of CO₂ emissions, mostly because they tend not to have to work as hard (and therefore require as much energy) to perform their driving task. Although a manufacturer's

fleet average standards could be estimated throughout the model year based on the projected production volume of its vehicle fleet (and are estimated as part of EPA's certification process), the standards to which the manufacturer must comply are determined by its final model year production figures. A manufacturer's calculation of its fleet average standards as well as its fleets' average performance at the end of the model year will thus be based on the production-weighted average target and performance of each model in its fleet.²³⁰

For passenger cars, consistent with prior rulemakings, NHTSA is defining fuel economy targets as follows:

$$TARGET_{FE} = \frac{1}{MIN \left[MAX \left(c \times FOOTPRINT + d, \frac{1}{a} \right), \frac{1}{b} \right]}$$

where:

$TARGET_{FE}$ is the fuel economy target (in mpg) applicable to a specific vehicle model type with a unique footprint combination,

a is a minimum fuel economy target (in mpg),

b is a maximum fuel economy target (in mpg),

c is the slope (in gallons per mile per square foot, or gpm, per square foot) of a line relating fuel consumption (the inverse of fuel economy) to footprint, and

d is an intercept (in gpm) of the same line.

Here, MIN and MAX are functions that take the minimum and maximum

values, respectively, of the set of included values. For example, $MIN[40, 35] = 35$ and $MAX(40, 25) = 40$, such that $MIN[MAX(40, 25), 35] = 35$.

For light trucks, also consistent with prior rulemakings, NHTSA is defining fuel economy targets as follows:

$$TARGET_{FE} = MAX \left(\frac{1}{MIN \left[MAX \left(c \times FOOTPRINT + d, \frac{1}{a} \right), \frac{1}{b} \right]}, \frac{1}{MIN \left[MAX \left(g \times FOOTPRINT + h, \frac{1}{e} \right), \frac{1}{f} \right]} \right)$$

where:

$TARGET_{FE}$ is the fuel economy target (in mpg) applicable to a specific vehicle model type with a unique footprint combination,

a, b, c , and d are as for passenger cars, but taking values specific to light trucks,

e is a second minimum fuel economy target (in mpg),

f is a second maximum fuel economy target (in mpg),

g is the slope (in gpm per square foot) of a second line relating fuel consumption (the inverse of fuel economy) to footprint, and

h is an intercept (in gpm) of the same second line.

Although the general model of the target function equation is the same for each vehicle category (passenger cars and light trucks) and each model year, the parameters of the function equation differ for cars and trucks. For MYs 2020–2026, the parameters are unchanged, resulting in the same stringency in each of those model years.

Mathematical functions defining the CO₂ targets are expressed as functions that are similar, with coefficients a – h corresponding to those listed above.²³¹ For passenger cars, EPA is defining CO₂ targets mathematically equivalent to the following:

$$TARGET_{CO2} = MIN[b, MAX[a, c \times FOOTPRINT + d]]$$

where:

$TARGET_{CO2}$ is the CO₂ target (in grams per mile, or g/mi) applicable to a specific vehicle model configuration,

a is a minimum CO₂ target (in g/mi),

b is a maximum CO₂ target (in g/mi),

c is the slope (in g/mi, per square foot) of a line relating CO₂ emissions to footprint, and

d is an intercept (in g/mi) of the same line.

For light trucks, CO₂ targets are defined as follows:

$$TARGET_{CO2} = MIN[MIN[b, MAX[a, c \times FOOTPRINT + d]], MIN[f, MAX[e, g \times FOOTPRINT + h]]$$

²²⁹ EPCA/EISA requires NHTSA to separate passenger cars into domestic and import passenger car fleets whereas EPA combines all passenger cars into one fleet.

²³⁰ As discussed in prior rulemakings, a manufacturer may have some vehicle models that exceed their target and some that are below their target. Compliance with a fleet average standard is

determined by comparing the fleet average standard (based on the production-weighted average of the target levels for each model) with fleet average performance (based on the production-weighted average of the performance of each model).

²³¹ EPA regulations use a different but mathematically equivalent approach to specify targets. Rather than using a function with nested

minima and maxima functions, EPA regulations specify requirements separately for different ranges of vehicle footprint. Because these ranges reflect the combined application of the listed minima, maxima, and linear functions, it is mathematically equivalent and more efficient to present the targets as in this Section.

where:

$TARGET_{CO_2}$ is the CO_2 target (in g/mi) applicable to a specific vehicle model configuration,

a , b , c , and d are as for passenger cars, but taking values specific to light trucks,

e is a second minimum CO_2 target (in g/mi),

f is a second maximum CO_2 target (in g/mi),

g is the slope (in g/mi per square foot) of a second line relating CO_2 emissions to footprint, and

h is an intercept (in g/mi) of the same second line.

To be clear, as has been the case since the agencies began establishing attribute-based standards, no vehicle need meet the specific applicable fuel economy or CO_2 targets, because compliance with either CAFE or CO_2

standards is determined based on corporate *average* fuel economy or fleet average CO_2 emission rates. In this respect, CAFE and CO_2 standards are unlike, for example, safety standards and traditional vehicle emissions standards. CAFE and CO_2 standards apply to the average fuel economy levels and CO_2 emission rates achieved by manufacturers' entire fleets of vehicles produced for sale in the U.S. Safety standards apply on a vehicle-by-vehicle basis, such that every single vehicle produced for sale in the U.S. must, on its own, comply with minimum FMVSS. Similarly, criteria pollutant emissions standards are applied on a per-vehicle basis, such that every vehicle produced for sale in the U.S. must, on its own,

comply with all applicable emissions standards. When first mandating CAFE standards in the 1970s, Congress specified a more flexible averaging-based approach that allows some vehicles to "under comply" (*i.e.*, fall short of the overall flat standard, or fall short of their target under attribute-based standards) as long as a manufacturer's overall fleet is in compliance.

The required CAFE level applicable to a given fleet in a given model year is determined by calculating the production-weighted harmonic average of fuel economy targets applicable to specific vehicle model configurations in the fleet, as follows:

$$CAFE_{required} = \frac{\sum_i PRODUCTION_i}{\sum_i \frac{PRODUCTION_i}{TARGET_{FE,i}}}$$

where:

$CAFE_{required}$ is the CAFE level the fleet is required to achieve,

i refers to specific vehicle model/configurations in the fleet,

$PRODUCTION_i$ is the number of model configuration i produced for sale in the U.S., and

$TARGET_{FE,i}$ the fuel economy target (as defined above) for model configuration i .

Similarly, the required average CO_2 level applicable to a given fleet in a

given model year is determined by calculating the production-weighted average (not harmonic) of CO_2 targets applicable to specific vehicle model configurations in the fleet, as follows:

$$CO2_{required} = \frac{\sum_i PRODUCTION_i \times TARGET_{CO2,i}}{\sum_i PRODUCTION_i}$$

where:

$CO2_{required}$ is the average CO_2 level the fleet is required to achieve,

i refers to specific vehicle model/configurations in the fleet,

$PRODUCTION_i$ is the number of model configuration i produced for sale in the U.S., and

$TARGET_{CO2,i}$ is the CO_2 target (as defined above) for model configuration i .

Section VI.A.1 describes the advantages of attribute standards, generally. Section VI.A.2 explains the agencies' specific decision to use

vehicle footprint as the attribute over which to vary stringency for past and current rules. Section VI.A.3 discusses the policy considerations in selecting the specific mathematical function. Section VI.A.4 discusses the methodologies used to develop current attribute-based standards, and the agencies' current proposal to continue to do so for MYs 2021–2026. Section VI.A.5 discusses the methodologies used to reconsider the mathematical function for the proposed standards.

1. Why attribute-based standards, and what are the benefits?

Under attribute-based standards, every vehicle model has fuel economy and CO_2 targets, the levels of which depend on the level of that vehicle's determining attribute (for the MYs 2021–2026 standards, footprint is the determining attribute, as discussed below). The manufacturer's fleet average CAFE performance is calculated by the harmonic production-weighted average of those targets, as defined below:

$$Required\ CAFE = \frac{\sum_{i \in OEM\ Fleet} Production_i}{\sum_{i \in OEM\ Fleet} \frac{Production_i}{Target_i}}$$

Here, i represents a given model²³² in a manufacturer's fleet, $Production_i$ represents the U.S. production of that model, and $Target_i$ represents the target as defined by the

attribute-based standards. This means no vehicle is required to meet its target; instead, manufacturers are free to balance improvements however they deem best

within (and, given credit transfers, at least partially across) their fleets.

Because CO_2 is on a gram per mile basis rather a mile per gallon basis,

²³² If a model has more than one footprint variant, here each of those variants is treated as a unique

model, i , since each footprint variant will have a unique target.

harmonic averaging is not necessary when calculating required CO₂ levels:

$$\text{Required CO}_2 = \frac{\sum_{i \in \text{OEM Fleet}} \text{Production}_i \times \text{Target}_i}{\sum_{i \in \text{OEM Fleet}} \text{Production}_i}$$

The idea is to select the shape of the mathematical function relating the standard to the fuel economy-related attribute to reflect the trade-offs manufacturers face in producing more of that attribute over fuel efficiency (due to technological limits of production and relative demand of each attribute). If the shape captures these trade-offs, every manufacturer is more likely to continue adding fuel-efficient technology across the distribution of the attribute within their fleet, instead of potentially changing the attribute—and other correlated attributes, including fuel economy—as a part of their compliance strategy. Attribute-based standards that achieve this have several advantages.

First, assuming the attribute is a measurement of vehicle size, attribute-based standards help to at least partially reduce the incentive for manufacturers to respond to CAFE and CO₂ standards by reducing vehicle size in ways harmful to safety, as compared to “flat,” non-attribute based standards.²³³ Larger vehicles, in terms of mass and/or crush space, generally consume more fuel and produce more carbon dioxide emissions, but are also generally better able to protect occupants in a crash.²³⁴ Because each vehicle model has its own target (determined by a size-related attribute), properly fitted attribute-based standards reduce the incentive to build smaller vehicles simply to meet a fleet-wide average, because smaller vehicles are subject to more stringent compliance targets.

²³³ The 2002 NAS Report described at length and quantified the potential safety problem with average fuel economy standards that specify a single numerical requirement for the entire industry. See Transportation Research Board and National Research Council. 2002. *Effectiveness and Impact of Corporate Average Fuel Economy (CAFE) Standards*. Washington, DC: The National Academies Press (“2002 NAS Report”) at 5, finding 12, available at <https://www.nap.edu/catalog/10172/effectiveness-and-impact-of-corporate-average-fuel-economy-cafe-standards> (last accessed June 15, 2018). Ensuing analyses, including by NHTSA, support the fundamental conclusion that standards structured to minimize incentives to downsize all but the largest vehicles will tend to produce better safety outcomes than flat standards.

²³⁴ Bento, A., Gillingham, K., & Roth, K. (2017). *The Effect of Fuel Economy Standards on Vehicle Weight Dispersion and Accident Fatalities*. NBER Working Paper No. 23340. Available at <http://www.nber.org/papers/w23340> (last accessed June 15, 2018).

Second, attribute-based standards, if properly fitted, provide automakers with more flexibility to respond to consumer preferences than do single-valued standards. As discussed above, a single-valued standard encourages a fleet mix with a larger share of smaller vehicles by creating incentives for manufacturers to use downsizing the average vehicle in their fleet (possibly through fleet mixing) as a compliance strategy, which may result in manufacturers building vehicles for compliance reasons that consumers do not want. Under a size-related, attribute-based standard, reducing the size of the vehicle for compliance’s sake is a less-viable strategy because smaller vehicles have more stringent regulatory targets. As a result, the fleet mix under such standards is more likely to reflect aggregate consumer demand for the size-related attribute used to determine vehicle targets.

Third, attribute-based standards provide a more equitable regulatory framework across heterogeneous manufacturers who may each produce different shares of vehicles along attributes correlated with fuel economy.²³⁵ An industry-wide single-value CAFE standard imposes disproportionate cost burden and compliance challenges on manufacturers who produce more vehicles with attributes inherently correlated with lower fuel economy—i.e. manufacturers who produce, on average, larger vehicles. As discussed above, retaining flexibility for manufacturers to produce vehicles which respect heterogeneous market preferences is an important consideration. Since manufacturers may target different markets as a part of their business strategy, ensuring that these manufacturers do not incur a disproportionate share of the regulatory cost burden is an important part of conserving consumer choices within the market.

Industry commenters generally supported attribute-based standards, while other commenters questioned their benefits. IPI argued that preserving the current vehicle mix was not necessarily desirable or necessary for consumer welfare, and suggested that

some vehicle downsizing in the fleet might be beneficial both for safety and for compliance.²³⁶ IPI also argued that compliance credit trading would “help smooth out any disproportionate impacts on certain manufacturers” and “ensure that manufacturers with relatively efficient fleets still have an incentive to continue improving fuel economy (in order to generate credits)”²³⁷ Similarly, citing Ito and Sallee, Kathryn Doolittle commented that “. . . Ito and Sallee (2018) have found ABR [“attribute-based regulations”] inefficient in cost when juxtaposed with flat standard with compliance trading.”²³⁸

The agencies have considered these comments. IPI incorrectly characterizes the agencies’ prior statements as claims that it is important to preserve the current vehicle mix. EPA and NHTSA have never claimed, and are not today claiming that it is important to preserve the current fleet mix. The agencies have said, and are today reiterating, that it is reasonable to expect that reducing the tendency of standards to distort the market should reduce at least part of the tendency of standards to reduce consumer welfare. Or, more concisely, it is better to work with the market than against it. Single-value (aka flat) CAFE standards in place from the 1970s through 2010 were clearly distortionary. Recognizing this, the National Academy of Sciences recommended in 2002 that NHTSA adopt attribute-based CAFE standards. NHTSA did so in 2006, for light trucks produced starting MY 2008. As mentioned above, in 2007, Congress codified the requirement for attribute-based passenger car and light truck CAFE standards. Agreeing with this history, premise, and motivation, EPA has also adopted attribute-based CO₂ standards. None of this is to say the agencies consider it important to hold fleet mix constant. Rather, the agencies expect that, compared to flat standards, attribute-based standards can allow the market—including fleet mix—to better

²³⁵ 2002 NAS Report at 4–5, finding 10.

follow its natural course, and all else equal, consumer acceptance is likely to be greater if the market does so.

The agencies also disagree with comments implying that compliance credit trading can address all of the market distortion that flat standards would entail. Evidence thus far suggests that trading is fragmented, with some manufacturers apparently willing to trade only with some other specific manufacturers. The Ito and Sallee article cited by one commenter is a highly idealized theoretical construction, with the authors noting, *inter alia*, that their model “assumes perfect competition.”²³⁹ Its findings regarding comparative economic efficiency of flat- and attribute-based standards are, therefore, merely hypothetical, and the agencies find little basis in recent transactions to suggest the compliance credit trading market reflects the authors’ idealized assumptions. Even if the agencies did expect credit trading markets to operate as in an idealized textbook example, basing the structure of standards on the presumption of perfect trading would not be appropriate. FCA commented that “. . . when flexibilities are considered while setting targets, they cease to be flexibilities and become simply additional technology mandates,” and the Alliance commented, similarly, that “the Agencies should keep ‘flexibilities’ as optional ways to comply and not unduly assume that each flexibility allows additional stringency of footprint-based standards.”²⁴⁰ Perhaps recognizing this reality, Congress has barred NHTSA from considering manufacturers’ ability to use compliance credits (even credits earned and used by the same OEM, much less credits traded between OEMs). As discussed further in Section VIII.A.2, EPA believes that while credit trading may be a useful flexibility to reduce the overall costs of the program, it is important to set standards in a way that does not rely on credit purchasing availability as a compliance mechanism.

Considering these comments and realities, considering EPCA’s requirement for attribute-based CAFE standards, and considering the benefits of regulatory harmonization, the agencies are, again, finalizing attribute-based CAFE and CO₂ standards rather

than, for either program, finalizing flat standards.

Why footprint as the attribute?

It is important that the CAFE and CO₂ standards be set in a way that does not unnecessarily incentivize manufacturers to respond by selling vehicles that are less safe. Vehicle size is highly correlated with vehicle safety—for this reason, it is important to choose an attribute correlated with vehicle size (mass or some dimensional measure). Given this consideration, there are several policy and technical reasons why footprint is considered to be the most appropriate attribute upon which to base the standards, even though other vehicle size attributes (notably, curb weight) are more strongly correlated with fuel economy and tailpipe CO₂ emissions.

First, mass is strongly correlated with fuel economy; it takes a certain amount of energy to move a certain amount of mass. Footprint has some positive correlation with frontal surface area, likely a negative correlation with aerodynamics, and therefore fuel economy, but the relationship is less deterministic. Mass and crush space (correlated with footprint) are both important safety considerations. As discussed below and in the accompanying PRIA, NHTSA’s research of historical crash data indicates that holding footprint constant, and decreasing the mass of the largest vehicles, will result in a net positive safety impact to drivers overall, while holding footprint constant and decreasing the mass of the smallest vehicles will result in a net decrease in fleetwide safety. Properly fitted footprint-based standards provide little, if any, incentive to build smaller footprint vehicles to meet CAFE and CO₂ standards, and therefore help minimize the impact of standards on overall fleet safety.

Second, it is important that the attribute not be easily manipulated in a manner that does not achieve the goals of EPCA or other goals, such as safety. Although weight is more strongly correlated with fuel economy than footprint, there is less risk of artificial manipulation (*i.e.*, changing the attribute(s) to achieve a more favorable target) by increasing footprint under footprint-based standards than there would be by increasing vehicle mass under weight-based standards. It is relatively easy for a manufacturer to add enough weight to a vehicle to decrease its applicable fuel economy target a significant amount, as compared to increasing vehicle footprint, which is a much more complicated change that

typically takes place only with a vehicle redesign.

Further, some commenters on the MY 2011 CAFE rulemaking were concerned that there would be greater potential for such manipulation under multi-attribute standards, such as those that also depend on weight, torque, power, towing capability, and/or off-road capability. As discussed in NHTSA’s MY 2011 CAFE final rule,²⁴¹ it is anticipated that the possibility of manipulation is lowest with footprint-based standards, as opposed to weight-based or multi-attribute-based standards. Specifically, standards that incorporate weight, torque, power, towing capability, and/or off-road capability in addition to footprint would not only be more complex, but by providing degrees of freedom with respect to more easily adjusted attributes, they could make it less certain that the future fleet would actually achieve the projected average fuel economy and CO₂ levels. This is not to say that a footprint-based system eliminates manipulation, or that a footprint-based system eliminates the possibility that manufacturers will change vehicles in ways that compromise occupant protection, but footprint-based standards achieve the best balance among affected considerations.

Several stakeholders commented on whether vehicular footprint is the most suitable attribute upon which to base standards. IPI commented that “. . . footprint-based standards may be unnecessary to respect consumer preferences, may negatively impact safety, and may be overall inefficient. Several arguments call into question the footprint-based approach, but a particularly important one is that large vehicles can impose a negative safety externality on other drivers.”²⁴² IPI commented, further, that the agencies should consider the relative merits of other vehicle attributes, including vehicle fuel type, suggesting that it would be more difficult for manufacturers to manipulate a flatter standard or one “differentiated by fuel type.”²⁴³ Similarly, Michalek and Whitefoot recommended “that the agencies reexamine automaker response to the footprint-based standards to determine if adjustments should be made to avoid inducing increases to vehicle size.”²⁴⁴

Conversely, ICCT commented that “the switch to footprint-based CAFE and [CO₂] standards has been widely credited with diminishing safety concerns with efficiency standards. Footprint standards encourage larger vehicles with wider track width, which reduces rollovers, and longer wheelbase, which increases the crush space and reduces deceleration forces for both vehicles in a two-vehicle collision.”²⁴⁵ Similarly, BorgWarner commented that “the use of a footprint standard not only provides greater incentive for mass reduction, but also encourages a larger footprint for a given vehicle mass, thus providing increased safety for a given mass vehicle,”²⁴⁶ and the Aluminum Association commented footprint based standards drive “fuel-efficiency improvement across all vehicle classes,” “eliminate the incentive to shift fleet volume to smaller cars which has been shown to slightly decrease safety in vehicle-to-vehicle collisions,” and provide “an incentive for reducing weight in the larger vehicles, where weight reduction is of the most benefit for societal safety,” citing Ford’s aluminum-intensive F150 pickup truck as an example.²⁴⁷ NADA urged the agencies to continue basing standards on vehicle footprint, as doing so “serves both to require and allow OEMs to build more fuel-efficient vehicles across the broadest possible light-duty passenger car and truck spectrum,”²⁴⁸ and UCS commented that footprint-based standards “increase consumer choice, ensuring that the vehicles available for purchase in every vehicle class continue to get more efficient.”²⁴⁹ Furthermore, regarding concerns that footprint-based standards may be susceptible to manipulation, the Alliance commented that “the data above [from Novation Analytics] shows there are no systemic footprint increases (or any type of target manipulation) occurring.”²⁵⁰ While FCA’s comments supported this Alliance comment, FCA commented further that, lacking some utility-related vehicle attributes such as towing capability, 4-wheel-drive, and ride height, “it is clear the footprint standard does not fully account for pickup truck capability and the components needed such as larger powertrains, greater mass and frontal area,” and requested the agencies “correct LDT standards to

reflect the current market preference for capability over efficiency, and introduce mechanisms into the regulation that can adjust for efficiency and capability tradeoffs that footprint standards currently ignore.”²⁵¹

When first electing to adopt footprint-based standards, NHTSA carefully considered other alternatives, including vehicle mass and “shadow” (overall width multiplied by overall length). Compared to both of these other alternatives, footprint is much less susceptible to gaming, because while there is some potential to adjust track width, wheelbase is more expensive to change, at least outside a planned vehicle redesign. EPA agreed with NHTSA’s assessment, nothing has changed the relative merits of at least these three potential attributes, and nothing in the evolution of the fleet demonstrates that footprint-based standards are leading manufacturers to increase the footprint of specific vehicle models by more than they would in response to customer demand. Also, even if footprint-based standards are encouraging some increases in vehicle size, NHTSA continues to maintain, and EPA to agree, that such increases should tend to improve overall highway safety rather than degrading it. Regarding FCA’s request that the agencies adopt an approach that accounts for a wider range of vehicle attributes related to both vehicle fuel economy and customer-facing vehicle utility, the agencies are concerned that doing so could further complicate already-complex standards and also lead to unintended consequences. For example, it is not currently clear how a multi-attribute approach would appropriately balance emphasis between vehicle attributes (e.g., how much relative fuel consumption should be attributed to, respectively, vehicle footprint, towing capacity, drive type, and ground clearance). Also, basing standards on, in part, ground clearance would encourage manufacturers to increase ride height, potentially increasing the frequency of vehicle rollover crashes. Regarding IPI’s recommendation that fuel type be included as a vehicle attribute for attribute-based standards, the agencies note that both CAFE and CO₂ standards already account for fuel type in the procedures for measuring fuel economy levels and CO₂ emission rates, and for calculating fleet average CAFE and CO₂ levels.

Therefore, having considered public comments on the choice of vehicle attributes for CAFE and CO₂ standards, the agencies are finalizing standards

that, as proposed, are defined in terms of vehicle footprint.

3. What mathematical function should be used to specify footprint-based standards?

In requiring NHTSA to “prescribe by regulation separate average fuel economy standards for passenger and non-passenger automobiles based on 1 or more vehicle attributes related to fuel economy and express each standard in the form of a mathematical function,” EPCA/EISA provides ample discretion regarding not only the selection of the attribute(s), but also regarding the nature of the function. The CAA provides no specific direction regarding CO₂ regulation, and EPA has continued to harmonize this aspect of its CO₂ regulations with NHTSA’s CAFE regulations. The relationship between fuel economy (and CO₂ emissions) and footprint, though directionally clear (i.e., fuel economy tends to decrease and CO₂ emissions tend to increase with increasing footprint), is theoretically vague, and quantitatively uncertain; in other words, not so precise as to *a priori* yield only a single possible curve.

The decision of how to specify this mathematical function therefore reflects some amount of judgment. The function can be specified with a view toward achieving different environmental and petroleum reduction goals, encouraging different levels of application of fuel-saving technologies, avoiding any adverse effects on overall highway safety, reducing disparities of manufacturers’ compliance burdens, and preserving consumer choice, among other aims. The following are among the specific technical concerns and resultant policy tradeoffs the agencies have considered in selecting the details of specific past and future curve shapes:

- Flatter standards (i.e., curves) increase the risk that both the size of vehicles will be reduced, potentially compromising highway safety, and reducing any utility consumers would have gained from a larger vehicle.

- Steeper footprint-based standards may create incentives to upsize vehicles, potentially oversupplying vehicles of certain footprints beyond what consumers would naturally demand, and thus increasing the possibility that fuel savings and CO₂ reduction benefits will be forfeited artificially.

- Given the same industry-wide average required fuel economy or CO₂ standard, flatter standards tend to place greater compliance burdens on full-line manufacturers.

- Given the same industry-wide average required fuel economy or CO₂

standard, dramatically steeper standards tend to place greater compliance burdens on limited-line manufacturers (depending of course, on which vehicles are being produced).

- If cutpoints are adopted, given the same industry-wide average required fuel economy, moving small-vehicle cutpoints to the left (*i.e.*, up in terms of fuel economy, down in terms of CO₂ emissions) discourages the introduction of small vehicles, and reduces the incentive to downsize small vehicles in ways that could compromise overall highway safety.

- If cutpoints are adopted, given the same industry-wide average required

fuel economy, moving large-vehicle cutpoints to the right (*i.e.*, down in terms of fuel economy, up in terms of CO₂ emissions) better accommodates the design requirements of larger vehicles—especially large pickups—and extends the size range over which downsizing is discouraged.

4. What mathematical functions have been used previously, and why?

Notwithstanding the aforementioned discretion under EPCA/EISA, data should inform consideration of potential mathematical functions, but how relevant data is defined and interpreted, and the choice of methodology for

fitting a curve to that data, can and should include some consideration of specific policy goals. This section summarizes the methodologies and policy concerns that were considered in developing previous target curves (for a complete discussion see the 2012 FRIA).

As discussed below, the MY 2011 final curves followed a constrained logistic function defined specifically in the final rule.²⁵² The MYs 2012–2021 final standards and the MYs 2022–2025 augural standards are defined by constrained linear target functions of footprint, as shown below:²⁵³

$$Target = \frac{1}{\min\left(\max\left(c * Footprint + d, \frac{1}{a}\right), \frac{1}{b}\right)}$$

Here, *Target* is the fuel economy target applicable to vehicles of a given footprint in square feet (*Footprint*). The upper asymptote, *a*, and the lower asymptote, *b*, are specified in mpg; the reciprocal of these values represent the lower and upper asymptotes, respectively, when the curve is instead specified in gallons per mile (gpm). The slope, *c*, and the intercept, *d*, of the linear portion of the curve are specified as gpm per change in square feet, and gpm, respectively.

The min and max functions will take the minimum and maximum values within their associated parentheses. Thus, the max function will first find the maximum of the fitted line at a given footprint value and the lower asymptote from the perspective of gpm. If the fitted line is below the lower asymptote it is replaced with the floor, which is also the minimum of the floor and the ceiling by definition, so that the target in mpg space will be the reciprocal of the floor in mpg space, or simply, *a*. If, however, the fitted line is not below the lower asymptote, the fitted value is returned from the max function and the min function takes the minimum value of the upper asymptote (in gpm space) and the fitted line. If the fitted value is below the upper asymptote, it is between the two asymptotes and the fitted value is appropriately returned from the min function, making the overall target in mpg the reciprocal of the fitted line in gpm. If the fitted value is above the

upper asymptote, the upper asymptote is returned from the min function, and the overall target in mpg is the reciprocal of the upper asymptote in gpm space, or *b*.

In this way curves specified as constrained linear functions are specified by the following parameters:

a = upper limit (mpg)

b = lower limit (mpg)

c = slope (gpm per sq.ft.)

d = intercept (gpm)

The slope and intercept are specified as gpm per sq. ft. and gpm instead of mpg per sq. ft. and mpg because fuel consumption and emissions appear roughly linearly related to gallons per mile (the reciprocal of the miles per gallon).

a) NHTSA in MY 2008 and MY 2011 CAFE (Constrained Logistic)

For the MY 2011 CAFE rule, NHTSA estimated fuel economy levels by footprint from the MY 2008 fleet after normalization for differences in technology,²⁵⁴ but did not make adjustments to reflect other vehicle attributes (*e.g.*, power-to-weight ratios). Starting with the technology-adjusted passenger car and light truck fleets, NHTSA used minimum absolute deviation (MAD) regression without sales weighting to fit a logistic form as a starting point to develop mathematical functions defining the standards.

NHTSA then identified footprints at which to apply minimum and maximum values (rather than letting the standards extend without limit) and transposed these functions vertically (*i.e.*, on a gallons-per-mile basis, uniformly downward) to produce the promulgated standards. In the preceding rule, for MYs 2008–2011 light truck standards, NHTSA examined a range of potential functional forms, and concluded that, compared to other considered forms, the constrained logistic form provided the expected and appropriate trend (decreasing fuel economy as footprint increases), but avoided creating “kinks” the agency was concerned would provide distortionary incentives for vehicles with neighboring footprints.²⁵⁵

b) MYs 2012–2016 Standards (Constrained Linear)

For the MYs 2012–2016 rule, potential methods for specifying mathematical functions to define fuel economy and CO₂ standards were reevaluated. These methods were fit to the same MY 2008 data as the MY 2011 standard. Considering these further specifications, the constrained logistic form, if applied to post-MY 2011 standards, would likely contain a steep mid-section that would provide undue incentive to increase the footprint of midsize passenger cars.²⁵⁶ A range of

²⁵² See 74 FR 14196, 14363–14370 (Mar. 30, 2009) for NHTSA discussion of curve fitting in the MY 2011 CAFE final rule.

²⁵³ The right cutpoint for the light truck curve was moved further to the right for MYs 2017–2021, so that more possible footprints would fall on the sloped part of the curve. In order to ensure that, for all possible footprints, future standards would be at least as high as MY 2016 levels, the final standards

for light trucks for MYs 2017–2021 is the maximum of the MY 2016 target curves and the target curves for the give MY standard. This is defined further in the 2012 final rule. See 77 FR 62624, at 62699–700 (Oct. 15, 2012).

²⁵⁴ See 74 FR 14196, 14363–14370 (Mar. 30, 2009) for NHTSA discussion of curve fitting in the MY 2011 CAFE final rule.

²⁵⁵ See 71 FR 17556, 17609–17613 (Apr. 6, 2006) for NHTSA discussion of “kinks” in the MYs 2008–2011 light truck CAFE final rule (there described as “edge effects”). A “kink,” as used here, is a portion of the curve where a small change in footprint results in a disproportionately large change in stringency.

²⁵⁶ 75 FR at 25362.

methods to fit the curves would have been reasonable, and a minimum absolute deviation (MAD) regression without sales weighting on a technology-adjusted car and light truck fleet was used to fit a linear equation. This equation was used as a starting point to develop mathematical functions defining the standards. Footprints were then identified at which to apply minimum and maximum values (rather than letting the standards extend without limit). Finally, these constrained/piecewise linear functions were transposed vertically (*i.e.*, on a gpm or CO₂ basis, uniformly downward) by multiplying the initial curve by a single factor for each MY standard to produce the final attribute-based targets for passenger cars and light trucks described in the final rule.²⁵⁷ These transformations are typically presented as percentage improvements over a previous MY target curve.

c) MYs 2017 and Beyond Standards (Constrained Linear)

The mathematical functions finalized in 2012 for MYs 2017 and beyond changed somewhat from the functions for the MYs 2012–2016 standards. These changes were made both to address comments from stakeholders, and to consider further some of the technical concerns and policy goals judged more preeminent under the increased uncertainty of the impacts of finalizing and proposing standards for model years further into the future.²⁵⁸ Recognizing the concerns raised by full-line OEMs, it was concluded that continuing increases in the stringency of the light truck standards would be more feasible if the light truck curve for MYs 2017 and beyond was made steeper than the MY 2016 truck curve and the right (large footprint) cut-point was extended only gradually to larger footprints. To accommodate these considerations, the 2012 final rule finalized the slope fit to the MY 2008 fleet using a sales-weighted, ordinary least-squares regression, using a fleet that had technology applied to make the technology application across the fleet more uniform, and after adjusting the

data for the effects of weight-to-footprint. Information from an updated MY 2010 fleet was also considered to support this decision. As the curve was vertically shifted (with fuel economy specified as mpg instead of gpm or CO₂ emissions) upwards, the right cutpoint was progressively moved for the light truck curves with successive model years, reaching the final endpoint for MY 2021.

5. Reconsidering the Mathematical Functions for Today's Rulemaking

a) Why is it important to reconsider the mathematical functions?

By shifting the developed curves by a single factor, it is assumed that the underlying relationship of fuel consumption (in gallons per mile) to vehicle footprint does not change significantly from the model year data used to fit the curves to the range of model years for which the shifted curve shape is applied to develop the standards. However, it must be recognized that the relationship between vehicle footprint and fuel economy is not necessarily constant over time; newly developed technologies, changes in consumer demand, and even the curves themselves could influence the observed relationships between the two vehicle characteristics. For example, if certain technologies are more effective or more marketable for certain types of vehicles, their application may not be uniform over the range of vehicle footprints. Further, if market demand has shifted between vehicle types, so that certain vehicles make up a larger share of the fleet, any underlying technological or market restrictions which inform the average shape of the curves could change. That is, changes in the technology or market restrictions themselves, or a mere re-weighting of different vehicles types, could reshape the fit curves.

For the above reasons, the curve shapes were reconsidered in the proposal using the newest available data from MY 2016. With a view toward corroboration through different techniques, a range of descriptive statistical analyses were conducted that do not require underlying engineering models of how fuel economy and

footprint might be expected to be related, and a separate analysis that uses vehicle simulation results as the basis to estimate the relationship from a perspective more explicitly informed by engineering theory was conducted as well. Despite changes in the new vehicle fleet both in terms of technologies applied and in market demand, the underlying statistical relationship between footprint and fuel economy has not changed significantly since the MY 2008 fleet used for the 2012 final rule; therefore, EPA and NHTSA proposed to continue to use the curve shapes fit in 2012. The analysis and reasoning supporting this decision follows.

b) What statistical analyses did EPA and NHTSA consider?

In considering how to address the various policy concerns discussed above, data from the MY 2016 fleet was considered, and a number of descriptive statistical analyses (*i.e.*, involving observed fuel economy levels and footprints) using various statistical methods, weighting schemes, and adjustments to the data to make the fleets less technologically heterogeneous were performed. There were several adjustments to the data that were common to all of the statistical analyses considered.

With a view toward isolating the relationship between fuel economy and footprint, the few diesels in the fleet were excluded, as well as the limited number of vehicles with partial or full electric propulsion; when the fleet is normalized so that technology is more homogenous, application of these technologies is not allowed. This is consistent with the methodology used in the 2012 final rule.

The above adjustments were applied to all statistical analyses considered, regardless of the specifics of each of the methods, weights, and technology level of the data, used to view the relationship of vehicle footprint and fuel economy. Table V–1, below, summarizes the different assumptions considered and the key attributes of each. The analysis was performed considering all possible combinations of these assumptions, producing a total of eight footprint curves.

| | OLS | MAD | Production-weighted | Model-weighted | Current Technology | Max. Technology |
| Details | Ordinary Least Squares Regression | Minimum Absolute Deviation Regression | Points weighted by production volumes of each model. | Equal weight for each model; collapses points with similar footprint, FE, and curb weight. | Current MY 2016 tech., excluding: HEV, PHEV, BEV, and FCV. | Maximum tech. applied, excluding: HEV, PHEV, BEV, and FCV. |
| Key Attributes | Describes the average relationship between footprint and fuel economy; outliers can skew results. | Describes the median relationship between footprint and fuel economy; does not give outliers as much weight. | Tends towards higher-volume models; may systematically disadvantage manufacturers who produce fewer vehicles. | Tends towards the space of the joint distribution of footprint and FE with the most models; gives low-volume models equal weight. | Describes current market, including demand factors; may miss changes in curve shape due to advanced technology application. | Captures relationship with homogenous technology application; may miss varying demand considerations for different segments. |

(1) Current Technology Level Curves

The “current technology” level curves exclude diesels and vehicles with electric propulsion, as discussed above, but make no other changes to each model year fleet. Comparing the MY 2016 curves to ones built under the same methodology from previous model year fleets shows whether the observed curve shape has changed significantly over time as standards have become more stringent. Importantly, these curves will include any market forces which make technology application variable over the distribution of footprint. These market forces will not be present in the “maximum technology” level curves: By making technology levels homogenous, this variation is removed. The current technology level curves built using both regression types and both regression weight methodologies from the MY 2008, MY 2010, and MY 2016 fleets, shown in more detail in Chapter 4.4.2.1 of the PRIA, support the curve slopes finalized in the 2012 final rule. The curves built from most methodologies using each fleet generally shift, but remain very similar in slope. This suggests that the relationship of footprint to fuel economy, including both technology and market limits, has not significantly changed.

(2) Maximum Technology Level Curves

As in prior rulemakings, technology differences between vehicle models were considered to be a significant factor producing uncertainty regarding the relationship between fuel consumption and footprint. Noting that attribute-based standards are intended to encourage the application of additional technology to improve fuel efficiency and reduce CO₂ emissions across the distribution of footprint in the fleet, approaches were considered in which technology application is simulated for purposes of the curve fitting analysis in order to produce fleets that are less varied in technology content. This approach helps reduce “noise” (*i.e.*, dispersion) in the plot of vehicle footprints and fuel consumption levels and identify a more technology-neutral relationship between footprint and fuel consumption. The results of updated analysis for maximum technology level curves are also shown in Chapter 4.4.2.2 of the PRIA. Especially if vehicles progress over time toward more similar size-specific efficiency, further removing variation in technology application both better isolates the relationship between fuel consumption and footprint and further supports the curve slopes finalized in the 2012 final rule.

c) What other methodologies were considered?

The methods discussed above are descriptive in nature, using statistical analysis to relate observed fuel economy levels to observed footprints for known vehicles. As such, these methods are clearly based on actual data, answering the question “how does fuel economy appear to be related to footprint?” However, being independent of explicit engineering theory, they do not answer the question “how might one expect fuel economy to be related to footprint?” Therefore, as an alternative to the above methods, an alternative methodology was also developed and applied that, using full-vehicle simulation, comes closer to answering the second question, providing a basis either to corroborate answers to the first, or suggest that further investigation could be important.

As discussed in the 2012 final rule, several manufacturers have confidentially shared with the agencies what they described as “physics-based” curves, with each OEM showing significantly different shapes for the footprint-fuel economy relationships. This variation suggests that manufacturers face different curves given the other attributes of the vehicles in their fleets (*i.e.*, performance

characteristics) and/or that their curves reflected different levels of technology application. In reconsidering the shapes of the proposed MYs 2021–2026 standards, a similar estimation of physics-based curves leveraging third-party simulation work from Argonne National Laboratories (Argonne) was developed. Estimating physics-based curves better ensures that technology and performance are held constant for all footprints; augmenting a largely statistical analysis with an analysis that more explicitly incorporates engineering theory helps to corroborate that the relationship between fuel economy and footprint is in fact being characterized.

Tractive energy is the amount of energy it will take to move a vehicle.²⁵⁹

Here, tractive energy effectiveness is defined as the share of the energy content of fuel consumed which is converted into mechanical energy and used to move a vehicle—for internal combustion engine (ICE) vehicles, this will vary with the relative efficiency of specific engines. Data from Argonne simulations suggest that the limits of tractive energy effectiveness are approximately 25 percent for vehicles with internal combustion engines which do not possess integrated starter generator, other hybrid, plug-in, pure electric, or fuel cell technology.

A tractive energy prediction model was also developed to support today's proposal. Given a vehicle's mass, frontal area, aerodynamic drag coefficient, and

rolling resistance as inputs, the model will predict the amount of tractive energy required for the vehicle to complete the Federal test cycle. This model was used to predict the tractive energy required for the average vehicle of a given footprint²⁶⁰ and “body technology package” to complete the cycle. The body technology packages considered are defined in Table V–2, below. Using the absolute tractive energy predicted and tractive energy effectiveness values spanning possible ICE engines, fuel economy values were then estimated for different body technology packages and engine tractive energy effectiveness values.

Table V-2 – Summary of Body Technology Packages Considered for Tractive Energy

Analysis

| Body Tech. Package | Mass Reduction Level | Aerodynamics Level | Roll Resistance Level |
|--------------------|----------------------|--------------------|-----------------------|
| 1 | 0% | 0% | 0% |
| 2 | 0% | 10% | 10% |
| 3 | 10% | 10% | 10% |
| 4 | 10% | 15% | 20% |
| 5 | 15% | 20% | 20% |

Chapter 6 of the PRIA show the resultant CAFE levels estimated for the vehicle classes Argonne simulated for this analysis, at different footprint values and by vehicle “box.” Pickups are considered 1-box, hatchbacks and minivans are 2-box, and sedans are 3-box. These estimates are compared with the MY 2021 standards finalized in 2012. The general trend of the simulated data points follows the pattern of the previous MY 2021 standards for all technology packages and tractive energy effectiveness values presented in the PRIA. The tractive energy curves are intended to validate the curve shapes against a physics-based alternative, and the analysis suggests that the curve shapes track the physical relationship between fuel economy and tractive energy for different footprint values.

Physical limitations are not the only forces manufacturers face; their success

is dependent upon producing vehicles that consumers desire and will purchase. For this reason, in setting future standards, the analysis will continue to consider information from statistical analyses that do not homogenize technology applications in addition to statistical analyses which do, as well as a tractive energy analysis similar to the one presented above.

The relationship between fuel economy and footprint remains directionally discernable but quantitatively uncertain. Nevertheless, each standard must commit to only one function. Approaching the question “how is fuel economy related to footprint” from different directions and applying different approaches has given EPA and NHTSA confidence that the function applied here appropriately and reasonably reflects the relationship between fuel economy and footprint.

The agencies invited comments on this conclusion and the supporting analysis. IPI raised concerns that “. . . several dozen models (mostly subcompacts and sports cars) fall in the 30–40 square feet range, which are all subject to the same standards” and that “manufacturers of these models may have an incentive to decrease footprints as a compliance strategy, since doing so would not trigger more stringent standards.”²⁶¹ NHTSA and EPA agree that, all else equal, downsizing the smallest cars (e.g., Chevrolet Spark, Ford Fiesta, Mini Cooper, Mazda MX–5, Porsche 911, Toyota Yaris) would most likely tend to degrade overall highway safety. At the same time, as discussed above, the agencies recognize that small vehicles do appear attractive to some market segments (although obviously the Ford Fiesta and Porsche 911 compete in different segments).

²⁵⁹ Thomas, J. “Drive Cycle Powertrain Efficiencies and Trends Derived from EPA Vehicle Dynamometer Results,” *SAE Int. J. Passeng. Cars—Mech. Syst.* 7(4):2014, doi:10.4271/2014-01-2562. Available at <https://www.sae.org/publications/>

technical-papers/content/2014-01-2562/ (last accessed June 15, 2018).

²⁶⁰ The mass reduction curves used elsewhere in this analysis were used to predict the mass of a vehicle with a given footprint, body style box, and mass reduction level. The ‘Body style Box’ is 1 for

hatchbacks and minivans, 2 for pickups, and 3 for sedans, and is an important predictor of aerodynamic drag. Mass is an essential input in the tractive energy calculation.

²⁶¹ IPI, NHTSA–2018–0067–12362, p. 14.

Therefore, there is a tension between on one hand, avoiding standards that unduly encourage safety-eroding downsizing and, on the other, avoiding standards that unduly penalize the market for small vehicles. The agencies examined this issue, and note that the market for the smallest vehicles has not evolved at all as estimated in the analysis supporting the 2012 final rule, and attribute this more to fuel prices and consumer demand for larger vehicles than to attribute-based CAFE and CO₂ standards. For example, the market for vehicles with footprints less than 40 square foot was about 45 percent smaller in MY 2017 than in MY 2010. The agencies also found that

among the smallest vehicle models produced throughout MYs 2010–2017, most have become larger, not smaller. For example, while the Mazda MX–5's footprint decreased by 0.1 square foot (0.3 percent) during that time, the MY 2017 versions of the Mini Cooper, Smart fortwo, Porsche 911, and Toyota Yaris had larger footprints than in MY 2010. With the market for very small vehicles shrinking, and with manufacturers not evidencing a tendency to make the smallest vehicles even smaller, the agencies are satisfied that it would be unwise to change the target functions such that targets never stop becoming more stringent as vehicle footprint becomes ever smaller, because doing so

could further impede an already-shrinking market.

B. No-Action Alternative

As in the proposal, the No-Action Alternative applies the augural CAFE and final CO₂ targets announced in 2012 for MYs 2021–2025.²⁶² For MY 2026, this alternative applies the same targets as for MY 2025. The carbon dioxide equivalent of air conditioning refrigerant leakage credits, nitrous oxide, and methane emissions are included for compliance with the EPA standards for all model years under the no-action alternative.²⁶³

²⁶² <https://www.govinfo.gov/content/pkg/CFR-2014-title40-vol19/pdf/CFR-2014-title40-vol19-sec86-1818-12.pdf>

²⁶³ EPA regulations use a different but mathematically equivalent approach to specify

targets. Rather than using a function with nested minima and maxima functions, EPA regulations specify requirements separately for different ranges of vehicle footprint. Because these ranges reflect the combined application of the listed minima,

maxima, and linear functions, it is mathematically equivalent and more efficient to present the targets as in this Section.

In comments on the DEIS, CBD *et al.* indicated that it was appropriate for NHTSA to use the augural CAFE standards as the baseline No Action regulatory alternative.²⁶⁴ However, CARB commented that the baseline regulatory alternative should include CARB's ZEV mandate, in part because EPA must consider "other regulations promulgated by EPA or other government entities," and, according to CARB, there will be much more vehicle electrification in the future as manufacturers respond to market demand and also work to comply with the ZEV mandate.²⁶⁵ Similarly, EPA's Science Advisory Board recommended—despite the action taken in the One National Program Action—that the baseline include state ZEV mandates "to be consistent with policies that would prevail in the absence of the rule change."²⁶⁶ EPA's Science Advisory Board further recommended including sensitivity analyses with different penetration rates of ZEVs.

On the other hand, arguing for consideration of standards less stringent than those proposed in the NPRM, Walter Kreucher commented that rather than using the augural standards as the baseline, "a better approach would be to assume a clean sheet of paper and start from the existing 2016MY fleet and its associated standards as the baseline

using 0%/year increases for both passenger cars and light trucks for MYs 2017–2026."²⁶⁷ Similarly, AVE argued that because previously-promulgated standards for MYs 2018–2021 already present a significant challenge that "will likely require almost every automaker to continue using credits for compliance, . . . AVE believes this rulemaking should reset . . . the current compliance baseline for cars and light trucks at MY 2018 . . ."²⁶⁸ BorgWarner commented similarly that "Beginning in MY 2018, standards should be reset to the levels the industry actually achieved. For MY 2018 and beyond, succeeding model year targets should be set with an annual rate of improvement defined by the slope of improvement the industry has achieved over the last six years. . . . Based on these data, our analysis suggests the most reasonable and logical rate of improvement falls between 2.0% to 2.6% for cars and trucks. Additionally, a single rate of improvement for the combined fleet should be considered."²⁶⁹

The No-Action Alternative represents expectations regarding the world in the absence of a proposal, accounting for applicable laws already in place. Although manufacturers are already making significant use of compliance credits toward compliance with even MY 2017 standards, the agencies are

obligated to evaluate regulatory alternatives against the standards already in place through MY 2025. Similarly, even though manufacturers are already producing electric vehicles, EPA and NHTSA appropriately excluded California's ZEV mandate from the No-Action alternative for the NPRM, for several reasons. First, the ZEV mandate is not Federal law; second, as described in the proposal and subsequently finalized in regulatory text, the ZEV mandate is expressly and impliedly preempted by EPCA; third, EPA proposed to withdraw the waiver of CAA preemption in the NPRM and subsequently finalized this withdrawal. Accordingly, the agencies have, therefore, appropriately excluded the ZEV mandate from the No-Action alternative. However, as discussed below, the agencies' analysis does account for the potential that under every regulatory alternative, including the No-Action Alternative, vehicle electrification could increase in the future, especially if batteries become less expensive as gasoline becomes more expensive.

C. Action Alternatives

1. Alternatives in Final Rule

Table V–5 below shows the different alternatives evaluated in today's notice.

Table V-5 – Regulatory Alternatives Currently under Consideration

| Alternative | Change in stringency |
|------------------------|---|
| Baseline/ No-Action | MY 2021 standards remain in place; MYs 2022-2025 augural CAFE standards are finalized and CO ₂ standards remain unchanged; MY 2026 standards are set at MY 2025 levels |
| 1 (Proposed) | Existing standards through MY 2020, then 0%/year increases for both passenger cars and light trucks, for MYs 2021-2026 |
| 2 | Existing standards through MY 2020, then 0.5%/year increases for both passenger cars and light trucks, for MYs 2021-2026 |
| 3 (Preferred) | Existing standards through MY 2020, then 1.5%/year increases for both passenger cars and light trucks, for MYs 2021-2026 |
| 4 | Existing standards through MY 2020, then 1%/year increases for passenger cars and 2%/year increases for light trucks, for MYs 2021-2026 |
| 5 | Existing standards through MY 2021, then 1%/year increases for passenger cars and 2%/year increases for light trucks, for MYs 2022-2026 |
| 6 | Existing standards through MY 2020, then 2%/year increases for passenger cars and 3%/year increases for light trucks, for MYs 2021-2026 |
| 7 | Existing standards through MY 2021, then 2%/year increases for passenger cars and 3%/year increases for light trucks, for MYs 2022-2026 |

With one exception, the alternatives considered in the NPRM included the changes in stringency for the above alternatives. Alternative 3, the preferred alternative, is newly included for today's notice.²⁷⁰

Regulations regarding implementation of NEPA requires agencies to “rigorously explore and objectively evaluate all reasonable alternatives, and for alternatives which were eliminated from detailed study, briefly discuss the reasons for their having been eliminated.”²⁷¹ This does not amount to a requirement that agencies evaluate the widest conceivable spectrum of alternatives. For example, a State considering adding a single travel lane to a preexisting section of highway would not be required to consider adding three lanes, or to consider dismantling the highway altogether.

Among thousands of individual comments that mentioned the proposed standards very generally, some comments addressed the range and definition of these regulatory alternatives in specific terms, and these specific comments include comments on the stringency, structure, and particular provisions defining the set of regulatory alternatives under consideration.

As discussed throughout today's notice, the agencies have updated and otherwise revised many aspects of the analysis. The agencies have also reconsidered whether the set of alternatives studied in detail should be expanded to include standards less stringent than the proposal's preferred alternative, or to include standards more stringent than the proposal's no-action alternative. On one hand, comments from Walter Kreucher and AVE cited above indicate the agencies should consider relaxing standards below MY 2020 levels, and CEI challenged the agencies' failure to include less-stringent alternatives in the following comments on this question:

DOT failed to consider the possibility of freezing CAFE at an even more lenient standard than currently exists, nor did it consider making its proposed freeze take effect sooner than MY 2020. However, as DOT's own analysis strongly indicates, doing so would lead to even greater benefits and an even greater reduction in CAFE-related deaths and injuries. In short, DOT's failure to

consider this possibility is arbitrary and capricious. It has an opportunity to remedy this in its final rule, and it should do so by selecting a standard that is even more lenient than the one it proposed. . . . It should have gone beyond its original set of alternatives and examined less stringent ones as well—until it found one that, for some reason or another, failed to produce greater safety benefits or failed to meet the statutory factors.²⁷²

On the other hand, a coalition of ten environmental advocacy organizations stated that the agencies should consider alternatives more stringent than those defining the baseline no action alternative, arguing that in light of CEQ guidance and the 2018 IPCC report on climate change, “the increasing danger, increasing urgency, and increasing importance of vehicle emissions all rationally counsel for strengthening emission standards.”²⁷³ CBD *et al.* observe that “none of these alternatives [considered in the NPRM] increases fuel economy in comparison with the No Action Alternative, none conserves energy . . .” and go on to assert that “none represents maximum feasible CAFE standards.”²⁷⁴ Similarly, EDF commented that “. . . given its clear statutory directive to maximize fuel savings, NHTSA should have considered a range of alternatives that would be more protective than the existing standards,”²⁷⁵ and three State agencies in Minnesota commented that “more stringent standards are consistent with EPCA's purpose of energy conservation and the CAA's purpose of reducing harmful air pollutants.”²⁷⁶ The North Carolina Department of Environmental Quality acknowledged the agencies' determination in the proposal that alternatives beyond the augural standards might be economically impracticable, but nevertheless argued that “alternatives that exceed the stringency of the current standards are consistent with EPCA's purpose”²⁷⁷ In oral testimony before the agencies, the New York State Attorney General also indicated that the agencies should consider alternatives more stringent than the augural standards.²⁷⁸

²⁷⁷ North Carolina Department of Environmental Quality, NHTSA–2018–0067–12025, at 37–38.

²⁷⁸ New York State Attorney General, Testimony of Austin Thompson, NHTSA–2018–0067–12305, at 13.

A coalition of States and cities commented that “at a minimum, the existing standards should be left in place, but EPA should also consider whether to make the standards more stringent, not less, just as it has done in prior proposals.”²⁷⁹ More specifically, through International Mosaic, some individuals commented that the agencies must “fully and publicly consider a few options that require at least a seven annual percent [sic] improvement in vehicle fleet mileage.”²⁸⁰ In comments on the DEIS, CBD, *et al.* went further, commenting that “NHTSA's most stringent alternative must be set at no lower than a 9 percent improvement per year.”²⁸¹ Most manufacturers who commented on stringency did not identify specific regulatory alternatives that the agencies should consider, although Honda suggested that standards be set to increase in stringency at 5 percent annually for both passenger cars and light trucks throughout model years 2021–2026.^{282 283}

The agencies carefully considered these comments to expand the range of stringencies to be evaluated as possible candidates for promulgation. To inform this consideration, the agencies used the CAFE model to examine a progression of stringencies extending outside the range presented in the proposal and draft EIS, and as a point of reference, using a case that reverts to MY 2018 standards starting in MY 2021. Scenarios included in this initial screening exercise ranged as high as increasing annually at 9.5 percent during MYs 2021–2026, reaching average CAFE and CO₂ requirements of 66 mpg and 120 g/mi, respectively. Results of this analysis are presented in the following tables and charts. Focusing on MY 2029, the tables show average required and achieved CAFE (as mpg) and CO₂ (as g/mi) levels for each scenario, along with average per-vehicle costs (in 2018 dollars, relative to retaining MY 2017 technologies). The proposed (0%/0%), final (1.5%/1.5%), and baseline augural standards are shown in bold type. The charts present

²⁷⁹ NHTSA–2018–0067–11735, at 49.

²⁸⁰ International Mosaic NHTSA–2018–0067–11154, at 1

²⁸² Honda, NHTSA–2018–0067–12019, EPA–HQ–OAR–2018–0283, at 54.

²⁸³ In model year 2021, the baseline standards for passenger cars and light trucks increase by about 4% and 6.5%, respectively, relative to standards for model year 2020. Depending on the composition of the future new vehicle fleet (*i.e.*, the footprints and relative market shares of passenger cars and light trucks), this amounts to an overall average stringency increase of about 5.5% relative to model year 2020.

²⁷⁰ As the agencies indicated in the NPRM, they were considering and taking comment “on a wide range of alternatives and have specifically modeled eight alternatives.” 83 FR at 42990 (Aug. 24, 2018). The preferred alternative in this final rule was within the range of alternatives considered in the proposal, although it was not specifically modeled at that time. This issue is discussed in further detail below.

²⁷¹ 40 CFR 1502.14.

the same results on a percentage basis, relative to values shown below for the scenario that reverts to MY 2018 standards starting in MY 2021.

For example, reverting to the MY 2018 CAFE standards starting in MY 2021 yields an average CAFE requirement of 35 mpg by MY 2029, with the industry exceeding that standard by 5 mpg at an average cost of \$1,255 relative to MY 2017 technology. Under the augural standards, the MY 2029 requirement increases to 47 mpg, the average compliance margin falls to 1 mpg, and the average cost increases to \$2,770. In other words, compared to the scenario that reverts to MY 2018 stringency starting in MY 2021, the augural standards increase stringency by 34 percent (from 35 to 47 mpg), increase average fuel economy by 20 percent (from 40 to 48 mpg), and increase costs by 121 percent (from \$1,255 to \$2,770).

As indicated in the following two charts, the reality of diminishing returns

clearly applies in both directions. On one hand, relaxing stringency below the proposed standards by reverting to MY 2018 or MY 2019 standards reduces average MY 2029 costs by only modest amounts (\$54-\$121). As discussed in Section VIII, the agencies' updated analysis indicates that the proposed standards would not be maximum feasible considering the EPCA/EISA statutory factors, and would not be appropriate under the CAA after considering the appropriate factors. If further relaxation of standards appeared likely to yield more significant cost reductions, it is conceivable that such savings could outweigh further foregoing of energy and climate benefits. However, this screening analysis does not show dramatic cost reductions. Therefore, the agencies did not include these two less stringent alternatives in the detailed analysis presented in Section VII.

On the other hand, increases in stringency beyond the baseline augural standards show relative costs continuing to accrue much more rapidly than relative CAFE and CO₂ improvements. As discussed below in Section VIII, even the no action alternative is already well beyond levels that can be supported under the CAA and EPCA. If further stringency increases appeared likely to yield more significant additional energy and environmental benefits, it is conceivable that these could outweigh these significant additional cost increases. However, this screening analysis shows no dramatic relative acceleration of energy and environmental benefits. Therefore, the agencies did not include stringencies beyond the augural standards in the detailed analysis presented in Section VII.

Figure V-1 – Increase in Average CAFE and Increase in Cost (MY 2029) versus Increase in Stringency (as Average Required mpg in MY 2029) of CAFE Standards

Figure V-2 – CO₂ Reduction and Cost Increases versus (MY 2029) Increase in Stringency

BILLING CODE 4910-59-C

Specific to model year 2021, some commenters argued that EPCA's lead time requirement prohibits NHTSA from revising CAFE standards for model year 2021.²⁸⁴ Regarding the revision of standards for model year 2021, NHTSA did consider EPCA's lead time requirement, and determined that while the agency would need to finalize a stringency increase at least 18 months before the beginning of the first affected model year, the agency can finalize a stringency decrease closer (or even after) the beginning of the first affected model year. The agency's reasoning is explained further in Section VIII. Therefore, NHTSA did not change regulatory alternatives to avoid any relaxation of stringency in model year 2021.

The Auto Alliance stated that "the truck increase rate should be no greater than the car rate of increase and should be the 'equivalent task' per fleet."²⁸⁵

Supporting these Alliance comments, FCA elaborated by commenting that "(1) in MY2017, the latest data we have available, most trucks have a larger gap to standards than cars, and (2) all of the truck segments are challenged because consumers are placing a greater emphasis on capability than fuel economy."²⁸⁶ Similarly, Ford commented that "... the rates of increase in the stringency of the standards should remain equivalent between passenger cars and light duty trucks."²⁸⁷ Other commenters expressed general support for equalizing the rates at which the stringencies of passenger car and light truck standards increase.²⁸⁸

For the final rule, the agencies have added an alternative in which stringency for both cars and trucks increases at 1.5 percent. This is consistent with comments received requesting that both fleets' standards increase in stringency by the same

amount, and 1.5 percent represents a rate of increase within the range of rates of increase considered in the NPRM.

Throughout the NPRM, the agencies described their consideration as covering a range of alternatives.²⁸⁹ The preferred alternative for this final rule, an increase in stringency of 1.5 percent for both cars and trucks, falls squarely

²⁸⁹ 83 FR at 42986 (Aug. 24, 2018) (explaining, in "Summary" section of NPRM, that "comment is sought on a range of alternatives discussed throughout this document"); *id.* at 42988 (stating that the agencies are "taking comment on a wide range of alternatives, including different stringencies and retaining existing CO₂ standards and the augural CAFE standards"); 42990 ("As explained above, the agencies are taking comment on a wide range of alternatives and have specifically modeled eight alternatives (including the proposed alternative) and the current requirements (*i.e.*, baseline/no action)."); 43197 ("[T]oday's notice also presents the results of analysis estimating impacts under a range of other regulatory alternatives the agencies are considering."); 43229 (explaining that "technology availability, development and application, if it were considered in isolation, is not necessarily a limiting factor in the Administrator's selection of which standards are appropriate within the range of the Alternatives presented in this proposal."); 43369 ("As discussed above, a range of regulatory alternatives are being considered.").

within the range of alternatives proposed by the agencies.

The NPRM alternatives were bounded on the upper end by the baseline/no action alternative, and the proposed alternative on the lower end (0 percent per year increase in stringency for both cars and trucks). For passenger cars, the agencies considered a range of stringency increases between 0 percent and 2 percent per year for passenger cars, in addition to the baseline/no action alternative. For light trucks, the agencies considered a range of stringency increases between 0 percent and 3 percent per year, in addition to the baseline/no action alternative.

The agencies considered the same range of alternatives for this final rule. As with the proposal, the alternatives for stringency are bounded on the upper end by the baseline/no action alternative and on the lower end by 0 percent per year increases for both passenger cars and light trucks. Consistent with the proposal, for this final rule, the agencies considered stringency increases of between 0 and 2 percent per year for passenger cars and between 0 and 3 percent per year for light trucks, in addition to the baseline/no action alternative.

While it was not specifically modeled in the NPRM, the new preferred alternative of an increase in stringency of 1.5 percent for both cars and trucks was well within the range of alternatives considered. The proposal described the alternatives specifically modeled as options for the agencies, but also gave notice that they did not limit the agencies in selecting from among the range of alternatives under consideration.²⁹⁰

The agencies explained in the proposal that they were “taking comment on a wide range of alternatives and have specifically modeled eight alternatives.”²⁹¹ As with the proposal, for the final rule, the agencies specifically modeled the upper and lower bounds of the baseline/no action alternative and 0 percent per year stringency increases for both passenger cars and light trucks. In both the

proposal and the final rule, the agencies also modeled a stringency increase of 2 percent per year for passenger cars and 3 percent per year for light trucks, as well as a variety of other specific increases between 0 and 2 percent for passenger cars and 0 and 3 percent for light trucks.

The specific alternatives the agencies modeled for the final rule reflect their consideration of public comments. As discussed above, multiple commenters expressed support for equalizing the rates at which the stringencies of passenger car and light truck standards increase. To help the agencies evaluate alternatives that include the same stringency increase for passenger cars and light trucks, three of the seven alternatives (in addition to the baseline/no action alternative) that the agencies specifically modeled for the final rule included the same stringency increase for passenger cars and light trucks. This includes the new preferred alternative of an increase in stringency of 1.5 percent for both cars and trucks. This alternative, and all others specifically modeled for the final rule, falls within the range of alternatives for stringency considered by the agencies in the proposal.

Beyond these stringency provisions discussed in the NPRM, the agencies also sought comment on a number of additional compliance flexibilities for the programs, as discussed in Section IX.

2. Additional Alternatives Suggested by Commenters

Beyond the comments discussed above regarding the shapes of the functions defining fuel economy and CO₂ targets, regarding the inclusion of non-CO₂ emissions, and regarding the stringencies to be considered, the agencies also received a range of other comments regarding regulatory alternatives.

Some of these additional comments involved how CAFE and CO₂ standards compare to one another for any given regulatory alternative. With a view toward maximizing harmonization of the standards, the Alliance, supported by some of its members’ individual comments, indicated that “to the degree flexibilities and incentives are not completely aligned between the CAFE and [CO₂] programs, there must be an offset in the associated footprint-based targets to account for those differences. Some areas of particular concerns are air conditioning refrigerant credits, and incentives for advanced technology vehicles. The Alliance urges the Agencies to seek harmonization of the

standards and flexibilities to the greatest extent possible. . . .”²⁹²

On the other hand, discussing consideration of compliance credits but making a more general argument, the NYU Institute for Policy Integrity commented that “. . . EPA is not allowed to set lower standards just for the sake of harmonization; to the contrary, full harmonization may be inconsistent with EPA’s statutory responsibilities.”²⁹³ Similarly, ACEEE argued that “any consideration of an extension or expansion of credit provisions under the [carbon dioxide] or CAFE standards program should take as a starting point the assumption that the additional credits will allow the stringency of the standards to be increased.”²⁹⁴

EPCA’s requirement that NHTSA set standards at the maximum feasible levels is separate and “wholly independent” from the CAA’s requirement, per *Massachusetts v. EPA*, that EPA issue regulations addressing pollutants that EPA has determined endanger public health and welfare.²⁹⁵ Nonetheless, as recognized by the Supreme Court, “there is no reason to think the two agencies cannot both administer their obligations and yet avoid inconsistency.”²⁹⁶ This conclusion was reached despite the fact that EPCA has a range of very specific requirements about how CAFE standards are to be structured, how manufacturers are to comply, what happens when manufacturers are unable to comply, and how NHTSA is to approach setting standards, and despite the fact that the CAA has virtually no such requirements. This means that while nothing about either EPCA or the CAA, much less the combination of the two, guarantees “harmonization” defining “One National Program,” the agencies are expected to be able to work out the differences.

Since tailpipe CO₂ standards are *de facto* fuel economy standards, the more differences there are between CO₂ and CAFE standards and compliance provisions, the more challenging it is for manufacturers to plan year-by-year production that responds to both, and the more difficult it is for affected stakeholders and the general public to understand regulation in this space. Therefore, even if the two statutes, taken together, do not guarantee “full harmonization,” steps toward greater

²⁹⁰ See, e.g., 83 FR at 43003 (Aug. 24, 2018) (“These alternatives were examined because they will be considered as options for the final rule. The agencies seek comment on these alternatives, seek any relevant data and information, and will review responses. That review could lead to the selection of one of the other regulatory alternatives for the final rule or some combination of the other regulatory alternatives (e.g., combining passenger cars standards from one alternative with light truck standards from a different alternative).”); *id.* at 43229 (describing a factor relevant to “the Administrator’s selection of which standards are appropriate within the range of the Alternatives presented in this proposal”).

²⁹⁶ *Id.*

harmonization help with compliance planning and transparency—and meet the expectations set forth by the Supreme Court that the agencies avoid inconsistencies.

The agencies have taken important steps toward doing so. For example, EPA has adopted separate footprint-based CO₂ standards for passenger cars and light trucks, and has redefined CAFE calculation procedures to introduce recognition for the application of real-world fuel-saving technology that is not captured with traditional EPA two-cycle compliance testing. Detailed aspects of both sets of standards and corresponding compliance provisions are discussed at length in Section IX. The agencies never set out with the primary goal of achieving “full harmonization,” such that both sets of standards would lead each manufacturer to respond in exactly the same way in every model year.²⁹⁷ For example, EPA did not adopt the EPCA requirement that domestic passenger car fleets each meet a minimum standard, or the EPCA cap on compliance credit transfers between passenger car fleets. On the other hand, EPA also did not adopt the EPCA civil penalty provisions that have allowed some manufacturers to pay civil penalties as an alternative method of meeting EPCA obligations. These and other differences provide that even if CAFE and CO₂ standards are “mathematically” harmonized, for any given manufacturer, the two sets of standards will not be identically burdensome in each model year. Inevitably, one standard will be more challenging than the other, varying over time, between manufacturers, and between fleets. This means manufacturers need to have compliance plans for both sets of standards.

In 2012, recognizing that EPCA provides no clear basis to address HFC, CH₄, or N₂O emissions directly, the agencies “offset” CO₂ targets from fuel economy targets (after converting the latter to a CO₂ basis) by the amounts of credit EPA anticipated manufacturers would, on average, earn in each model years by reducing A/C leakage and adopting refrigerants with reduced GWPs. In 2012, EPA assumed that by 2021, all manufacturers would be earning the maximum available credit, and EPA’s analysis assumed that all manufacturers would make progress at the same rate. However, as discussed

above, data highlighted in comments by Chemours, Inc., demonstrate that actual manufacturers’ adoption of lower-GWP refrigerants thus far ranges widely, with some manufacturers (e.g., Nissan) having taken no such steps to move toward lower-GWP refrigerants, while others (e.g., JLR) have already applied lower-GWP refrigerants to all vehicles produced for sale in the U.S. Therefore, at least in practice, HFC provisions thus far continue to leave a gap (in terms of harmonization) between the two sets of standards. The proposal would have taken the additional step of decoupling provisions regarding HFC (*i.e.*, A/C leakage credits), CH₄, and N₂O emissions from CO₂ standards, addressing these in separate regulations to be issued in a new proposal. As discussed above, EPA did not finalize this proposal. Accordingly, for the regulatory alternatives considered today, EPA has reinstated offsets of CO₂ targets from fuel economy targets, reflecting the assumption that all manufacturers will be earning the maximum available A/C leakage credit by MY 2021.

In addition to general comments on harmonization, the agencies received a range of comments on specific provisions—especially involving “flexibilities”—that may or may not impact harmonization. With a view toward encouraging further electrification, NCAT proposed that EPA extend indefinitely the exclusion of upstream emissions from electricity generation, and also extend and potentially restructure production multipliers for PHEVs, EVs, and FCVs.²⁹⁸ On the other hand, connecting its comments back to the stringency of standards, NCAT also commented that “. . . expansion of compliance flexibilities in the absence of any requirement to improve [CO₂] reduction or fuel economy (as under the agencies’ preferred option) could result in an effective deterioration of existing [CO₂] and fuel economy performance, as well as little or no effective support for advanced vehicle technology development or deployment.”²⁹⁹ Global Automakers indicated that the final rule “should include a package of programmatic elements that provide automakers with flexible compliance options that promote the full breadth of vehicle technologies,” such options to include the extension of “advanced technology” production multipliers through MY 2026, the indefinite exclusion of emissions from electricity generation, the extension to passenger

cars of credits currently granted for the application of “game changing” technologies (e.g., HEVs) only to full-size pickup trucks, an increase (to 15 g/mi) of the cap on credits for off-cycle technologies, an updated credit “menu” of off-cycle technologies, and easier process for handling applications for off-cycle credits.³⁰⁰ The Alliance also called for expanded sales multipliers and a permanent exclusion of emissions from electricity generation.³⁰¹ Walter Kreucher recommended the agencies consider finalizing the proposed standards but also keeping the augural standards as “voluntary targets” to “provide compliance with the statutes and an aspirational goal for manufacturers.”³⁰²

The agencies have carefully considered these comments, and have determined that the current suite of “flexibilities” generally provide ample incentive more rapidly to develop and apply advanced technologies and technologies that produce fuel savings and/or CO₂ reductions that would otherwise not count toward compliance. The agencies also share some stakeholders’ concern that expanding these flexibilities could increase the risk of “gaming” that would make compliance less transparent and would unduly compromise energy and environmental benefits. Nevertheless, as discussed in Section IX, EPA is adopting new multiplier incentives for natural gas vehicles. EPA is also finalizing some changes to procedures for evaluating applications for off-cycle credits, and expects these changes to make this process more accurate and more efficient. Also, EPA is revising its regulations to not require manufacturers to account for upstream emissions associated with electricity use for electric vehicles and plug-in hybrid electric vehicles through model year 2026; compliance will instead be based on tailpipe emissions performance only and not include emissions from electricity generation until model year 2027. As discussed below, even with this change, and even accounting for continued increases in fuel prices and reductions in battery prices, BEVs are projected in this final rule analysis to continue to account for less than 5 percent of new light vehicle sales in the U.S. through model year 2026. To the extent that this projection turns out to reflect reality, this means that the impact of upstream emissions from electricity use on the projected CO₂

²⁹⁷ Full harmonization would mean that, for example, if Ford would do some set of things over time in response to CAFE standards in isolation, it would do exactly the same things on exactly the same schedule in response to CO₂ standards in isolation.

²⁹⁸ NCAT, NHTSA–2018–0067–11969, at 3–5.

³⁰² Kreucher, W., NHTSA–2018–0067–0444, at 9.

reductions associated with these standards would likely remain small. Regarding comments suggesting that the augural standards should be finalized as “voluntary targets,” the agencies have determined that having such targets exist alongside actual regulatory requirements would be, at best, unnecessary and confusing.

Beyond these additional proposals, some commenters’ proposals clearly fell outside authority provided under EPCA or the CAA. Ron Lindsay recommended the agencies “consider postponing the rule changes until the U.S. can establish a legally binding national and international carbon budget and a binding mechanism to adhere to it.”³⁰³ EPCA requires NHTSA to issue standards for MY 2022 by April 1, 2020, and previously-issued EPA regulations commit EPA to revisiting MY 2021–2025 standards on a similar schedule. These statutory and regulatory provisions do not include a basis to delay decisions pending an international negotiation for which prospects and schedules are both unknown.

SCAQMD, supported by Shyam Shukla, indicated that the agencies

should consider an alternative that keeps the waiver for California’s CO₂ standards in place.³⁰⁴ NCAT and the North Carolina DEQ offered similar comments and CBD, *et al.* commented that “among the set of more stringent alternatives that NEPA requires the agency to consider, NHTSA must include action alternatives that retain the standards California and other states have lawfully adopted.”³⁰⁵ As discussed above, the agencies recently issued a final rule addressing the issue of California’s authority. NEPA does not require NHTSA to include action alternatives that cannot be lawfully realized.

International Mosaic commented that NHTSA’s DEIS “is fatally flawed . . . because it does not consider any market-based alternatives (e.g., a ‘cap and trade’ type option).”³⁰⁶ While EPCA/EISA does include very specific provisions regarding trading of CAFE compliance credits, the statute provides no authority for a broad-based cap-and-trade program

involving other sectors. Similarly, Michalek, *et al.* wrote that “a more economically efficient approach of, taxing emissions and fuel consumption at socially appropriate levels would allow households to determine whether to reduce fuel consumption and emissions by driving less, by buying a vehicle with more fuel saving technologies, or by buying a smaller vehicle—or, alternatively, not to reduce fuel consumption and emissions at all but rather pay a cost based on the damages they cause. Forcing improvements only through one mechanism (fuel-saving technologies) increases the cost of achieving these outcomes.”³⁰⁷ While some economists would agree with these comments, Congress has provided no clear authority for NHTSA or EPA to implement either an emissions tax or a broad-based cap-and-trade program in which motor vehicles could participate.

3. Details of Alternatives Considered in Final Rule

a) Alternative 1

Alternative 1 holds the stringency of targets constant and MY 2020 levels through MY 2026.

c) Alternative 3

Alternative 3; the final standards promulgated today, increases the

stringency of targets annually during MYs 2021–2026 (on a gallon per mile basis, starting from MY 2020) by 1.5

percent for passenger cars and 1.5 percent for light trucks.

Table V-12 – Characteristics of Alternative 3 (Final Standards) – Passenger Cars

| | 2021 | 2022 | 2023 | 2024 | 2025 | 2026 |
|--------------------------|----------|----------|----------|----------|----------|----------|
| Fuel Economy Targets | | | | | | |
| <i>a (mpg)</i> | 49.48 | 50.24 | 51.00 | 51.78 | 52.57 | 53.37 |

EPCA, as amended by EISA, requires that any manufacturer's domestically-manufactured passenger car fleet must meet the greater of either 27.5 mpg on average, or 92 percent of the average fuel economy projected by the Secretary for the combined domestic and non-domestic passenger automobile fleets

manufactured for sale in the U.S. by all manufacturers in the model year, which projection shall be published in the **Federal Register** when the standard for that model year is promulgated in accordance with 49 U.S.C. 32902(b).³⁰⁸ Any time NHTSA establishes or changes a passenger car standard for a model

year, the MDPCS for that model year must also be evaluated or re-evaluated and established accordingly. Thus, this final rule establishes the applicable MDPCS for MYs 2021–2026. Table V–22 lists the minimum domestic passenger car standards.

Table V-22 – Minimum Standards for Domestic Passenger Car Fleets (mpg)

VI. Analytical Approach as Applied to Regulatory Alternatives

A. Overview of Methods

Like analyses accompanying the NPRM and past CAFE and CAFE/CO₂ rulemakings, the analysis supporting today's notice spans a range of technical topics, uses a range of different types of data and estimates, and applies several different types of computer models. The purpose of the analysis is not to determine the standards, but rather to provide information for consideration in doing so. The analysis aims to answer the question "what impacts might each of these regulatory alternatives have?"

Over time, NHTSA's and, more recently, NHTSA's and EPA's analyses have expanded to address an increasingly wide range of types of impacts. Today's analysis involves, among other things, estimating how the application of various combinations of technologies could impact vehicles' costs and fuel economy levels (and CO₂ emission rates), estimating how vehicle manufacturers might respond to standards by adding fuel-saving technologies to new vehicles, estimating how changes in new vehicles might impact vehicle sales and operation, and estimating how the combination of these changes might impact national-scale energy consumption, emissions, highway safety, and public health. In addition, the EIS accompanying today's notice addresses impacts on air quality and climate. The analysis of these factors informs and supports both NHTSA's application of the statutory requirements governing the setting of "maximum feasible" fuel-economy standards under EPCA, including, among others, technological feasibility and economic practicability, and EPA's application of the CAA requirements for tailpipe emissions.

Supporting today's analysis, the agencies have brought to bear a variety of different types of data, a few examples of which include fuel economy compliance reports, historical sales and average characteristics of light-duty vehicles, historical economic and demographic measures, historical travel demand and energy prices and consumption, and historical measures of highway safety. Also supporting today's analysis, the agencies have applied several different types of estimates, a few examples of which include projections of the future cost of different fuel-saving technologies, projections of future GDP and the number of households, estimates of the "gap" between "laboratory" and on-road fuel economy, and estimates of the social

cost of CO₂ emissions and petroleum "price shocks."

With a view toward transparency, repeatability, and efficiency, the agencies have used a variety of computer models to conduct the majority of today's analysis. For example, the agencies have applied DOE/EIA's National Energy Modeling System (NEMS) to estimate future energy prices, EPA's MOVES model to estimate tailpipe emission rates for ozone precursors and other criteria pollutants, DOE/Argonne's GREET model to estimate emission rates for "upstream" processes (e.g., petroleum refining), and DOE/Argonne's Autonomie simulation tool to estimate the fuel consumption impacts of different potential combinations of fuel-saving technology. In addition, the EIS accompanying today's notice applies photochemical models to estimate air quality impacts, and applies climate models to estimate climate impacts of overall emissions changes.

Use of these different types of data, estimates, and models is discussed further below in the most closely relevant sections. For example, the agencies' use of NEMS is discussed below in the portion of Section VI that addresses the macroeconomic context, which includes fuel prices, and the agencies use of Autonomie is discussed in the portion of Section VI.B.3 that addresses the agencies' approach to estimating the effectiveness of various technologies (in reducing fuel consumption and CO₂ emissions).

Providing an integrated means to estimate both vehicle manufacturers' potential responses to CAFE or CO₂ standards and, in turn, many of the different potential direct results (e.g., changes in new vehicle costs) and indirect impacts (e.g., changes in rates of fleet turnover) of those responses, the CAFE Model plays a central role in the agencies' analysis supporting today's notice. The agencies used the specific models mentioned above to develop inputs to the CAFE model, such as fuel prices and emission factors. Outputs from the CAFE Model are discussed in Sections VII and VIII of today's notice, and in the accompanying RIA. The EIS accompanying today's notice makes use of the CAFE Model's estimates of changes in total emissions from light-duty vehicles, as well as corresponding changes in upstream emissions. These changes in emissions are included in the set of inputs to the models used to estimate air quality and climate impacts.

The remainder of this overview focuses on the CAFE Model. The purpose of this overview is not to provide a comprehensive technical

description of the model,³⁰⁹ but rather to give an overview of the model's functions, to explain some specific aspects not addressed elsewhere in today's notice, and to discuss some model aspects that were the subject of significant public comment. Some model functions and related comments are addressed in other parts of today's notice. For example, the model's handling of Autonomie-based fuel consumption estimates is addressed in the portion of Section VI.B.3 that discusses the agencies' application of Autonomie. The model documentation accompanying today's notice provides a comprehensive and detailed description of the model's functions, design, inputs, and outputs.

1. Overview of CAFE Model

The basic design of the CAFE Model is as follows: The system first estimates how vehicle manufacturers might respond to a given regulatory scenario, and from that potential compliance solution, the system estimates what impact that response will have on fuel consumption, emissions, and economic externalities. A regulatory scenario involves specification of the form, or shape, of the standards (e.g., flat standards, or linear or logistic attribute-based standards), scope of passenger car and truck regulatory classes, and stringency of the CAFE and CO₂ standards for each model year to be analyzed.

Manufacturer compliance simulation and the ensuing effects estimation, collectively referred to as compliance modeling, encompass numerous subsidiary elements. Compliance simulation begins with a detailed user-provided initial forecast of the vehicle models offered for sale during the simulation period. The compliance simulation then attempts to bring each manufacturer into compliance with the standards defined by the regulatory scenario contained within an input file developed by the user. For example, a regulatory scenario may define CAFE or CO₂ standards that increase in stringency by 4 percent per year for 5 consecutive years.

The model applies various technologies to different vehicle models in each manufacturer's product line to simulate how each manufacturer might make progress toward compliance with the specified standard. Subject to a variety of user-controlled constraints, the model applies technologies based on

³⁰⁹ The CAFE Model is available at <https://www.nhtsa.gov/corporate-average-fuel-economy/compliance-and-effects-modeling-system> with documentation and all inputs and outputs supporting today's notice.

their relative cost-effectiveness, as determined by several input assumptions regarding the cost and effectiveness of each technology, the cost of compliance (determined by the change in CAFE or CO₂ credits, CAFE-related civil penalties, or value of CO₂ credits, depending on the compliance program being evaluated and the effective-cost mode in use), and the value of avoided fuel expenses. For a given manufacturer, the compliance simulation algorithm applies technologies either until the manufacturer runs out of cost-effective technologies, until the manufacturer exhausts all available technologies, or, if the manufacturer is assumed to be willing to pay civil penalties, until paying civil penalties becomes more cost-effective than increasing vehicle fuel economy. At this stage, the system assigns an incurred technology cost and updated fuel economy to each vehicle model, as well as any civil penalties incurred by each manufacturer. This compliance simulation process is repeated for each model year available during the study period.

This point marks the system's transition between compliance simulation and effects calculations. At the conclusion of the compliance simulation for a given regulatory scenario, the system contains multiple copies of the updated fleet of vehicles corresponding to each model year analyzed. For each model year, the vehicles' attributes, such as fuel types (*e.g.*, diesel, electricity), fuel economy values, and curb weights have all been updated to reflect the application of technologies in response to standards

throughout the study period. For each vehicle model in each of the model year specific fleets, the system then estimates the following: Lifetime travel, fuel consumption, carbon dioxide and criteria pollutant emissions, the magnitude of various economic externalities related to vehicular travel (*e.g.*, noise), and energy consumption (*e.g.*, the economic costs of short-term increases in petroleum prices). The system then aggregates model-specific results to produce an overall representation of modeling effects for the entire industry.

Different categorization schemes are relevant to different types of effects. For example, while a fully disaggregated fleet is retained for purposes of compliance simulation, vehicles are grouped by type of fuel and regulatory class for the energy, carbon dioxide, criteria pollutant, and safety calculations. Therefore, the system uses model-by-model categorization and accounting when calculating most effects, and aggregates results only as required for efficient reporting.

2. Representation of the Market

As a starting point, the model needs enough information to represent each manufacturer covered by the program. As discussed below in Section VI.B.1, the MY 2017 analysis fleet contains information about each manufacturer's:

- Vehicle models offered for sale—their current (*i.e.*, MY 2017) production volumes, manufacturer suggested retail prices (MSRPs), fuel saving technology content and other attributes (curb weight, drive type, assignment to technology class and regulatory class);

- Production considerations—product cadence of vehicle models (*i.e.*, schedule of model redesigns and “freshenings”), vehicle platform membership, degree of engine and/or transmission sharing (for each model variant) with other vehicles in the fleet; and

- Compliance constraints and flexibilities—preference for full compliance or penalty payment/credit application, willingness to apply additional cost-effective fuel saving technology in excess of regulatory requirements, projected applicable flexible fuel credits, and current credit balance (by model year and regulatory class) in first model year of simulation.

Representation of Fuel-Saving Technologies

The modeling system defines technology pathways for grouping and establishing a logical progression of technologies that can be applied to a vehicle. Technologies that share similar characteristics form cohorts that can be represented and interpreted within the CAFE Model as discrete entities. The following Table VI–1 shows the technologies available within the modeling system used for this final rule. Each technology is discussed in detail below. However, an understanding of the technologies considered and how they are defined in the model (*e.g.*, a 6-speed manual transmission is defined as “MT6”) is helpful for the following explanation of the compliance simulation and the inputs required for that simulation.

BILLING CODE 4910–59–P

Table VI-1 – CAFE Model Technologies

| Technology | Technology Description | Technology | Technology Description |
|------------|--|------------|---|
| SOHC | Single Overhead Camshaft Engine | CVT | Continuously Variable Transmission |
| DOHC | Double Overhead Camshaft Engine | CVTL2 | CVT, Level 2 |
| EFR | Improved Engine Friction Reduction | EPS | Electric Power Steering |
| VVT | Variable Valve Timing | IACC | Improved Accessories |
| VVL | Variable Valve Lift | CONV | Conventional Powertrain (Non-Electric) |
| SGDI | Stoichiometric Gasoline Direct Injection | SS12V | 12V Micro-Hybrid (Stop-Start) |
| DEAC | Cylinder Deactivation | BISG | Belt Mounted Integrated Starter/Generator |
| TURBO1 | Turbocharging and Downsizing, Level 1 (1.5271 bar) | SHEVP2 | P2 Strong Hybrid/Electric Vehicle |
| TURBO2 | Turbocharging and Downsizing, Level 2 (2.0409 bar) | SHEVPS | Power Split Strong Hybrid/Electric Vehicle |
| CEGR1 | Cooled Exhaust Gas Recirculation, Level 1 (2.0409 bar) | P2HCR0 | SHEVP2 with HCR0 Engine |
| ADEAC | Advanced Cylinder Deactivation | P2HCR1 | SHEVP2 with HCR1 Engine |
| HCR0 | High Compression Ratio Engine, Level 0 | P2HCR2 | SHEVP2 with HCR2 Engine |
| HCR1 | High Compression Ratio Engine, Level 1 | PHEV20 | 20-mile Plug-In Hybrid/Electric Vehicle with HCR Engine |
| HCR2 | High Compression Ratio Engine, Level 2 | PHEV50 | 50-mile Plug-In Hybrid/Electric Vehicle with HCR Engine |
| VCR | Variable Compression Ratio Engine | PHEV20T | 20-mile Plug-In Hybrid/Electric Vehicle with Turbo Engine |
| VTG | Variable Turbo Geometry | PHEV50T | 50-mile Plug-In Hybrid/Electric Vehicle with Turbo Engine |
| VTGE | Variable Turbo Geometry (Electric) | PHEV20H | PHEV20 with HCR Engine |
| TURBOD | Turbocharging and Downsizing with DEAC | PHEV50H | PHEV50 with HCR Engine |
| TURBOAD | Turbocharging and Downsizing with ADEAC | BEV200 | 200-mile Electric Vehicle |
| ADSL | Advanced Diesel | BEV300 | 300-mile Electric Vehicle |
| DSLI | Diesel Engine Improvements | FCV | Fuel Cell Vehicle |
| DSLIAD | Diesel Engine Improvements with ADEAC | LDB | Low Drag Brakes |
| CNG | Compressed Natural Gas Engine | SAX | Secondary Axle Disconnect |
| MT5 | 5-Speed Manual Transmission | ROLL0 | Baseline Tires |
| MT6 | 6-Speed Manual Transmission | ROLL10 | Low Rolling Resistance Tires, Level 1 (10% Reduction) |
| MT7 | 7-Speed Manual Transmission | ROLL20 | Low Rolling Resistance Tires, Level 2 (20% Reduction) |

| Technology | Technology Description | Technology | Technology Description |
|------------|--|------------|--|
| AT5 | 5-Speed Automatic Transmission | AERO0 | Baseline Aero |
| AT6 | 6-Speed Automatic Transmission | AERO5 | Aero Drag Reduction, Level 1 (10% Reduction) |
| AT6L2 | 6-Speed Automatic Transmission, Level 2 | AERO10 | Aero Drag Reduction, Level 1 (10% Reduction) |
| AT7L2 | 7-Speed Automatic Transmission, Level 2 | AERO15 | Aero Drag Reduction, Level 1 (10% Reduction) |
| AT8 | 8-Speed Automatic Transmission | AERO20 | Aero Drag Reduction, Level 2 (20% Reduction) |
| AT8L2 | 8-Speed Automatic Transmission, Level 2 | MR0 | Baseline Mass |
| AT8L3 | 8-Speed Automatic Transmission, Level 3 | MR1 | Mass Reduction, Level 1 (5% Reduction in Glider Weight) |
| AT9L2 | 9-Speed Automatic Transmission, Level 2 | MR2 | Mass Reduction, Level 2 (7.5% Reduction in Glider Weight) |
| AT10L2 | 10-Speed Automatic Transmission, Level 2 | MR3 | Mass Reduction, Level 3 (10% Reduction in Glider Weight) |
| AT10L3 | 10-Speed Automatic Transmission, Level 3 | MR4 | Mass Reduction, Level 4 (15% Reduction in Glider Weight) |
| DCT6 | 6-Speed Dual Clutch Transmission | MR5 | Mass Reduction, Level 5 (20% Reduction in Glider Weight) |
| DCT8 | 8-Speed Dual Clutch Transmission | MR6 | Mass Reduction, Level 6 (28.2% Reduction in Glider Weight) |

BILLING CODE 4910-59-C

These entities are then laid out into pathways (or paths), which the system uses to define relations of mutual exclusivity between conflicting sets of technologies. For example, as presented in the next section, technologies on the Turbo Engine path are incompatible with those on the HCR Engine or the Diesel Engine paths. As such, whenever a vehicle uses a technology from one pathway (e.g., turbo), the modeling system immediately disables the incompatible technologies from one or more of the other pathways (e.g., HCR and diesel).

In addition, each path designates the direction in which vehicles are allowed to advance as the modeling system evaluates specific technologies for application. Enforcing this directionality within the model ensures that a vehicle that uses a more advanced or more efficient technology (e.g., AT8) is not allowed to “downgrade” to a less efficient option (e.g., AT5). Visually, as portrayed in the charts in the sections that follow, this is represented by an arrow leading from a preceding technology to a succeeding one, where vehicles begin at the root of each path,

and traverse to each successor technology in the direction of the arrows.

The modeling system incorporates twenty technology pathways for evaluation as shown below. Similar to individual technologies, each path carries an intrinsic application level that denotes the scope of applicability of all technologies present within that path, and whether the pathway is evaluated on one vehicle at a time, or on a collection of vehicles that share a common platform, engine, or transmission.

Table VI-2 – Technology Pathways

| Technology Pathway | Application Level |
|--|-------------------|
| Engine Configuration Path | Engine |
| Engine Improvements Path | Engine |
| Basic Engine Path | Engine |
| Turbo Engine Path | Engine |
| Advanced Cylinder Deactivation (ADEAC) Engine Path | Engine |
| High Compression Ratio (HCR) Engine Path | Engine |
| Variable Compression Ratio (VCR) Engine Path | Engine |
| Variable Turbo Geometry (VTG) Engine Path | Engine |
| Advanced Turbo Engine Path | Engine |
| Diesel Engine Path | Engine |
| Alternative Fuel Engine Path | Engine |
| Manual Transmission Path | Transmission |
| Automatic Transmission Path | Transmission |
| Electric Improvements Path | Vehicle |
| Electrification Path | Vehicle |
| Hybrid/Electric Path | Vehicle |
| Dynamic Load Reduction (DLR) Path | Vehicle |
| Low Rolling Resistance Tires (ROLL) Path | Vehicle |
| Aerodynamic Improvements (AERO) Path | Vehicle |
| Mass Reduction (MR) Path | Platform |

Even though technology pathways outline a logical progression between related technologies, all technologies available to the system are evaluated concurrently and independently of each other. Once all technologies have been examined, the model selects a solution deemed to be most cost-effective for application on a vehicle. If the modeling system applies a technology that resides later in the pathway, it will subsequently disable all preceding technologies from further consideration to prevent a vehicle from potentially downgrading to a less advanced option. Consequently, the system skips any technology that is already present on a vehicle (either those that were available on a vehicle from the input fleet or those that were previously applied by the model). This “parallel technology” approach, unlike the “parallel path” methodology utilized in the preceding versions of the model, allows the system always to consider the entire set of available technologies instead of foregoing the application of potentially more cost-effective options that happen to reside further down the pathway.³¹⁰ This revised approach addresses

comments summarized below, and allows the system to analyze all available technology options concurrently and independently of one other without having to first apply one or more “predecessor” technologies. For example, if model inputs are such that a 7-speed transmission is cost-effective, but not as cost-effective as an 8-speed transmission, the revised approach enables the model to skip over the 7-speed transmission entirely, whereas the NPRM version of the model might first apply the 7-speed transmission and then consider whether to proceed immediately to the 8-speed transmission. As such, the model’s choices for evaluation of new technology solutions becomes slightly less restrictive, allowing it immediately to consider and apply more advanced options, and increasing the likelihood that the a globally optimum solution is selected.

Some commenters supported the agencies’ use of such pathways in the simulation of manufacturers’ potential application of technologies. As one of a dozen examples of CAFE model design elements that lead to the transparent representation of real-world factors, the Alliance highlighted “recognition of the need for manufacturers to follow ‘technology’ pathways that retain capital and implementation expertise, such as

specializing in one type of engine or transmission instead of following an unconstrained optimization that would cause manufacturers to leap to unrelated technologies and show overly optimistic costs and benefits.”³¹¹ Similarly, Toyota commented that “the inertia of capital investments and engineering expertise dedicated to one compliance technology or set of technologies makes it unreasonable for manufacturers to immediately switch to another technology path.”³¹²

Other commenters cited the use of technology pathways as inherently overly restrictive. For example, as an example of “arbitrary model constraints,” a coalition of commenters cited the fact the model “prohibit[s] manufacturers from switching vehicle technology pathways.”³¹³ Also, EDF, UCS, and CARB cited the combination of technology pathways, decision making criteria, and model inputs as producing unrealistic results.³¹⁴ Regarding the technology pathways, specifically, EDF’s consultant argued that the technology paths are not

³¹¹ Alliance, NHTSA–2018–0067–12073, at 9.

³¹² Toyota, NHTSA–2018–0067–12098, at 7.

³¹³ CBD, et al., NHTSA–2018–0067–12057, at 3.

³¹⁴ EDF, NHTSA–2018–0067–12108, Appendix A, at 57 *et seq.*; UCS, NHTSA–2018–0067–12039, Appendix, at 25 *et seq.*; Roush Industries, NHTSA–2018–0067–11984, at 5.

³¹⁰ Previous versions of the CAFE Model followed a “low-cost” first approach where the system would stop evaluating technologies residing within a given pathway as soon as the first cost-effective option within that path was reached.

transparent, and cited the potential that specific paths may not necessarily be arranged in progression from least to most cost-effective—that “NHTSA ignores the cost of the technology when developing this list.”³¹⁵ Relatedly, as EDF’s consultant commented:

[T]he Volpe Model is not designed to look backwards along its technology paths. Thus, the opportunity to recover the expenditure of inefficient technology is missed. NHTSA might argue that a manufacturer will not invest in 10-speed transmissions, for example, and then return to an older design. Whether or not this is true in real life, such a view would put too much stake in the Volpe Model projections. The model simply projects what could be done, not what will be. Anyone examining the progression of technology and noting the reversion of transmission technology could easily modify the model inputs to avoid this. Also, if NHTSA evaluated combinations of technologies prior to entering them in the model piecemeal, it would automatically avoid such apparent problems.³¹⁶

The agencies also received additional public comments on specific paths and specific interactions between paths (e.g., involving engines and hybridization). These comments are addressed below.

The agencies have carefully considered these comments and the approach summarized below reflects some corresponding revision. As mentioned above, the CAFE model now approaches the technology paths in a such way that, faced with two cost-effective technologies on the same path, the model can proceed directly to the more advanced technology if that technology is the more cost effective of the two.

However, the agencies reject assertions that the model’s use of technology paths is not transparent. The agencies provided extensive explanatory text, figures, model documentation, and model source code specifically addressing these paths (and other model features). This transparency appears evident in that commenters (sometimes while claiming that a specific feature of the model is not transparent) presented analytical results involving changes to corresponding inputs that required a detailed understanding of that feature’s operation.

Regarding comments that the technology paths should be arranged in order of cost-effectiveness, the agencies note that such comments presume, without merit, that costs, fuel consumption impacts, and other inputs (e.g., fuel prices) that logically impact manufacturers’ decision-making are not

subject to uncertainty. These inputs are all subject to uncertainty, and the CAFE Model’s arrangement of technologies into several paths is responsive to these uncertainties. Nevertheless, the agencies maintain that some technologies *do* reflect a higher level of advancement than others (e.g., 10-speed transmissions vs. 5-speed transmissions), and while manufacturers may, in practice, occasionally revert to less advanced technologies, it is appropriate and reasonable to conduct the agencies’ analysis in a manner that assumes manufacturers will continue to make forward progress. As observed by EDF’s consultant’s remarks, the CAFE Model “simply projects what could be done, not what will be.” While no model, much less any model relying on information that can be made publicly available, can hope to represent precisely each manufacturers’ actual detailed constraints related to product development and planning, such constraints are real and important. The agencies agree that the CAFE Model’s representation of such constraints—including the Model’s use of technology paths—provides a reasonable means of accounting for them.

4. Compliance Simulation

The CAFE model provides a way of estimating how vehicle manufacturers could attempt to comply with a given CAFE standard by adding technology to fleets that the agencies anticipate they will produce in future model years. This exercise constitutes a simulation of manufacturers’ decisions regarding compliance with CAFE or CO₂ standards.

This compliance simulation begins with the following inputs: (a) The analysis fleet of vehicles from model year 2017 discussed below in Section VI.B.1, (b) fuel economy improving technology estimates discussed below in Section VI.C, (c) economic inputs discussed below in Section VI.D, and (d) inputs defining baseline and potential new CAFE or CO₂ standards discussed above in Section V. For each manufacturer, the model applies technologies in both a logical sequence and a cost-optimizing strategy in order to identify a set of technologies the manufacturer could apply in response to new CAFE or CO₂ standards. The model applies technologies to each of the projected individual vehicles in a manufacturer’s fleet, considering the combined effect of regulatory and market incentives while attempting to account for manufacturers’ production constraints. Depending on how the model is exercised, it will apply

technology until one of the following occurs:

(1) The manufacturer’s fleet achieves compliance³¹⁷ with the applicable standard and adding additional technology in the current model year would be attractive neither in terms of stand-alone (*i.e.*, absent regulatory need) cost-effectiveness nor in terms of facilitating compliance in future model years;

(2) The manufacturer “exhausts” available technologies;³¹⁸ or

(3) For manufacturers assumed to be willing to pay civil penalties (in the CAFE program), the manufacturer reaches the point at which doing so would be more cost-effective (from the manufacturer’s perspective) than adding further technology.

The model accounts explicitly for each model year, applying technologies when vehicles are scheduled to be redesigned or freshened and carrying forward technologies between model years once they are applied (until, if applicable, they are superseded by other technologies). The model then uses these simulated manufacturer fleets to generate both a representation of the U.S. auto industry and to modify a representation of the entire light-duty registered vehicle population. From these fleets, the model estimates changes in physical quantities (gallons of fuel, pollutant emissions, traffic fatalities, etc.) and calculates the relative costs and benefits of regulatory alternatives under consideration.

The CAFE model accounts explicitly for each model year, in turn, because manufacturers actually “carry forward” most technologies between model years, tending to concentrate the application of new technology to vehicle redesigns or mid-cycle “freshenings,” and design cycles vary widely among manufacturers and specific products.

³¹⁷ When determining whether compliance has been achieved in the CAFE program, existing CAFE credits that may be carried over from prior model years or transferred between fleets are also used to determine compliance status. For purposes of determining the effect of maximum feasible CAFE standards, however, EPCA prohibits NHTSA from considering these mechanisms for years being considered (though it does so for model years that are already final) and the agency runs the CAFE model without enabling these options. 49 U.S.C. 32902(h)(3).

³¹⁸ In a given model year, it is possible that production constraints cause a manufacturer to “run out” of available technology before achieving compliance with standards. This can occur when: (a) An insufficient volume of vehicles are expected to be redesigned, (b) vehicles have moved to the ends of each (relevant) technology pathway, after which no additional options exist, or (c) engineering aspects of available vehicles make available technology inapplicable (e.g., secondary axle disconnect cannot be applied to two-wheel drive vehicles).

³¹⁵ EDF, NHTSA–2018–0067–12108, Appendix B, at 69.

³¹⁶ *Ibid.*, at 70.

Comments by manufacturers and model peer reviewers strongly support explicit year-by-year simulation. Year-by-year accounting also enables accounting for credit banking (*i.e.*, carry-forward), as discussed above, and at least four environmental organizations recently submitted comments urging the agencies to consider such credits, citing NHTSA's 2016 results showing impacts of carried-forward credits.³¹⁹ Moreover, EPCA/EISA requires that NHTSA make a year-by-year determination of the appropriate level of stringency and then set the standard at that level, while ensuring ratable increases in average fuel economy through MY 2020. The multi-year planning capability, simulation of "market-driven overcompliance," and EPCA credit mechanisms (again, for purposes of modeling the CAFE program) increase the model's ability to simulate manufacturers' real-world behavior, accounting for the fact that manufacturers will seek out compliance paths for several model years at a time, while accommodating the year-by-year requirement. This same multi-year planning structure is used to simulate responses to standards defined in grams CO₂/mile, and utilizing the set of specific credit provisions defined under EPA's program.

After the light-duty rulemaking analysis accompanying the 2012 final rule that finalized NHTSA's standards through MY 2021, NHTSA began work on changes to the CAFE model with the intention of better reflecting constraints of product planning and cadence for which previous analyses did not account. This involves accounting for expected future schedules for redesigning and "freshening" vehicle models, and accounting for the fact that a given engine or transmission is often shared among more than one vehicle model, and a given vehicle production platform often includes more than one vehicle model. These real product planning considerations are explained below.

Like earlier versions, the current CAFE model provides the capability for integrated analysis spanning different regulatory classes, accounting both for standards that apply separately to different classes and for interactions between regulatory classes. Light vehicle CAFE and CO₂ standards are specified separately for passenger cars and light trucks. However, there is considerable sharing between these two

regulatory classes, where a single engine, transmission, or platform can appear in both the passenger car and light truck regulatory class. For example, some sport-utility vehicles are offered in 2WD versions (classified as passenger cars for compliance purposes) and 4WD versions (classified as light trucks for compliance purposes). Integrated analysis of manufacturers' passenger car and light truck fleets provides the ability to account for such sharing and reduces the likelihood of finding solutions that could involve introducing impractical and unrealistic levels of complexity in manufacturers' product lines. In addition, integrated fleet analysis provides the ability to simulate the potential that manufacturers could earn CAFE and CO₂ credits by over complying with the standard in one fleet and use those credits toward compliance with the standard in another fleet (*i.e.*, to simulate credit transfers between regulatory classes).³²⁰

The CAFE model also accounts for EPCA's requirement that compliance be determined separately for fleets of domestic passenger cars and fleets of imported passenger cars. The model accounts for all three CAFE regulatory classes simultaneously (*i.e.*, in an integrated way) yet separately: Domestic passenger cars, imported passenger cars, and light trucks. The model further accounts for two related specific statutory requirements specifically involving this distinction between domestic and imported passenger cars. First, EPCA/EISA requires that any given fleet of domestic passenger cars meet a minimum standard, irrespective of any available compliance credits. Second, EPCA/EISA requires compliance with the standards applicable to the domestic passenger car fleet without regard to traded or transferred credits.³²¹

However, the CAA has no such limitation regarding compliance by domestic and imported vehicles; EPA did not adopt provisions similar to the aforementioned EPCA/EISA requirements and is not doing so today. Therefore, the CAFE model determines compliance for manufacturers' overall passenger car and light truck fleets for EPA's program.

Each manufacturer's regulatory requirement represents the production-weighted harmonic mean of their vehicle's targets in each regulated fleet.

This means that no individual vehicle has a "standard," merely a target, and each manufacturer is free to identify a compliance strategy that makes the most sense given its unique combination of vehicle models, consumers, and competitive position in the various market segments. As the CAFE model provides flexibility when defining a set of regulatory standards, each manufacturer's requirement is dynamically defined based on the specification of the standards for any simulation and the distribution of footprints within each fleet.

Given this information, the model attempts to apply technology to each manufacturer's fleet in a manner that, given product planning and engineering-related considerations, optimizes the selected cost-related metric. The metric supported by the NPRM version of the model is termed "effective cost." The effective cost captures more than the incremental cost of a given technology; it represents the difference between their incremental cost and the value of fuel savings to a potential buyer over the first 30 months of ownership.³²² In addition to the technology cost and fuel savings, the effective cost also includes the change in CAFE civil penalties from applying a given technology and any estimated welfare losses associated with the technology (*e.g.*, earlier versions of the CAFE model simulated low-range electric vehicles that produced a welfare loss to buyers who valued standard operating ranges between re-fueling events). Comments on this metric are discussed below, as are model changes responding to these comments.

This construction allows the model to choose technologies that both improve a manufacturer's regulatory compliance position and are most likely to be attractive to its consumers. This also means that different assumptions about future fuel prices will produce different rankings of technologies when the model evaluates available technologies for application. For example, in a high fuel price regime, an expensive but very efficient technology may look attractive to manufacturers because the value of the fuel savings is sufficiently high both to counteract the higher cost of the technology and, implicitly, to satisfy consumer demand to balance price increases with reductions in operating cost.

³¹⁹ Comment by Environmental Law & Policy Center, Natural Resources Defense Council (NRDC), Public Citizen, and Sierra Club, Docket ID EPA-HQ-OAR-2015-0827-9826, at 28–29.

³²⁰ Note, however, that EPCA prohibits NHTSA from considering the availability of such credit trading when setting maximum feasible fuel economy standards. 49 U.S.C. 32902(h)(3).

³²¹ 49 U.S.C. 32903(f)(2) and (g)(4).

³²² The length of time over which to value fuel savings in the effective cost calculation is a model input that can be modified by the user. This analysis uses 30 months' worth of fuel savings in the effective cost calculation, using the price of fuel at the time of vehicle purchase.

In general, the model adds technology for several reasons but checks these sequentially. The model then applies any “forced” technologies. Currently, only variable valve timing (VVT) is forced to be applied to vehicles at redesign since it is the root of the engine path and the reference point for all future engine technology applications.³²³ The model next applies any inherited technologies that were applied to a leader vehicle on the same vehicle platform and carried forward into future model years where follower vehicles (on the shared system) are freshened or redesigned (and thus eligible to receive the updated version of the shared component). In practice, very few vehicle models enter without VVT, so inheritance is typically the first step in the compliance loop. Next, the model evaluates the manufacturer’s compliance status, applying all cost-effective technologies regardless of compliance status.³²⁴ Then the model applies expiring overcompliance credits (if allowed to do so under the perspective of either the “unconstrained” or “standard setting” analysis, for CAFE purposes).³²⁵ At this point, the model checks the manufacturer’s compliance status again. If the manufacturer is still not compliant (and is unwilling to pay civil penalties, again for CAFE modeling), the model will add technologies that are not cost-effective until the manufacturer reaches compliance. If the manufacturer exhausts opportunities to comply with the standard by improving fuel economy/reducing emissions (typically due to a limited percentage of its fleet being redesigned in that year), the model will apply banked CAFE or CO₂ credits to offset the remaining deficit. If no credits exist to offset the remaining deficit, the model will reach back in time to alter technology solutions in earlier model years.

The CAFE model implements multi-year planning by looking back, rather than forward. When a manufacturer is unable to comply through cost-effective (*i.e.*, producing effective cost values less than zero) technology improvements or credit application in a given year, the

model will “reach back” to earlier years and apply the most cost-effective technologies that were not applied at that time and then carry those technologies forward into the future and re-evaluate the manufacturer’s compliance position. The model repeats this process until compliance in the current year is achieved, dynamically rebuilding previous model year fleets and carrying them forward into the future, and accumulating CAFE or CO₂ credits from over-compliance with the standard wherever appropriate.

In a given model year, the model determines applicability of each technology to each vehicle platform, model, engine, and transmission. The compliance simulation algorithm begins the process of applying technologies based on the CAFE or CO₂ standards specified during the current model year. This involves repeatedly evaluating the degree of noncompliance, identifying the next “best” technology (ranked by the effective cost discussed earlier) available on each of the parallel technology paths described above and applying the best of these. The algorithm combines some of the pathways, evaluating them sequentially instead of in parallel, to ensure appropriate incremental progression of technologies.

The algorithm first finds the best next applicable technology in each of the technology pathways and then selects the best among these. For CAFE purposes, the model applies the technology to the affected vehicles if a manufacturer is either unwilling to pay penalties or if applying the technology is more cost-effective than paying penalties. Afterwards, the algorithm reevaluates the manufacturer’s degree of noncompliance and continues application of technology. Once a manufacturer reaches compliance (*i.e.*, the manufacturer would no longer need to pay penalties), the algorithm proceeds to apply any additional technology determined to be cost-effective (as discussed above). Conversely, if a manufacturer is assumed to prefer to pay penalties, the algorithm only applies technology up to the point where doing so is less costly than paying penalties. The algorithm stops applying additional technology to this manufacturer’s products once no more cost-effective solutions are encountered. This process is repeated for each manufacturer present in the input fleet. It is then repeated for each model year. Once all model years have been processed, the compliance simulation algorithm concludes. The process for CO₂ standard compliance simulation is similar, but without the

option of penalty payment, such that technologies are applied until compliance (accounting for any modeled application of credits) is achieved. For both CAFE and CO₂ standards, the model also applies any additional (*i.e.*, beyond required for compliance) technology that “pays back” within a specified period (for the NPRM and today’s analysis, 30 months).

Some commenters argued that the CAFE model applies constraints that excessively limit options manufacturers have to add technology, causing the model to overestimate costs to achieve a given level of improvement.³²⁶ Some of these commenters further argued that the agencies should assume greater potential to apply technologies that contribute to compliance by improving air conditioner efficiency or otherwise reducing “off cycle” fuel consumption and CO₂ emissions.³²⁷ Other commenters argued that such constraints, while warranting some refinements, help the model to simulate manufacturers’ decision making realistically and to estimate technology effectiveness and costs reasonably.^{328 329}

Some commenters questioned the “effective cost” metric the model uses to decide among available options, claiming that the metric also causes the model to avoid selection of pathways that are not always economically optimal.³³⁰ One of these commenters recommended the agencies modify the effective cost metric for CO₂ compliance by removing the term placing a monetary value on progress toward compliance, and instead dividing the remaining net cost (*i.e.*, the increase in technology costs minus a portion of the fuel outlays expected to be avoided) by the additional CO₂ credits earned.³³¹ Another of these commenters claimed on one hand, that the effective cost metric “does not include a measurement of the technology’s reduction in fuel consumption or CO₂ emissions” and, on the other, that the metric inappropriately places a value on avoided fuel consumption.³³²

One commenter claimed that the model inappropriately allows earned

³²³ As a practical matter, this affects very few vehicles. More than 95 percent of vehicles in the market file either already have VVT present or have surpassed the basic engine path through the application of hybrids or electric vehicles.

³²⁴ For further explanation of how the CAFE model considers the effective cost of applying different technologies see the CAFE Model Documentation for the final rule, at S5.3 Compliance Simulation Algorithm.

³²⁵ As mentioned above, EPCA prohibits consideration of available credits when setting maximum feasible fuel economy standards. 49 U.S.C. 32902(h)(3).

credits (including CO₂ program credits for which EPA has granted a one-time exemption from carry-forward limits) to expire while also showing undue degrees overcompliance with standards, and further proposed that the model be modified to simulate both credit “carry back” (aka “borrowing”) and credit trading between manufacturers.³³³

In addition, some commenters indicated that the agencies’ analysis (impliedly, its modeling) should account for some States’ mandates that manufacturers sell minimum quantities of “Zero Emission Vehicles” (ZEVs).^{334 335}

Regarding the model’s representation of engineering and product planning constraints, the agencies maintain that having such constraints produces more realistic potential (as mentioned above, not “predicted”) pathways forward from manufacturers’ current fleets than would be the case were these constraints removed. For example, while manufacturers’ product plans are protected as confidential business information (CBI), some manufacturers’ public comments demonstrate year-by-year balancing such as the CAFE model emulates.³³⁶ Also, even manufacturers that have invested in technologies such as hybrid electric powertrains and Atkinson cycle engines have commented that a manufacturers’ past investments will constrain the pathways it can practicably take.³³⁷ Therefore, the agencies have retained the model’s basic structural constraints, have updated and expanded the model’s technology paths (and, as discussed, the model’s logic for approaching these paths), and have updated inputs defining the range of manufacturer-, technology-, and product-specific constraints. These updates are discussed below at greater length.

The agencies have also reconsidered opportunities manufacturers may have to expand the application of technologies that contribute to compliance by improving air conditioner efficiency or otherwise reducing “off cycle” fuel consumption and CO₂ emissions, or to earn credit toward CO₂ compliance by using refrigerants with lower global warming potential (GWP) or reducing the potential for refrigerant leaks. The version of the model used for the proposal accommodates inputs that, for

each of these adjustments or credits, applies the same value to every model year. The agencies have revised the model to accommodate inputs that specify the degree of adjustment or credit separately for each model year, and have applied inputs that assume manufacturers will increase application of these improvements to the highest levels reported within the industry.

Regarding comments on the effective cost metric the model uses to compare and select among available options to add technology, the agencies have considered changes such as those mentioned above. Given the myriad of factors that manufacturers can consider, any weighing to be conducted using publicly-available information will constitute a simplified representation. Nevertheless, within the model’s context, it is obvious that any weighing of options should, at a minimum, consider some measure of each option’s costs and benefits. Since this aspect of the model involves simulating manufacturers’ decisions, it is also clearly appropriate that these costs and benefits be considered from a manufacturer perspective rather than a social perspective.

The effective cost metric used for the NPRM version of the model represents the cost of a given option as the cost to apply a given technology to a given set of vehicles, and represents the benefit of the same option as the extent to which the manufacturer might expect buyers would be willing to pay for fuel economy (as represented by a portion of the projected fuel savings), combined with any reduction in CAFE civil penalties that the manufacturer might ultimately need to pass along to buyers. The reduction in CAFE civil penalties places a value on progress made toward compliance with CAFE standards. The CAA provides no direction regarding CO₂ standards, so the model accepts inputs specifying an analogous basis for valuing changes in the quantity of CO₂ credits earned from (or required by) a manufacturer’s fleet. Because each of these three components (technology cost, fuel benefit, and compliance benefit) is expressed in dollars, subtracting benefits from costs produces a net cost, and after dividing net costs by the number of affected vehicles, it is logical to, at each step, select the option that produces the most negative net unit cost. This approach can be interpreted as maximizing net benefits (to the manufacturer).

As an alternative, the agencies considered a simpler metric that considers only the cost of the option and the extent to which the option increases the quantity of earned credits,

and does not require input assumptions regarding how to value progress toward compliance. Such a metric is expressed in dollars per ton or dollars per gallon such that seeking options that produce the smallest (positive) values can be interpreted as maximizing cost effectiveness (of progress toward compliance). However, simply comparing technology costs to corresponding compliance improvements would implicitly assume that manufacturers do not respond at all to fuel prices. This assumption is clearly unrealistic. For example, if diesel fuel costs \$5 per gallon and gasoline costs \$2 per gallon, manufacturers will be reluctant to respond to stringent CAFE or CO₂ standards by replacing gasoline engines with diesel engines. Manufacturers’ comments credibly assert that fuel prices matter, and in the agencies’ judgment, simulations of decisions between available options should continue to account for avoided fuel outlays.

On the other hand, while any metric should incorporate some measure of progress toward compliance, it is not obvious that this progress must be expressed in monetary terms. While the CAFE civil penalty provisions provide a logical basis for doing so with respect to CAFE, the recently-introduced (through EISA) option to trade credit between manufacturers adds an alternative basis that is undefined and uncertain, in part because terms of past trades are not known to the agencies. Also, as mentioned above, EPCA/EISA’s civil penalty provisions are not applicable to noncompliance with CO₂ standards.

Therefore, for the purpose of selecting among available options to add technology, the agencies consider it reasonable to use the degree of compliance improvement in “raw” (*i.e.*, not monetized) form, and to divide net costs (*i.e.*, technology costs minus a portion of expected avoided fuel outlays) by this improvement. Under a range of side-by-side tests, this change to the effective cost metric most frequently produced lower overall estimates of compliance costs. However, differences vary among manufacturers, model years, and regulatory alternatives, and also depend on other model inputs. For example, at high fuel prices, the new metric tends to select more expensive pathways than the NPRM’s metric, and with the new metric, a case simulating “perfect trading” of CO₂ compliance credits tends to show such trading increasing compliance costs rather than, as expected, decreasing such costs.

The version of the model used for the proposal simulates the potential that, for

³³⁷ Toyota, Attachment 1, p. 10.

a given fleet in a given model year, a manufacturer might be able to use credits from an earlier model year or a different fleet. This version of the model did not explicitly simulate the potential that, for a given fleet in a given model year, a manufacturer might be to use credits from a future model year or a different manufacturer. However, the agencies did apply model inputs that reflected assumptions regarding possible trading of credits actually earned prior to model year 2016 (the earliest represented in detail in the agencies' analysis), and the agencies did examine a case (included in the sensitivity analysis) involving hypothetical "perfect" trading of CO₂ credits among manufacturers by treating the industry as a single "manufacturer." Although past versions of the CAFE Model had included code under development with a view toward eventually simulating one or both of these provisions, this code had never proceeded beyond preliminary experimentation, and had never been the focus of peer reviews or application in published analyses.

Nevertheless, the agencies considered expanding the model to simulate credit "carry back" (or "borrowing") and trading (explicitly, rather than in an idealized hypothetical way). The agencies closely examined the corresponding model revisions proposed by UCS and determined that such methods would not produce repeatable results. This is because the approach proposed by UCS "randomly swaps items in list to minimize trading bias."³³⁸

Even if such revisions could be modified to produce non-random results, including credit banking and trading would introduce highly speculative elements into the agencies' analysis. While manufacturers have occasionally indicated plans to carry back credits from future model years, those plans have sometimes backfired when projected credits have failed to materialize, *e.g.*, by misjudging consumer demand for more efficient vehicles. In the agencies' judgment, it would be inappropriate to set standards based on an analysis that relies on the type of borrowing that has been known to fail. To rely also on credit trading during the model years included in the analysis would compound this undue speculation. For example, including credit borrowing and trading throughout the analysis, as some commenters proposed, would lead to an analysis that depends on the potential that, in order

to comply with the MY 2022 standard for light trucks, FCA could use credits it expects to be able to buy from another manufacturer in MY 2025. Even if the agencies' analysis had knowledge of and made use of manufacturers' actual product plans, expectations about the ability to borrow others' unearned credits would necessarily be considered risky and unreliable. Within an analysis that, to provide for public disclosure, extrapolates forward many years from the most recent observed fleet, such transactions would add an unreasonable level of speculation. Therefore, the agencies have declined to introduce credit borrowing and trading into the model's logic.

The analysis presented in the proposal applied inputs reflecting potential application of credits earned earlier than the first year modeled explicitly. However, as observed by some commenters, those inputs did not fully account for the one-time exemption from the 5-year limit on the extent to which manufacturers may carry forward CO₂ credits. The agencies have updated the analysis fleet to MY 2017 and, in doing so, have updated inputs specifying how credits earned to MY 2017 might be applied. These updates implement a reasonably full accounting of these "legacy" credits, including of the one-time exemption from the credit life limit.

As mentioned above, some commenters also indicated that the model is unrealistically "reluctant" to apply credits carried forward from early model years. As explained in the proposal and in the model documentation, the model's application of carried-forward credits is partially controlled by model inputs, which, for the proposal, were set to assume that manufacturers would tend to retain credits as long as possible. This assumption is entirely consistent with manufacturers' past practice and logical in a context wherein the stringency of standards is generally increasing over time. Even though using credits in some model years might seem initially advantageous, doing so means foregoing actual improvements likely to be needed in later model years.

Regarding the model's treatment of mandates and credits for the sale of ZEVs, as indicated in the model documentation accompanying the proposal, these capabilities were experimental in that version of the model. The reference case analysis for today's notice, like that for the proposal,

does not simulate compliance with ZEV mandates.³³⁹

For the NPRM, the CAFE model was exercised with inputs extending this explicit simulation of technology application through MY 2032, as the agencies anticipated this was sufficiently beyond MY 2026 that nearly all multiyear planning attributable to MY 2026 standards should be accounted for, and any compliance credits carried forward from MY 2026 would have expired. The analysis met this expectation, and the agencies presented analysis of the resultant estimated impacts over the useful lives of vehicles produced prior to MY 2030. The agencies invited comment on all aspects of the analysis, and relevant to this aspect of the analysis—*i.e.*, its perspective and temporal span—EDF stated that these led the agencies to overstate the proposal's positive impacts on safety, in part because by explicitly representing vehicle model years only through 2032, the agencies had failed to account for the impact of distant model years prices and fuel economy levels on the retention and scrappage of vehicles produced through MY 2029.³⁴⁰ For example, some vehicles produced in MY 2026 will likely still be on the road during calendar years (CY) 2033–2050 and the rates at which these MY 2026 vehicles will be scrapped during CYs 2033–2050 will be impacted by the prices and fuel economy levels of vehicles produced during MYs 2033–2050.

The agencies have addressed this comment by expanding model inputs to extend the explicit simulation of technology application through MY 2050. Most of these expanded model inputs involve the analysis fleet and inputs defining the cost and availability of various fuel-saving technologies. These inputs are discussed below. The agencies also made minor modifications to the model in order to extend model outputs to cover this wider span and to carry forward each regulatory alternative's standards automatically through the last year to be modeled (*e.g.*, extending standards without change from MY 2032 through MY 2050). The model documentation discusses these

³³⁹ The agencies note their finalization of the One National Program Final Action, in which EPA partially withdrew a waiver of CAA preemption previously granted to the State of California relating to its ZEV mandate, and NHTSA finalized regulations providing that State ZEV mandates are impliedly and expressly preempted by EPCA. This joint action is available at 84 FR 51310.

minor changes.³⁴¹ In addition, although the agencies published detailed model output files documenting all estimated annual impacts through calendar year 2089, the notice and PRIA both emphasized the above-mentioned “model year” perspective, as in past regulatory analyses supporting CAFE and CO₂ standards. Recognizing that an alternative “calendar year” perspective is of interest to EDF and, perhaps other stakeholders, the agencies have expanded the presentation of results in today’s notice and FRIA by presenting some physical impacts (*e.g.*, fuel consumption and CO₂ emissions) as well as monetized benefits, costs, and net benefits for each of CYs 2017–2050. All of these results appear in the model output files published with today’s notice, as do corresponding results for more specific impacts (*e.g.*, year-by-year components of monetized social costs).³⁴²

5. Calculation of Physical Impacts

Once it has completed the simulation of manufacturers’ potential application of technology in response to CAFE/CO₂ standards and fuel prices, the CAFE Model calculates impacts of the resultant changes in new vehicle fuel economy levels and prices. This involves several steps.

The model calculates changes in the total quantity of new vehicles sold in each model year as well as the relative shares passenger cars and light trucks comprise of the overall new vehicle market. The agencies received many comments on the estimation of sales impacts, and as discussed below, today’s analysis applies methods and corresponding estimates that reflect careful consideration of these comments. Related to these calculations, the model now operates in an iterated fashion with a view toward obtaining sales impacts that are balanced with changes in vehicle prices and fuel economy levels. This involves solving for compliance, calculating sales impacts, re-solving for compliance, and repeating these steps as many times as specified in model inputs. For today’s analysis, the agencies operated the model with four iterations, as early testing suggested three iterations should be sufficient for fleetwide results to converge between iterations. The model documentation describes the procedures for iteration in detail.

The impacts on outlays for new vehicles occur coincident with the sale of these vehicles so the model can simply calculate and record these for each model year included in the analysis. However, virtually all other impacts result from vehicle operation that extends long after a vehicle is produced. Like other models (including, *e.g.*, NEMS), the CAFE Model includes procedures (sometimes referred to as “stock models” or as models of fleet turnover) to estimate annual rates at which new vehicles are used and subsequently scrapped. The agencies received many comments on procedures for estimating vehicle scrappage and on procedures for estimating annual quantities of highway travel, accounting for the elasticity of travel demand with respect to per-mile costs for fuel. Below, Section VI.D.1 discusses these comments and reviews procedures and corresponding estimates that also reflect careful consideration of these comments.

For each vehicle model in each model year, these procedures result in estimates of the number of vehicles remaining in service in each calendar year, as well as the annual mileage accumulation (*i.e.*, vehicle miles traveled, or VMT) in each calendar year. As mentioned above, most of the physical impacts of interest derive from this vehicle operation. Also discussed above, the simulated application of technology results in “initial” and “final” estimates of the cost, fuel type, fuel economy, and fuel share (for, in particular, PHEVs that can run on gasoline or electricity) applicable to each vehicle model in each model year. Together with quantities of travel, and with estimates of the “gap” between “laboratory” and “on-road” fuel economy, these enable calculation of quantities of fuel consumed in each year during the useful life of each vehicle model produced in each model year.³⁴³ The model documentation provides specific procedures and formulas implementing these calculations.

As for the NPRM, the model calculates emissions of CO₂ and other air pollutants, reporting emissions both from vehicle tailpipes and from upstream processes (*e.g.*, petroleum refining) involved in producing and supplying fuels. Section VI.D.3 below reviews methods, models, and estimates used in performing these calculations. The model also calculates impacts on highway safety, accounting for changes

in travel demand, changes in vehicle mass, and continued past and expected progress in vehicle safety (through, *e.g.*, the application of new crash avoidance systems). Section VI.D.2 discusses methods, data sources, and estimates involved in estimating safety impacts, comments on the same, and changes included in today’s analysis. In response to the NPRM, some comments urged the agencies also to quantify different types of health impacts from changes in air pollution rather than only accounting for such impacts in aggregate estimates of the social costs of air pollution. Considering these comments, the agencies added such calculations to the model, as discussed in Section VI.D.3.

6. Calculation of Benefits and Costs

Having estimated how technologies might be applied going forward, and having estimated the range of resultant physical impacts, the CAFE Model calculates a variety of private and social benefits and costs, reporting these from the consumer, manufacturer, and social perspectives, both in undiscounted and discounted present value form (given inputs specifying the corresponding discount rate and present year). Estimates of regulatory costs are among the direct outputs of the simulation of manufacturers’ potential responses to new standards. Other benefits and costs are calculated based on the above-mentioned estimates of travel demand, fuel consumption, emissions, and safety impacts. The agencies received many comments on the NPRM’s calculation of benefits and costs, and Section VI.D.1 discusses these comments and presents the methods, data sources, and estimates used in calculating benefits and costs reported here.

7. Structure of Model Inputs and Outputs

All CAFE Model inputs and outputs described above are specified in Microsoft Excel format, and the user can define and edit all inputs to the system. Table VI–3 describes (non-exhaustively) which inputs are contained within each input file and Table VI–4 describes which outputs are contained in each output file. This is important for three reasons: (1) Each file is discussed throughout the following sections; (2) several commenters conflated aspects of the model with its inputs; and (3) several commenters seemed confused about where to find specific information in the output files. This information was described in detail in the NPRM CAFE Model Documentation, but is reproduced here for quick reference. When specifically referencing the input

³⁴¹ The model and documentation are available at <https://www.nhtsa.gov/corporate-average-fuel-economy/compliance-and-effects-modeling-system>.

³⁴² Detailed model inputs and outputs are available at <https://www.nhtsa.gov/corporate-average-fuel-economy/compliance-and-effects-modeling-system>.

³⁴³ The agencies have applied the same estimates of the “on road gap” as applied for the analysis supporting the NPRM. For operation on gasoline, diesel, E85, and CNG, this gap is 20 percent; for electricity and hydrogen, 30 percent.

or output file used for the NPRM or final or FRM, respectively, will precede the rule in the following discussion, NPRM file name.

Table VI-3 – CAFE Model Input Files

| Input File | Contents |
|---------------------------------------|--|
| Market Data (Manufacturers Worksheet) | manufacturers included in analysis, and estimates of banked compliance credits and willingness to pay CAFE fines rather than applying technology |
| Market Data (Vehicles Worksheet) | description of each specific vehicle model/configuration produced in MY 2017, identifying corresponding engines and transmissions |
| Market Data (Engines Worksheet) | characteristics of each specific engine |
| Market Data (Transmissions Worksheet) | characteristics of each specific transmission |
| Technologies | applicability, availability, and cost of specific fuel-saving technologies included in analysis |
| Parameters | wide-ranging economic and other analytical inputs (e.g., fuel prices, discount rates, fatality risk rates, emission factors, emissions damage costs) |
| Scenarios | coefficients defining each regulatory alternative to be modeled |

Table VI-4 – CAFE Model Output Files

| Output File | Contents |
|--|--|
| Technology Utilization Report | rates at which specific technologies are added to and present in manufacturers' fleets |
| Compliance Report | required and achieved average CAFE and CO ₂ levels, regulatory costs, average footprint and curb weight, new vehicle sales volumes, labor utilization, CAFE and CO ₂ credit generation and use |
| Societal Effects Report | physical impacts (e.g., on-road fleet size and VMT, energy consumption and emissions, health and safety impacts) |
| Societal Costs Report | social benefits and costs |
| Annual Societal Effects Report | physical impacts attributable to each model year in each calendar year |
| Annual Societal Costs Report | social benefits and costs attributable to each model year in each calendar year |
| Annual Societal Effects Summary Report | physical impacts attributable to overall on-road fleet in each calendar year |
| Annual Societal Costs Summary Report | social benefits and costs attributable to overall on-road fleet in each calendar year |
| Consumer Costs Report | benefits and costs from consumer perspective |
| Vehicles Report | initial and final characteristics (fuel economy, CO ₂ rating, footprint, weight, price, and technology content) and sales of each vehicle model/configuration in each model year |

B. What inputs does the compliance analysis require?

1. Analysis Fleet

The starting point for the evaluation of the potential feasibility of different stringency levels for future CAFE and CO₂ standards is the analysis fleet, which is a snapshot of the recent vehicle market. The analysis fleet provides a baseline from which to project what and how additional technologies could feasibly be applied to vehicles in a cost-effective manner to raise those vehicles' fuel economy and lower their CO₂ emission levels.³⁴⁴ The fleet characterization also provides a reference point with data for other factors considered in the analysis, including environmental effects and effects estimated by the economic modules (*i.e.*, sales, scrappage, and labor utilization). When the scope of the analysis widens, another piece of data must be included for each vehicle in the analysis fleet to map a given element of the fleet appropriately onto an analysis module.

For the analysis presented in this final rule, the analysis fleet includes information about vehicles that is essential for each analysis module. The first part of projecting how additional technologies could be applied to vehicles is knowing which vehicles are produced by which manufacturers, the fuel economies of those vehicles, how many of each are sold, whether they are passenger cars or light trucks, and their

footprints. This is important because it improves understanding of the overall impacts of different levels of CAFE and CO₂ standards; overall impacts that result from industry's response to standards, and industry's response, is made up of individual manufacturer responses to the standards in light of the overall market and their individual assessment of consumer acceptance. Establishing an accurate representation of manufacturers' existing fleets (and the vehicle models in them) that will be subject to future standards helps in predicting potential individual manufacturer responses to those future standards in addition to potential changes in those standards.

Another part of projecting how additional fuel economy improving technologies could be applied to vehicles is knowing which fuel saving technologies manufacturers have equipped on which vehicles. In many cases, the agencies also collect and reference additional information on other vehicle attributes to help with this process.³⁴⁵ Accounting for technologies already applied to vehicles helps avoid "double-counting" the value of those technologies, by assuming they are still available to be applied to improve fuel economy and reduce CO₂ emissions. It also promotes more realistic determinations of what additional technologies can feasibly be applied to those vehicles: If a manufacturer has already started down a technological path to fuel economy or performance improvements, the agencies do not

assume it will completely abandon that path because doing so would be unrealistic and fails to represent accurately manufacturer responses to standards. Each vehicle model (and configurations of each model) in the analysis fleet, therefore, has a comprehensive list of its technologies, which is important because different configurations may have different technologies applied to them.³⁴⁶ In addition, to properly account for technology costs, the agencies assign each vehicle to a technology class and an engine class. Technology classes reference each vehicle to a set of full vehicle simulations, so that the agencies may project fuel efficiency with combinations of additional fuel saving equipment and hybrid and electric vehicle battery costs.

Yet another part of projecting which vehicles might exist in future model years is developing reasonable real-world assumptions about when and how manufacturers might apply certain technologies to vehicles. The analysis fleet accounts for links between vehicles, recognizing vehicle platforms will share technologies, and the vehicles that make up that platform should receive (or not receive) additional technological improvements together. Shared engines, shared transmissions, and shared vehicle platforms for mass reduction technology are considered. In addition, each vehicle model/configuration in the analysis fleet also has information about its redesign

³⁴⁴ The CAFE model does not generate compliance paths a manufacturer should, must, or will deploy. It is intended as a tool to demonstrate a compliance pathway a manufacturer *could* choose. It is almost certain all manufacturers will make compliance choices differing from those projected by the CAFE model.

³⁴⁵ For instance, curb weight, horsepower, drive configuration, pickup bed length, oil type, body style, aerodynamic drag coefficients, and rolling resistance coefficients, and (if applicable) battery sizes are all required to assign technology content properly.

³⁴⁶ Considering each vehicle model/configuration also improves the ability to consider the differential impacts of different levels of potential standards on different manufacturers, since all vehicle model/configurations "start" at different places, in terms of technologies already used and how those technologies are used.

schedule, *i.e.*, the last year it was redesigned and when the agencies expect it to be redesigned again. Redesign schedules are a key part of manufacturers' business plans, as each new product can cost more than \$1B, and involve a significant portion of a manufacturer's scarce research, development, and manufacturing and equipment budgets and resources.³⁴⁷ Manufacturers have repeatedly told the agencies that sustainable business plans require careful management of resources and capital spending, and that the length of time each product remains in production is crucial to recouping the upfront product development and plant/equipment costs, as well as the capital needed to fund the development and manufacturing equipment needed for future products. Because the production volume of any given vehicle model varies within a manufacturer's product line, and varies among different manufacturers, redesign schedules typically vary for each model and manufacturer. Some (relatively few) technological improvements are small enough that they can be applied in any model year; a few other technological improvements may be applied during a refreshing (when a few additional changes are made, but well short of a full redesign), but others are major enough that they can only be cost-effectively applied at a vehicle redesign, when many other things about the vehicle are already changing. Ensuring the CAFE model makes technological improvements to vehicles only when it is feasible to do so also helps the analysis better represent manufacturer responses to different levels of standards.

Finally, the agencies restrict the applications of some technologies on some vehicles upon determining the technology is not compatible with the functional and performance requirements of the vehicle, or if the manufacturers are unlikely to apply a specific technology to a specific vehicle for reasons articulated with confidential business information that the agencies found credible.

Other data important for the analysis that are referenced to the analysis fleet include baseline economic, environmental, and safety information. Vehicle fuel tank size is required to estimate range and refueling benefit while curb weights and safety class assignments help the agencies consider how changes in vehicle mass may affect

safety. The agencies identify the final assembly location for each vehicle, engine, and transmission, as well as the percent of U.S. content to support the labor impact analysis. In addition, the aforementioned accounting for first-year vehicle production volumes (*i.e.*, the number of vehicles of each new model sold in MY 2017, for this analysis) is the foundation for estimating how future vehicle sales might change in response to different potential standards.

The input file for the CAFE model characterizing the analysis fleet, referred to as the "market inputs" file or "market data" file, accordingly includes a large amount of data about vehicles, their technological characteristics, the manufacturers and fleets to which they belong, and initial prices and production volumes, which provide the starting points for projection (by the sales model) to ensuing model years. In the Draft TAR (which utilized a MY 2015 analysis fleet) and NPRM (which utilized a MY 2016 analysis fleet), the agencies needed to populate about 230,000 cells in the market data file to characterize the fleet. For this final rule (which utilized a MY 2017 analysis fleet), the agencies populated more than 400,000 cells to characterize the fleet. While the fleet is not actually much more heterogeneous in reality,³⁴⁸ the agencies have provided and collected more data to justify the characterization of the analysis fleet, and to support the functionality of modules in the CAFE model.

A solid characterization of a recent model year as an analytical starting point helps realistically estimate ways manufacturers could potentially respond to different levels of standards, and the modeling strives to simulate realistically how manufacturers could progress from that starting point. While manufacturers can respond in many ways beyond those represented in the analysis (*e.g.*, applying other technologies, shifting production volumes, changing vehicle footprint), such that it is impossible to predict with any certainty exactly how each manufacturer will respond, it is still important to establish a solid foundation from which to estimate potential costs and benefits of potential future standards. The following sections discuss aspects of how the analysis fleet was built for this analysis, and includes discussion of the comments on fleet that the agencies received on the proposed rule.

a) Principles on Data Sources Used To Populate the Analysis Fleet

The source data for vehicles in the analysis fleet and their technologies is a central input for the analysis. The sections below discuss pros and cons of different potential sources and what the agencies used for this analysis, and responds to comments the agencies received on data sources in the proposal.

(1) Use of Confidential Business Information Versus Publicly-Releasable Sources

Since 2001, CAFE analysis has used either confidential, forward-estimating product plans from manufacturers, or publicly available data on vehicles already sold as a starting point for determining what technologies can be applied to what vehicles in response to potential different levels of standards. The use of either data source requires certain tradeoffs. Confidential product plans comprehensively represent what vehicles a manufacturer expects to produce in coming years, accounting for plans to introduce new vehicles and fuel-saving technologies and, for example, plans to discontinue other vehicles and even brands. This information can be very thorough and can improve the accuracy of the analysis, but cannot be publicly released. This makes it difficult for public commenters to reproduce the analysis for themselves as they develop their comments. Some non-industry commenters have also expressed concern about manufacturers having an incentive in the submitted plans to underestimate (deliberately or not) their future fuel economy capabilities and overstate their expectations about, for example, the levels of performance of future vehicle models in order to affect the analysis. Accordingly, since 2010, EPA and NHTSA have based analysis fleets almost exclusively on information from commercial and public sources, starting with CAFE compliance data and adding information from other sources.

An analysis fleet based primarily on public sources can be released to the public, solving the issue of commenters being unable to reproduce the overall analysis. However, industry commenters have argued such an analysis fleet cannot accurately reflect manufacturers' actual plans to apply fuel-saving technologies (*e.g.*, manufacturers may apply turbocharging to improve not just fuel economy, but also to improve vehicle performance) or manufacturers' plans to change product offerings by introducing some vehicles and brands and discontinuing other

³⁴⁷ Shea, T., Why Does It Cost So Much For Automakers To Develop New Models? Autoblog (Jul. 27, 2010), <https://www.autoblog.com/2010/07/27/why-does-it-cost-so-much-for-automakers-to-develop-new-models/>.

³⁴⁸ The expansion of cells is primarily due to (1) considering more technologies, and (2) listing trim levels separately, which often yields more precise curb weights and more accurate manufacturer suggested retail prices.

vehicles and brands, precisely because that information is typically confidential business information (CBI). A fully-publicly-releasable analysis fleet holds vehicle characteristics unchanged over time and lacks some level of accuracy when projected into the future. For example, over time, manufacturers introduce new products and even entire brands. On the other hand, plans announced in press releases do not always ultimately bear out, nor do commercially available third-party forecasts. Assumptions could be made about these issues to improve the accuracy of a publicly releasable analysis fleet, but concerns include that this information would either be largely incorrect, or, if the assumptions were correct, information would be released that manufacturers would consider CBI.

Furthermore, some technologies considered in the rulemaking are difficult to observe in the analysis fleet without expensive teardown study and time-consuming benchmarking. Not giving credit for these technologies puts the analysis at significant risk of double-counting the effectiveness of these technologies, as manufacturers cannot equip technologies twice to the same vehicle for double the fuel economy benefit. As discussed in the Draft TAR, the agencies assigned little (if any) technology application in the baseline fleet for some of these technologies.³⁴⁹ For the NPRM MY 2016 fleet development process, the agencies again offered the manufacturers the opportunity to volunteer CBI to the agencies to help inform the technology content of the analysis fleet, and many manufacturers did. The agencies were able to confirm that many manufacturers had already included many hard-to-observe technologies in the MY 2016 fleet (which they were not properly given credit for in the characterization of the MY 2014 and MY 2015 fleets presented in Draft TAR) so the agencies reflected this new information in the NPRM analysis and in the analysis presented today.

In addition, many manufacturers provided confidential comment on the potential applicability of fuel-saving technologies to their fleet. In particular, many manufacturers confidentially identified specific engine technologies

that they will *not* use in the near term, either on specific vehicles, or at all. Reasons varied: Some manufacturers cited intellectual property concerns, and others stated functional performance concerns for some engine types on some vehicles. Other manufacturers shared forward-looking product plans, and explained that it would be cost prohibitive to scrap significant investments in one technology in favor of another. This topic is discussed in more detail in Section VI.B.1.b)(6), below.

The agencies sought comment on how to address this issue going forward, recognizing both the competing interests involved and the typical timeframes for CAFE and CO₂ standards rulemakings.

Many commenters expressed concern with the agencies using any CBI as part of the rulemaking process. Some commenters expressed concern that use of CBI would make the CAFE model subject to inaccuracies because manufacturers would only provide additional information in situations in which a correction to the agencies' baseline assumptions would favor the manufacturers.³⁵⁰ The agencies recognize this as a reasonable concern, but the analysis presented in the Draft TAR consistently assumed very little (if any) technology had been applied in the baseline. In addition, many manufacturers shared information on advanced technologies that were not yet in production in MY 2017, but could be used in the future; manufacturer contributions helped the agencies better model many advanced engine technologies and to include them in today's analysis, and inclusion of these technologies (and costs) in the analysis sometimes lowered the projected cost of compliance for stringent alternatives. Other commenters expressed concern that automakers would supply false or incomplete information that would unduly restrict what technologies can be deployed.³⁵¹ When possible, the agencies sought independently to verify manufacturer CBI (or claims made by other stakeholders) through lab testing and benchmarking.³⁵² The agencies found no evidence of misrepresentation of engineering specifications in the MY 2017 fleet in manufacturer CBI; instead, the agencies were able to verify independently many CBI submissions, and confirm the credibility of

information provided from those sources.

Some commenters requested that more CBI be used in the analysis. For instance, some commenters suggested that the agencies should return to the use of product plans and announcements regarding future fleets because manufacturers had already committed investments to bring announced products to market.³⁵³ However, if the agencies were to assume that these commitments were already in the baseline, the agencies would underestimate the cost of compliance for stringent alternatives. Moreover, while upfront investments to bring technologies to market are significant, the total marginal costs of components are typically large in comparison over the entire product life-cycle, and these costs have not yet been realized in vehicles not yet produced.

The agencies did make use of some forward-looking CBI in the analysis. The agencies received many comments from manufacturers on the technological feasibility, or functional applicability of some fuel saving technologies to certain vehicles, or certain vehicle applications, and the agencies took this information into consideration when projecting compliance pathways. These cases are discussed generally in Section VI.B.1.b)(6), below, and specifically for each technology in those technology sections. Some commenters expressed that the use of CBI for future product plans would be acceptable, but only if the agencies disclosed the CBI affecting all vehicles through MY 2025 at the time of publication.³⁵⁴ Functionally, this is not possible. Manufacturer's confidential product plans cannot be made public, as prohibited under NHTSA's regulations at 49 CFR part 512, and if the information meets the requirements of section 208(c) of the Clean Air Act. If the agencies disclosed confidential information, it would not only violate the terms on which the agencies obtained the CBI, but it is unlikely that manufacturers would continue to offer CBI, which in turn would likely degrade the quality of the analysis. The agencies believe that the use of CBI in the NPRM and final rule analysis—to confirm, reference, or to otherwise modify aspects of the analysis that can be made public—threats the needle between a more accurate but less transparent analysis (using more CBI) and a less accurate but more transparent analysis (using less CBI).

³⁴⁹ These technologies include low rolling resistance technology (incorrectly applied to zero baseline vehicles in Draft TAR), low-drag brakes (incorrectly applied to zero baseline vehicles in Draft TAR), electric power steering (incorrectly applied to too few vehicles in Draft TAR), accessory drive improvements (incorrectly applied to zero baseline vehicles in Draft TAR), engine friction reduction (previously named LUBEFR1, LUBEFR2, and LUBEFR3), secondary axle disconnect and transmission improvements.

³⁵⁰ NHTSA–2018–0067–12039, Union of Concerned Scientists.

³⁵¹ NHTSA–2018–0067–11741, ICCT.

³⁵² For instance, the agencies continue to evaluate tire rolling resistance on production vehicles via independent lab testing, and the agencies benchmarked the operating behavior and calibration of many engines and transmissions.

³⁵³ NHTSA–2018–0067–11956, PA Department of Environmental Protection.

³⁵⁴ NHTSA–2018–0067–11741.

(2) Source Data and Vintage Used in the Analysis

Based on the assumption that a publicly-available analysis fleet continued to be desirable, manufacturer compliance submissions to EPA and NHTSA were used as a starting point for the NPRM and final rule analysis fleets. Generally, manufacturer compliance submissions break down vehicle fuel economy and production volume by regulatory class, and include some very basic product information (typically including vehicle nameplate, engine displacement, basic transmission information, and drive configuration). Many different trim levels of a product are typically rolled up and reported in an aggregated fashion, and these groupings can make decomposition of different fuel-saving, road load reducing technologies extremely difficult. For instance, vehicles in different test weight classes, with different tires or aerodynamic profiles may be aggregated and reported together.³⁵⁵ A second portion of the compliance submission summarizes production volume by vehicle footprints (a key compliance measure for standard setting) by nameplate, and includes some basic information about engine displacement, transmission, and drive configuration. Often these production volumes by footprint do not fit seamlessly together with the production volumes for fuel economy, so the agencies must reconcile this information.

Information from the MY 2016 fleet was chosen as the foundation for the NPRM analysis fleet because, at the time the rulemaking analysis was initiated, the 2016 fleet represented the most up-to-date information available in terms of individual vehicle models and configurations, production technology levels, and production volumes. If MY 2017 data had been used while this analysis was being developed, the agencies would have needed to use product planning information that could not be made available to the public until a later date.

The NPRM analysis fleet was initially developed with 2016 mid-model year compliance data because final compliance data was not available at that time, and the timing provided manufacturers the opportunity to review and comment on the characterization of their vehicles in the fleet. With a view toward developing an accurate characterization of the 2016 fleet to serve as an analytical starting point,

corrections and updates to mid-year data (e.g., to production estimates) were sought, in addition to corroboration or correction of technical information obtained from commercial and other sources (to the extent that information was not included in compliance data), although future product planning information from manufacturers (e.g., future product offerings, products to be discontinued) was not requested, as most manufacturers view such information as CBI. Manufacturers offered a range of corrections to indicate engineering characteristics (e.g., footprint, curb weight, transmission type) of specific vehicle model/configurations, as well as updates to fuel economy and production volume estimates in mid-year reporting. After following up on a case-by-case basis to investigate significant differences, the analysis fleet was updated.

Sales, footprint, and fuel economy values with final compliance data were also updated if that data was available. In a few cases, final production and fuel economy values were slightly different for specific MY 2016 vehicle models and configurations than were indicated in the NPRM analysis; however, other vehicle characteristics (e.g., footprint, curb weight, technology content) important to the analysis were reasonably accurate. While some commenters have, in the past, raised concerns that non-final CAFE compliance data is subject to change, the potential for change is likely not significant enough to merit using final data from an earlier model year reflecting a more outdated fleet. Moreover, even ostensibly final CAFE compliance data is frequently subject to later revision (e.g., if errors in fuel economy tests are discovered), and the purpose of the analysis was not to support enforcement actions but rather to provide a realistic assessment of manufacturers' potential responses to future standards.

Manufacturers integrated a significant amount of new technology in the MY 2016 fleet, and this was especially true for newly-designed vehicles launched in MY 2016. While subsequent fleets will involve even further application of technology, using available data for MY 2016 provided the most realistic detailed foundation for analysis that could be made available publicly in full detail, allowing stakeholders to reproduce the analysis presented in the proposal independently. Insofar as future product offerings are likely to be more similar to vehicles produced in 2016 than to vehicles produced in earlier model years, using available data regarding the 2016 model year provided

the most realistic, publicly releasable foundation for constructing a forecast of the future vehicle market for this proposal. Many comments responding to the Draft TAR, EPA's Proposed Determination, EPA's 2017 Request for Comment, and the NPRM preceding today's notice stated that the most up-to-date analysis fleet possible should be used, because a more up-to-date analysis fleet will better capture how manufacturers apply technology and will account better for vehicle model/configuration introductions and deletions.^{356 357}

On the other hand, some commenters suggested that because manufacturers continue improving vehicle performance and utility over time, an older analysis fleet should be used to estimate how the fleet could have evolved had manufacturers applied all technological potential to fuel economy rather than continuing to improve vehicle performance and utility.³⁵⁸ Because manufacturers change and improve product offerings over time, conducting analysis with an older analysis fleet (or with a fleet using fuel economy levels and CO₂ emissions rates that have been adjusted to reflect an assumed return to levels of performance and utility typical of some past model year) would miss this real-world trend. While such an analysis could project what industry *could* do if, for example, manufacturers devoted all technological improvements toward raising fuel economy and reducing CO₂ emissions (and if consumers decided to purchase these vehicles), the agencies do not believe it would be consistent with a transparent examination of what effects different levels of standards would have

³⁵⁶ 82 FR 39551 (Aug. 21, 2017).

³⁵⁷ For example, in 2016 comments to dockets EPA-HQ-OAR-2015-0827 and NHTSA-2016-0068, the Alliance of Automobile Manufacturers commented that "the Alliance supports the use of the most recent data available in establishing the baseline fleet, and therefore believes that NHTSA's selection [of, at the time, model year 2015] was more appropriate for the Draft TAR." Alliance at 82, Docket ID. EPA-HQ-OAR-2015-0827-4089. Global Automakers commented that "a one-year difference constitutes a technology change-over for up to 20% of a manufacturer's fleet. It was also generally understood by industry and the agencies that several new, and potentially significant, technologies would be implemented in MY 2015. The use of an older, outdated baseline can have significant impacts on the modeling of subsequent Reference Case and Control Case technologies." Global Automakers at A-10, Docket ID EPA-HQ-OAR-2015-0827-4009.

³⁵⁸ For example, in 2016 comments to dockets EPA-HQ-OAR-2015-0827 and NHTSA-2016-0068, UCS stated "in modeling technology effectiveness and use, the agencies should use 2010 levels of performance as the baseline." UCS at 4, Docket ID. EPA-HQ-OAR-2015-0827-4016.

³⁵⁵ Some fuel-economy compliance information for pickup trucks span multiple cab and box configurations, but manufacturers reported these disparate vehicles together.

on individual manufacturers and the fleet as a whole.

All else being equal, using a newer analysis fleet will produce more realistic estimates of impacts of potential new standards than using an outdated analysis fleet. However, among relatively current options, a balance must be struck between input freshness, and input completeness and accuracy.³⁵⁹ During assembly of the inputs for the NPRM analysis, final compliance data was available for the MY 2015 model year but not, in a few cases, for MY 2016. However, between mid-year compliance information and manufacturers' specific updates discussed above, a robust and detailed characterization of the MY 2016 fleet was developed. While information continued to develop regarding the MY 2017 and, to a lesser extent MY 2018 and even MY 2019 fleets, this information was—even in mid-2017—too incomplete and inconsistent to be assembled with confidence into an analysis fleet for modeling supporting deliberations regarding the NPRM analysis.

Manufacturers requested that the baseline fleet supporting the final rule incorporate the MY 2018 or most recent information available.³⁶⁰ Other commenters expressed desire for multiple fleets of various vintages to compare the updated model outputs with those of previous rule-makings. Specifically, some commenters requested that older fleet vintages (MY 2010, for instance) be developed in parallel with the MY 2017 fleet so that those too may be used as inputs for the model.³⁶¹

Between the NPRM and this final rule, manufacturers submitted final compliance data for the MY 2017 fleet. When the agencies pulled together information for the fleet for the final rule, the agencies decided to use the

highest-quality, most up-to-date information available. Given that pulling this information together takes some time, and given that “final” compliance submissions often lag production by a few years, the agencies decided to use 2017 model year as the base year for the analysis fleet, as the agencies stated in the NPRM.³⁶² While the agencies could have used preliminary 2018 data or even very early 2019 data, this information was not available in time to support the final rulemaking. Likewise, the agencies chose not to revert to a previous model year (for instance 2016 or 2012) because many manufacturers have incorporated fuel savings technologies over the last few years, realized some benefits for fuel economy, and adjusted the performance or sales mix of vehicles to remain competitive in the market. Also, using an earlier model year would provide less accurate projections because the analysis would be based on what manufacturers could have done in past model years and would have estimated the fuel economy improvements instead of using known information on the technologies that were employed and the actual fuel economy that resulted from applying those technologies.

Some additional information (about off-cycle technologies, for instance) was often not reported by manufacturers in MY 2017 formal compliance submissions in a way that provided clear information on which technologies were included on which products. As part of the formal compliance submission, some manufacturers voluntarily submitted additional information (about engine technologies, for instance). While this data was generally of very high quality, there were some mistakes or inconsistencies with publicly available information, causing the agencies to contact the manufacturers to understand and correct identified issues. In most cases, however, the formal compliance data was very limited in nature, and the agencies collected additional information necessary to characterize fully the fleet from other sources, and scrutinized additional information submitted by manufacturers carefully, independently verifying when possible.

Specifically, the agencies downloaded and reviewed numerous marketing brochures and product launch press releases to confirm information

submitted by manufacturers and to fill in information necessary for the analysis fleet that was not provided in the compliance data. Product brochures often served as the basis for the curb weights used in the analysis. This publicly available manufacturer information sometimes also included aerodynamic drag coefficients, information about steering architecture, start-stop systems, pickup bed lengths, fuel tank capacities, and high-voltage battery capacities. The agencies recorded vehicle horsepower, compression ratio, fuel-type, and recommended oil weight rating from a combination of manufacturer product brochures and owner's manuals. The product brochures, as well as online references such as Autobyte, informed which combinations of fuel saving technologies were available on which trim levels, and what the manufacturer suggested retail price was for many products. Overall this information proved helpful for assigning technologies to vehicles, and for getting data (such as fuel tank size³⁶³) necessary for the analysis. These reference materials have been included in the rulemaking documentation.³⁶⁴

The agencies elected not to develop fleets of previous model year vintages that could be used in parallel as an input to the CAFE model. Developing a detailed characterization of the fleet of any vintage would be a huge undertaking with few benefits. As the scope has increased, and as additional modules are added, going back in time to re-characterize a previous fleet in a format that works with CAFE model updates can be time- and resource-prohibitive for the agencies, even if that work is adapting a fleet that was used in previous rule-making analysis. Doing so also offers little value in determining what potential fuel saving technology can be added to a more recent fleet during the rulemaking timeframe.

The MY 2017 manufacturer-submitted data, verified and supplemented by the agencies with publicly-available information, therefore presented the fullest, most up-to-date data set that the agencies could have used to support this analysis.

³⁶³ The quality of data for today's analysis fleet is notably improved for fuel tank capacity, which factors into the calculation of refueling time benefits. In many previous analyses, fuel tank sizes were often stated as estimates or proxies, and not sourced so carefully.

³⁶⁴ Publicly available data used to supplement analysis fleet information is available in the docket.

³⁵⁹ Comments provided through a recent peer review of the CAFE model recognize the competing interests behind this balance. For example, referring to NHTSA's 2016 Draft TAR analysis, one of the peer reviewers commented as follows: “The NHTSA decision to use MY 2015 data is wise. In the TAR they point out that a MY 2016 foundation would require the use of confidential data, which is less desirable. Clearly they would also have a qualitative vision of the MY 2016 landscape while employing MY 2015 as a foundation. Although MY 2015 data may still be subject to minor revision, this is unlikely to impact the predictive ability of the model . . . A more complex alternative approach might be to employ some 2016 changes in technology, and attempt a blend of MY 2015 and MY 2016, while relying of estimation gained from only MY 2015 for sales. This approach may add some relevancy in terms of technology, but might introduce substantial error in terms of sales.”

³⁶⁰ NHTSA-2018-0067-12150, Toyota North America.

³⁶¹ NHTSA-2018-0067-11741, ICCT.

³⁶² 83 FR 43006 (“If newer compliance data (*i.e.*, MY 2017) becomes available and can be analyzed during the pendency of this rulemaking, and if all other necessary steps can be performed, the analysis fleet will be updated, as feasible, and made publicly available.”).

b) Characterizing Vehicles and Their Technology Content

The starting point for projecting what additional fuel economy improving technologies could feasibly be applied to vehicles is knowing what vehicles are produced by which manufacturers and what technologies exist on those vehicles. Rows in the market data file are the smallest portion of the fleet to which technology may be applied as part of a projected compliance pathway. For the analysis presented in this final rule, the agencies, when possible, attempted to include vehicle trim level information in discrete rows. A manufacturer, for example GM, may produce one or more vehicle makes (or brands), for example Chevrolet, Buick and others. Each vehicle make may offer one or more vehicle models, for example Malibu, Traverse and others. And each vehicle model may be available in one or more trim levels (or standard option levels), for example “RS,” “Premier” and others, which have different levels of standard options, and in some cases, different engines and transmissions.

Manufacturer compliance submissions, discussed above, were used as a starting point to define working rows in the market data file; however, often the rows needed to be further disaggregated to correctly characterize vehicle information covered in the scope of the analysis, and analysis fleet. Manufacturers often grouped vehicles with multiple trim levels together because they often included the same fuel-saving technologies and may be aggregated to simplify reporting. However, the manufacturer suggested retail prices of different trim levels are certainly

different, and other features relevant to the analysis are occasionally different.

As a result of further disaggregating compliance information, the number of rows in the market data file increased from 1,667 rows used in the NPRM to 2,952 rows for this final rule analysis. The agencies do not have data on sales volumes for each nameplate by trim level, and used an approach that evenly distributed volume across offered trim levels, within the defined constraints of the compliance data.³⁶⁵ Evenly distributing the volume across trim levels is a simplification, but this action should (1) highlight some difficulties that could be encountered when acquiring data for a full-vehicle consumer choice model should the agencies pursue developing one in the future (discussed further, below), and (2) lower the average sales volume per row in the market data file, thereby allowing the application of very advanced electrification technologies in smaller lumps. The latter effect is responsive to comments (discussed below) that suggested electrification technologies could be more cost-effectively deployed in lower volumes, and that the CAFE model artificially constrains cost effective technologies that may be deployed, resulting in higher costs and large over-compliance.

(1) Assigning Vehicle Technology Classes

While each vehicle in the analysis fleet has its list of observed technologies and equipment, the ways in which manufacturers apply technologies and equipment do not always coincide

³⁶⁵ The sum of volumes by nameplate configuration, for fuel economy value, and for footprint value remains the same.

perfectly with how the analysis characterizes the various technologies that improve fuel economy and reduce CO₂ emissions. To improve how the observed vehicle fleet “fits into” the analysis, each vehicle model/configuration is “mapped” to the full-vehicle simulation modeling by Argonne National Laboratory that is used to estimate the effectiveness of the fuel economy-improving/CO₂ emissions-reducing technologies considered. Argonne produces full-vehicle simulation modeling for many combinations of technologies, on many types of vehicles, but it did not simulate literally every single manufacturer’s vehicle model/configuration in the analysis fleet because it would be impractical to assemble the requisite detailed information—much of which would likely only be provided on a confidential basis—specific to each vehicle model/configuration and because the scale of the simulation effort would correspondingly increase by at least two orders of magnitude. Instead, Argonne simulated 10 different vehicle types corresponding to the “technology classes” generally used in CAFE analysis over the past several rulemakings (*e.g.*, small car, small performance car, pickup truck, etc.). Each of those 10 different vehicle types was assigned a set of “baseline characteristics” to which Argonne added combinations of fuel-saving technologies and then ran simulations to determine the fuel economy achieved when applying each combination of technologies to that vehicle type given its baseline characteristics.

BILLING CODE 4910-59-P

**Table VI-7 – Summary of Baseline Technology Class Attributes, in Argonne National
Laboratory Simulations**

| | SmallCar | SmallCarPerf | MedCar | MedCarPerf | SmallSUV | SmallSUVPerf | MedSUV | MedSUVPerf | Pickup | PickupHT |
|---|-----------------|---------------------|---------------|-------------------|-----------------|---------------------|---------------|-------------------|---------------|-----------------|
| Baseline Curb Weight (lbs.) at MRO | 3100 | 3300 | 3800 | 3800 | 3600 | 4100 | 4100 | 4600 | 4500 | 5400 |

| Percent of MY 2017 Volume Mapped to Technology Class | 13.3% | 12.7% | 4.1% | 8.3% | 19.4% | 7.1% | 3.2% | 19.6% | 3.5% | 8.6% |

BILLING CODE 4910-59-C

In the analysis fleet, inputs assign each specific vehicle model/configuration to a technology class, and once there, map to the simulation within that technology class most closely matching the combination of observed technologies and equipment on that vehicle. This mapping to a specific simulation result most closely representing a given vehicle model/configuration's initial technology "state" enables the CAFE model to estimate the same vehicle model/configuration's fuel economy after application of some other combination of technologies, leading to an alternative technology state.

(2) Assigning Vehicle Technology Content

As explained above, the analysis fleet is defined not only by the vehicles it

contains, but also by the technologies on those vehicles. Each vehicle in the analysis fleet has an associated list of observed technologies and equipment that can improve fuel economy and reduce CO₂ emissions.³⁶⁶ With a portfolio of descriptive technologies arranged by manufacturer and model, the analysis fleet can be summarized and project how vehicles in that fleet may increase fuel economy over time via the application of additional technology.

In many cases, vehicle technology is clearly observable from the 2017 compliance data (e.g., compliance data indicates clearly which vehicles have turbochargers and which have continuously variable transmissions), but in some cases technology levels are less observable. For the latter, like levels of mass reduction, the analysis

categorized levels of technology already used in a given vehicle. Similarly, engineering judgment was used to determine if higher mass reduction levels may be used practicably and safely for a given vehicle.

Either in mid-year compliance data for MY 2016, final compliance data for MY 2017, or separately and at the agencies' invitation prior to the NPRM or in comments in responses to the NPRM, most manufacturers provided guidance on the technology already present in each of their vehicle model/configurations. This information was not as complete for all manufacturers' products as needed for the analysis, so, in some cases, information was supplemented with publicly available data, typically from manufacturer media sites. In limited cases, manufacturers did not supply information, and

³⁶⁶ These technologies are generally grouped into the following categories: Vehicle technologies include mass reduction, aerodynamic drag reduction, low rolling resistance tires, and others. Engine technologies include engine attributes describing fuel type, engine aspiration, valvetrain configuration, compression ratio, number of cylinders, size of displacement, and others. Transmission technologies include different transmission arrangements like manual, 6-speed automatic, 10-speed automatic, continuously variable transmission, and dual-clutch transmissions. Hybrid and electric powertrains may complement traditional engine and transmission designs or replace them entirely.

³⁶⁷ NHTSA-2018-0067-11741.

information from commercial and publicly available sources was used.

The agencies continued to evaluate emerging technologies in the analysis. In response to comments,³⁶⁷ and given recent product launches for MY 2020, and some very recently announced future product offerings, the agencies elevated some technologies that were discussed in the NPRM to the compliance simulation. As a result,

several additional engine technologies, expanded levels of mass reduction technology, and some additional combinations of engines with plug-in hybrid, or strong hybrid technology are available in the compliance pathways for the final rule analysis.

In addition, some redundant technologies, or technologies that were inadvertently represented on the technology tree as being available to be applied twice, have been consolidated.

For instance, previous basic versions of engine friction reduction were layered on top of basic engine maps, but the efficiency in many modern engine maps already include the benefits of that engine friction reduction technology. The following Table VI–8 lists the technologies considered in the final rule analysis, with the data sources used to map those technologies to vehicles in the analysis fleet.

BILLING CODE 4910-59-C

Industry commenters generally stated the MY 2016 baseline technology content presented in the NPRM as an improvement over previous analyses because it more accurately accounted for technology already used in the

fleet.^{368 369} In contrast, some commenters expressed preference for EPA's baseline technology assignment

³⁶⁸ NHTSA-2018-0067-12073, Alliance of Automobile Manufacturers.

³⁶⁹ NHTSA-2018-0067-12150, Toyota North America.

assumptions presented in the Draft TAR for mass reduction, tire rolling resistance, and aerodynamic drag because those assumptions projected very few technology improvements were present in the baseline fleet. In assessing the comments, the agencies found that

using the EPA Draft TAR approach would lead to projected compliance pathways with overestimated fuel economy improvements and underestimated costs.³⁷⁰

Many of those assumptions were neither scientifically meritorious, nor isolated examples. For instance, for the EPA Draft TAR and Proposed Determination analyses, the BMW i3, a vehicle with full carbon fiber bodysides and downsized, mass-reduced wheels and tires (some of the most advanced mass reducing technologies commercialized in the automotive industry), was assumed to have 1.0 percent mass reduction (a very minor level of mass reduction). Similarly, previous analyses assigned the Chevrolet Corvette, a performance vehicle that has long been a platform for commercializing advanced weight saving technologies,³⁷¹ with zero mass reduction. For aerodynamic drag, previous EPA analysis assumed that pickup trucks could achieve the aerodynamic drag profile typical of a sedan, with little regard for form drag constraints or frontal area (and headroom, or ground clearance) considerations. These assumptions commonly led to projections of a 20 percent improvement in mass, aerodynamic drag, and tire rolling resistance, even when a large portion of those improvements had either already been implemented, or were not technologically feasible. On the other hand, in the Draft TAR, NHTSA presented methodologies to evaluate content for mass reduction technology, aerodynamic drag improvements, and rolling resistance technologies that better accounted for the actual level of technologies in the analysis fleet. Throughout the rulemaking process, the agencies reconciled these differences, jointly presented improved approaches in the NPRM similar to what NHTSA presented in the Draft TAR, and again used those reconciled approaches in today's analysis.³⁷²

Many commenters correctly observed that the analysis fleet in the NPRM recognized more technology content in the baseline than in the Draft TAR (with higher penetration rates of tire rolling

resistance and aerodynamic drag improvements, for instance), but also that the fuel economy values of the fleet had not improved all that much from the previous year. Some commenters concluded that the NPRM baseline technology assignment process was arbitrary and overstated the technology content already present in the baseline fleet.³⁷³ The agencies agree that there was a large increase in the amount of road load technology credited in the baseline fleet between EPA's Draft TAR and the jointly produced NPRM, and clarify that this change was largely due to a recognition of technologies that were actually present in the fleet, but not properly accounted for in previous analyses. The change in penetration rates of road load technologies (after accounting for glider share updates, which is discussed in more detail in the mass reduction technology section) between the NPRM and today's analysis is relatively small.

Many commenters noted that the different baseline road load assumptions (and other technology modeling) materially affect compliance pathways, and projected costs.³⁷⁵ ICCT commented that the agencies should conduct sensitivity analyses assuming every vehicle in the analysis fleet is set to zero percent road load technology improvement, to demonstrate how the technology content of the analysis fleet affected the compliance scenarios.³⁷⁶

While the agencies have clearly described the methods by which initial road load technologies are assigned in Section VI.C.4 Mass Reduction, Section VI.C.5 Aerodynamics, and Section VI.C.6 Tire Rolling Resistance below, the agencies considered a sensitivity case that assumed no mass reduction, rolling resistance, or aerodynamic improvements had been made to the MY 2017 fleet (*i.e.*, setting all vehicle road levels to zero—MRO, AERO and ROLL0). While this is an unrealistic characterization of the initial fleet, the agencies conducted a sensitivity analysis to understand any affect it may have on technology penetration along other paths (*e.g.* engine and hybrid technology). Under the CAFE program, the sensitivity analysis shows a slight decrease in reliance on engine technologies (HCR engines, turbocharge engines, and engines utilizing cylinder deactivation) and hybridization (strong hybrids and plug-in hybrids) in the

baseline (relative to the central analysis). The consequence of this shift to reliance on lower-level road load technologies is a reduction in compliance cost in the baseline of about \$300 per vehicle (in MY 2026). As a result, cost savings in the preferred alternative are reduced by about \$200 per vehicle. Under the CO₂ program, the general trend in technology shift is less dramatic (though the change in BEVs is larger) than the CAFE results. The cost change is also comparable, but slightly smaller (\$200 per vehicle in the baseline) than the CAFE program results. Cost savings under the preferred alternative are further reduced by about \$100. With the lower technology costs in all cases, the consumer payback periods decreased as well. These results are consistent with the approach taken by manufacturers who have already deployed many of the low-level road load reduction opportunities to improve fuel economy.

Some commenters preferred that the agencies develop a different methodology based on reported road load coefficients (“A,” “B” and “C” coastdown coefficients) to estimate levels of aerodynamic drag improvement and rolling resistance in the baseline fleet that did not rely on CBI.³⁷⁷ The agencies considered this, but determined that using CBI to assign baseline aerodynamic drag levels and rolling resistance values was more accurate and appropriate. Estimating aerodynamic drag levels and rolling resistance levels from coastdown coefficients is not straightforward, and to do it well would require information the agencies do not have (much of which is also CBI). For instance, rotational inertias of wheel, tire, and brake packages can affect coastdown, so mass of the vehicle is not sufficient. The frontal area of the vehicles, a key component for calculating aerodynamic drag, is rarely known, and often requires manufacturer input to get an accurate value. Other important vehicle features like all-wheel-drive should also be accounted for, and the agencies would struggle to correctly identify improvements in rolling resistance, low-drag brakes, and secondary axle disconnect, because all of these technologies would present similar signature on a coast down test. All of these technologies are represented as technology pathways in today's analysis. Manufacturers acknowledged the possibility of using road load coefficients to estimate rolling resistance and aerodynamic features, but warned that the process “required

³⁷⁰ NHTSA–2018–0067–11741, ICCT.

³⁷² Because these road load technologies are no longer double counted, the projected compliance pathway in the NPRM, and in today's analysis for stringent alternatives, often requires more advanced fuel saving technologies than previously projected, including higher projected penetration rates of hybrid and electric vehicle technologies.

³⁷³ NHTSA–2018–0067–11741, ICCT.

³⁷⁷ NHTSA–2018–0067–11741, ICCT.

various assumptions and is not very accurate,” and stated that the use of CBI to assess aerodynamic and rolling resistance technologies is an “accurate and practical solution” to assign these difficult to observe technologies.³⁷⁸

(3) Assigning Engine Configurations

Engine technology costs can vary significantly by the configuration of the engine. For instance, adding variable valve lift to each cylinder on an engine would cost more for an engine with eight cylinders than an engine with four cylinders. Similarly, the cost of adding a turbocharger to an engine and downsizing the engine would be different going from a naturally aspirated V8 to a turbocharged V6 than going from a naturally aspirated V6 to a turbocharged I4. As discussed in detail in the engine technology section of this document, the cost files for the CAFE model account for instances such as these examples.

Information in the analysis fleet enables the CAFE model to reference the intended engine costs. The “Engine Technology Class (Observed)” lists the architecture of the observed engine. Notably, the analysis assumes that nearly all turbo charged engines take advantage of downsizing to optimize fuel efficiency, minimize the cost of turbo charging, and to maintain performance (to the extent practicable) with the naturally aspirated counterpart engine. Therefore, engines observed in the fleet that have already been downsized must reference costs for a larger basic engine, which assumes downsizing with the application of turbo technology. In these cases, the “Engine Technology Class” which is used to reference costs will be larger than the “Engine Technology Class (Observed).”

This is the same process agencies used in the NPRM, and it corrects a previous error in the Draft TAR analysis, which incorrectly underestimated turbocharged engine costs.³⁷⁹ Some commenters expressed confusion and disagreement with this correction, with some even commenting that the analysis baselessly inflated costs of turbocharging technologies between the Draft TAR and the NPRM.³⁸⁰ To be clear, this was a correction so that the costs used to calculate turbocharged engine costs accurately reflected the total costs for a turbocharged engine.

(4) Characterizing Shared Vehicle Platforms, Engines, and Transmissions

Another aspect of characterizing vehicle model/configurations in the analysis fleet is based on whether they share a “platform” with other vehicle model/configurations. A “platform” refers to engineered underpinnings shared on several differentiated products. Manufacturers share and standardize components, systems, tooling, and assembly processes within their products (and occasionally with the products of another manufacturer) to manage complexity and costs for development, manufacturing, and assembly.

The concept of platform sharing has evolved over time. Years ago, manufacturers rebadged vehicles and offered luxury options only on premium nameplates (and manufacturers shared some vehicle platforms in limited cases). Today, manufacturers share parts across highly differentiated vehicles with different body styles, sizes, and capabilities that may share the same platform. For instance, the Honda Civic and Honda CR-V share many parts and are built on the same platform. Engineers design chassis platforms with the ability to vary wheelbase, ride height, and even driveline configuration. Assembly lines can produce hatchbacks and sedans to cost-effectively utilize manufacturing capacity and respond to shifts in market demand. Engines made on the same line may power small cars or mid-size sport utility vehicles. In addition, although the agencies’ analysis, like past CAFE analyses, considers vehicles produced for sale in the U.S., the agency notes these platforms are not constrained to vehicle models built for sale in the U.S.; many manufacturers have developed, and use, global platforms, and the total number of platforms is decreasing across the industry. Several automakers (for example, General Motors and Ford) either plan to, or already have, reduced their number of platforms to less than 10 and account for the overwhelming majority of their production volumes on that small number of platforms.

Vehicle model/configurations derived from the same platform are so identified in the analysis fleet. Many manufacturers’ use of vehicle platforms is well documented in the public record and widely recognized among the vehicle engineering community. Engineering knowledge, information from trade publications, and feedback from manufacturers and suppliers was also used to assign vehicle platforms in the analysis fleet.

When the CAFE model is deciding where and how to add technology to vehicles, if one vehicle on the platform receives new technology, other vehicles on the platform also receive the technology as part of their next major redesign or refresh.³⁸¹ Similar to vehicle platforms, manufacturers create engines that share parts. For instance, manufacturers may use different piston strokes on a common engine block, or bore out common engine block castings with different diameters to create engines with an array of displacements. Head assemblies for different displacement engines may share many components and manufacturing processes across the engine family. Manufacturers may finish crankshafts with the same tools to similar tolerances. Engines on the same architecture may share pistons, connecting rods, and the same engine architecture may include both six and eight cylinder engines. One engine family may appear on many vehicles on a platform, and changes to that engine may or may not carry through to all the vehicles. Some engines are shared across a range of different vehicle platforms. Vehicle model/configurations in the analysis fleet that share engines belonging to the same platform are also identified as such.

It is important to note that manufacturers define common engines differently. Some manufacturers consider engines as “common” if the engines shared an architecture, components, or manufacturing processes. Other manufacturers take a narrower definition, and only assume “common” engines if the parts in the engine assembly are the same. In some cases, manufacturers designate each engine in each application as a unique powertrain. For example, a manufacturer may have listed two engines separately for a pair that share designs for the engine block, the crank shaft, and the head because the accessory drive components, oil pans, and engine calibrations differ between the two. In practice, many engines share parts, tooling, and assembly resources, and manufacturers often coordinate design updates between two similar engines. Engine families, designated in the analysis using “engine codes,” for each manufacturer were tabulated and assigned based on data-driven criteria. If engines shared a common cylinder count and configuration, displacement, valvetrain, and fuel type, those engines

³⁷⁸ NHTSA–2018–0067–12073, Alliance of Automobile Manufacturers.

³⁷⁹ For instance, the Draft TAR engine costs would map an observed V6 Turbo engine to I4 Turbo engine costs, by referencing a 4C1B engine cost.

³⁸⁰ NHTSA–2018–0067–11741, ICCT.

³⁸¹ The CAFE model assigns mass reduction technology at a platform level, but many other technologies may be assigned and shared at a vehicle nameplate or vehicle model level.

may have been considered together. In addition, if the compression ratio, horsepower, and displacement of engines were only slightly different, those engines were considered the same for the purposes of redesign and sharing.

Vehicles in the analysis fleet with the same engine family will, therefore, adopt engine technology in a coordinated fashion. Specifically, if such vehicles have different design schedules (*i.e.*, refresh and redesign schedules), and a subset of vehicles using a given engine add engine technologies during of a redesign or refresh that occurs in an early model year (*e.g.*, 2018), other vehicles using the same engine “inherit” these technologies at the soonest ensuing refresh or redesign. This is consistent with a view that, over time, most manufacturers are likely to find it more practicable to shift production to a new version of an engine than to continue production of both the new engine and a “legacy” engine indefinitely. By grouping engines together, the CAFE model controls future engine families to ensure reasonable powertrain complexity. This means, however, that for manufacturers that submitted highly atomized engine and transmission portfolios, there is a practical cap on powertrain complexity and the ability of the manufacturer to optimize the displacement of (*i.e.*, “right size”) engines perfectly for each vehicle configuration. This concept is discussed further in Section VI.B.4.a), below.

Like with engines, manufacturers often use transmissions that are the same or similar on multiple vehicles. Manufacturers may produce transmissions that have nominally different machining to castings, or manufacturers may produce transmissions that are internally identical, except for the final gear ratio. In some cases, manufacturers subcontract with suppliers that deliver whole transmissions. In other cases, manufacturers form joint ventures to develop shared transmissions, and these transmission platforms may be offered in many vehicles across manufacturers. Manufacturers use supplier and joint-venture transmissions to a greater extent than they do with engines. To reflect this reality, shared transmissions were considered for manufacturers as appropriate. Transmission configurations are referred to in the analysis as “transmission codes.” Like the inheritance approach outlined for engines, if one vehicle application of a shared transmission family upgraded the transmission, other vehicle applications also upgraded the

transmission at the next refresh or redesign year. To define common transmissions, the agencies considered transmission type (manual, automatic, dual-clutch, continuously variable), number of gears, and vehicle architecture (front-wheel-drive, rear-wheel-drive, all-wheel-drive based on a front-wheel drive platform, or all-wheel-drive based on a rear-wheel-drive platform). If vehicles shared these attributes, these transmissions were grouped for the analysis. Vehicles in the analysis fleet with the same transmission configuration will adopt transmission technology together, as described above.

Having all vehicles that share a platform (or engines that are part of a family) adopt fuel economy-improving/CO₂ emissions-reducing technologies together, subject to refresh/redesign constraints, reflects the real-world considerations described above, but also overlooks some decisions manufacturers might make in the real world in response to market pull. Accordingly, even though the analysis fleet is incredibly complex, it is also oversimplified in some respects compared to the real world. For example, the CAFE model does not currently attempt to simulate the potential for a manufacturer to shift the application of technologies to improve performance rather than fuel economy. Therefore, the model’s representation of the “inheritance” of technology can lead to estimates a manufacturer might eventually exceed fuel economy standards as technology continues to propagate across shared platforms and engines. While the agencies have previously seen examples of extended periods during which some manufacturers exceeded one or both CAFE and/or CO₂ standards, in plenty of other examples, manufacturers chose to introduce (or even reintroduce) technological complexity into their vehicle lineups in response to buyer preferences. Going forward, and recognizing the recent trend for consolidating platforms, it seems likely manufacturers will be more likely to choose efficiency over complexity in this regard; therefore, the potential should be lower that today’s analysis turns out to be oversimplified compared to the real world.

Manufacturers described shared engines, transmissions, and vehicle platforms as “standard business practice” and they were encouraged that the NHTSA analysis in the Draft TAR, and the jointly issued NPRM placed realistic limits on the number of unique engines and transmissions in a

powertrain portfolio.³⁸² In previous rulemakings, stakeholders pointed out that shared parts and portfolio complexity should be considered (but were not), and that the proliferation of unique technology combinations resulting from unconstrained compliance pathways would jeopardize economies of scale in the real world.³⁸³

HD Systems acknowledged that previous rulemakings did not appropriately consider part sharing, but contended that in today’s global marketplace, manufacturers have flexibility to compete in new ways that break old part sharing rules.³⁸⁴ The agencies acknowledge that some transmissions are now sourced through suppliers, and that economies of scale could, in the future be achieved at an industry level instead of a manufacturer level; however, even when manufacturers outsource a transmission, recent history suggests they apply that transmission to multiple vehicles to control assembly plant and service parts complexity, as they would if they were making the transmission themselves. Similarly, even for global platforms, or global powertrains, there is little evidence that manufacturers fragment powertrain line-ups for a vehicle, or a set of vehicles that have typically used the same engine. The agencies will continue to consider how to capture more accurately the ways vehicles share engines, transmissions, and platforms in future rulemakings, but the part-sharing and modeling approach presented in the NPRM and this final rule represents a marked improvement over previous analysis.

(5) Characterizing Production Design Cycles

Another aspect of characterizing vehicles in the analysis fleet is based on when they can next be refreshed or redesigned. Redesign schedules play an important role in determining when new technologies may be applied. Many technologies that improve fuel economy and reduce CO₂ emissions may be difficult to incorporate without a major product redesign. Therefore, each vehicle model in the analysis fleet has an associated redesign schedule, and the CAFE model uses that schedule to implement significant advances in some technologies (like major mass reduction) to redesign years, while allowing manufacturers to include minor advances (such as improved tire rolling

³⁸² NHTSA–2018–0067–12150, Toyota North America.

³⁸³ Alliance of Automobile Manufacturers, EPA–HQ–OAR–0827 and NHTSA–2016–0068.

³⁸⁴ NHTSA–2018–0067–11985, HD Systems.

resistance) during a vehicle “refresh,” or a smaller update made to a vehicle, which can happen between redesigns. In addition to refresh and redesign schedules associated with vehicle model/configurations, vehicles that share a platform subsequently have platform-wide refresh and redesign schedules for mass reduction technologies.

To develop the refresh/redesign cycles used for the NPRM vehicles in the analysis fleet, information from commercially available sources was used to project redesign cycles through MY 2022, as was done for NHTSA’s analysis for the 2016 Draft TAR.³⁸⁵ Commercially available sources’ estimates through MY 2022 are generally supported by detailed consideration of public announcements plus related intelligence from suppliers and other sources, and recognize that uncertainty increases considerably as the forecasting horizon is extended. For MYs 2023–2035, in recognition of that uncertainty, redesign schedules were extended considering past pacing for each product, estimated schedules

through MY 2022, and schedules for other products in the same technology classes. As mentioned above, potentially confidential forward-looking information was not requested from manufacturers; nevertheless, all manufacturers had an opportunity to review the estimates of product-specific redesign schedules. A few manufacturers provided related forecasts and, for the most part, that information corroborated the estimates.

Some commenters suggested supplanting these estimated redesign schedules with estimates applying faster cycles (e.g., four to five years), and this approach was considered for the analysis. Some manufacturers tend to operate with faster redesign cycles and may continue to do so, and manufacturers tend to redesign some products more frequently than others. However, especially considering that information presented by manufacturers largely supports estimates discussed above, applying a “one size fits all” acceleration of redesign cycles would not improve the analysis; instead, assuming a fixed, shortened redesign

schedule across the industry would likely reduce consistency with the real world, especially for light trucks, which are redesigned, on average, no less than every six years (see Table VI–9, below). Moreover, if some manufacturers accelerate redesigns in response to new standards, doing so would likely involve costs (greater levels of stranded capital, reduced opportunity to benefit from “learning”-related cost reductions) greater than reflected in other inputs to the analysis.

As discussed in the NPRM, manufacturers use diverse strategies with respect to when, and how often they update vehicle designs. While most vehicles have been redesigned sometime in the last five years, many vehicles have not. In particular, vehicles with lower annual sales volumes tend to be redesigned less frequently, perhaps giving manufacturers more time to recoup the investment needed to bring the product to market. In some cases, manufacturers continue to produce and sell vehicles designed more than a decade ago.

BILLING CODE 4910–59–P

Table VI-9 – Sales Distribution by Age of Vehicle Engineering Design

| Most Recent Engineering Redesign Model Year of the Observed MY 2017 Vehicle | % of MY 2017 Fleet (Unit Sales) by Engineering Design Age | Portion of the Analysis Fleet Observations in MY 2017 Fleet by Engineering Design Age | Age of Vehicle Engineering Design | Portion of total New Vehicle Sales with Engineering Designs As New or Newer than “Age of Vehicle Engineering Design” |
|---|---|---|-----------------------------------|--|

| 2017 | 13.0% | 9.2% | 0 | 13.0% |

³⁸⁵ In some cases, data from commercially available sources was found to be incomplete or inconsistent with other available information. For instance, commercially available sources identified some newly imported vehicles as new platforms, but the international platform was midway through

the product lifecycle. While new to the U.S. market, treating these vehicles as new entrants would have resulted in artificially short redesign cycles if carried forward, in some cases. Similarly, commercially available sources labeled some product refreshes as redesigns, and vice versa. In

these limited cases, the data was revised to be consistent with other available information or typical redesign and refresh schedules for CAFE modeling. In these limited cases, the forecast time between redesigns and refreshes was updated to match the observed past product timing.

Each manufacturer may use different strategies throughout their product portfolio, and a component of each strategy may include the timing of refresh and redesign cycles. Table VI-10

summarizes the average time between redesigns, by manufacturer, by vehicle technology class. Dashes mean the manufacturer has no volume in that vehicle technology class in the MY 2017

analysis fleet. Across the industry, manufacturers average 6.6 years between product redesigns.

Table VI-10 – Summary of Sales Weighted Average Time between Engineering Redesigns, by Manufacturer, by Vehicle Technology Class

Trends on redesign schedules identified in the NPRM remain in place for today's analysis. Pick-up trucks have much longer redesign schedules than small cars. Some manufacturers redesign vehicles often, while other manufacturers redesign vehicles less often. Even if two manufacturers have similar redesign cadence, the model

years in which the redesigns occur may still be different and dependent on where each of the manufacturer's products are in their life cycle.

Table VI-11 summarizes the average age of manufacturers' offering by vehicle technology class. A value of "0.0" means that every vehicle for a manufacturer in the vehicle technology

class, represented by the MY 2017 analysis fleet was new in MY 2017. Across the industry manufacturers redesigned MY 2017 vehicles an average of 3.5 years earlier, meaning the average MY 2017 vehicle was last redesigned in approximately MY 2013, also on average near a midpoint in their product lifecycle.

Table VI-11 – Summary of Sales Weighted Average Age of Engineering Design in MY 2017 by
Manufacturer, by Vehicle Technology Class

BILLING CODE 4910-59-C

Some commenters cited examples of vehicles in the NPRM analysis fleet where the redesign years were off by a year here or there in the 2017–2022 timeframe relative to the most recent public announcements, or that the extended forecasts were too rigid.³⁸⁶ The CAFE model structurally requires an input for the redesign years, and the agencies worked to make these generally representative without disclosing precise CBI product plans. Many of the redesign schedules were carried over from the NPRM, with a few minor updates.

Some commenters contended that the agencies should not look at the historical data to project the timing between redesigns (“business as usual”), but should instead adopt a “policy case” with an accelerated pace of redesigns and refreshes.³⁸⁷ Some

commenters suggested that the agencies use a standard 5 or 6 year redesign schedule for all manufacturers and all products as a way to lower projected costs.³⁸⁸ Other stakeholders commented that the entire industry should be modeled with the ability to redesign everything at one time in the near term because that would not presuppose precisely how manufacturers may adjust their fleet.³⁸⁹

If the agencies were to implement any such approaches, the agencies would need to more precisely account for tooling costs, research and development costs, and product lifecycle marketing costs, or risk missing “hidden costs” of a shortened cadence. To account properly for these, the CAFE model would require major changes, and would require specific inputs that are currently covered generically under the

retail price equivalency (RPE) factor.³⁹⁰ The agencies considered these comments, and decided the process for refresh and redesign outlined in the NPRM was a reasonable and realistic approach to characterize product changes. The agencies conducted sensitivity analysis with compressed redesign and refresh schedules, though these ignore the resulting compressed amortization schedules, missing important costs that are incorporated in the current RPE assumptions.

Some commenters claimed that the agency had extraordinarily extended redesign schedule of 17.7 years for FCA between 2021–2025, and an average redesign time of 25.8 years for Ford between 2022–2025.³⁹¹ The agencies found these claims inaccurate and without basis. Table VI-10, “Summary of Sales Weighted Average Time

³⁸⁹ NHTSA–2018–0067–12039, Union of Concerned Scientists.

³⁹⁰ Shorter redesign schedules are likely to put upward pressure on RPE, as the manufacturers would have less time to recoup investments.

³⁹¹ NHTSA–2018–0067–11723, Natural Resources Defense Council.

between Engineering Redesigns, by Manufacturer, by Vehicle Technology Class” summarizes the data used in today’s analysis (which is very similar to the information used in the NPRM, with some minor adjustments and updates to the fleet), and the detailed information vehicle-by-vehicle is reported in the “market data” file. The agencies recognize that the natural sequence of redesigns for some manufacturers and some products is not ideal to meet stringent alternatives, which is part of the consideration for economic practicability and technological feasibility. Manufacturers commented supportively on the idea of vehicle specific redesign schedules, and the redesign cadence used in the NPRM, as these contribute to realistic assessments of new technology penetration within the fleet, and acknowledge the heterogeneity in the product development approaches and business practices for each manufacturer.³⁹² One commenter recognized that redesign and refresh schedules represented a vast improvement over phase-in caps to model the adoption of mature technologies.³⁹³

Other commenters argued that the structural construct of technologies only being available at redesign or at refresh (via inheritance) did not reflect real world actions and was not supported by any actual data.³⁹⁴ Other commenters acknowledged the inheritance of engine and transmission technologies at refresh as an important, positive feature of the CAFE model.³⁹⁵ HD Systems argued that an engine or transmission package available in other markets on a global platform could be imported to the U.S.

market during refresh, and did not require a “leader” at redesign in the U.S. market to seed adoption. HDS cited a few examples where manufacturers have introduced strong hybrid powertrains on an existing vehicle a year or two after the product launch, not associated with any particular vehicle redesign or refresh.

The agencies carefully considered these comments, and observed that some relatively low volume hybrid options may appear after launch, or that some transmissions were quickly replaced shortly after a major redesign. In many of these cases, launch delays, warranty claims, or other external factors contributed to, at least in part, an atypically timed introduction of fuel saving technology to the fleet.³⁹⁶ At this point, this does not appear to be a mainstream, or preferred industry practice. However, the agencies will continue to evaluate this. For future rulemaking, the agencies may consider engine refresh and redesign cycles for engines and transmissions. These may be separate from vehicle redesign and refresh schedules because the powertrain product lifecycles may be longer on average than the typical vehicle redesign schedules. This approach, if researched and implemented in future analysis, could provide some opportunity for manufacturers to introduce new powertrain technologies independent of the vehicle redesign schedules, in addition to inheriting advanced powertrain technology as refresh as already modeled in the NPRM and today’s analysis.

For today’s analysis, the agencies, with a few exceptions based on updated publicly available information, carried over redesign cadences for each vehicle nameplate as presented in the NPRM.

The agencies do not claim that the projected redesign years will perfectly match what industry does—notably because refresh and redesign information is CBI and the agencies have applied more generalized schedules to protect the CBI. Also, what any individual manufacturer may choose to do today could be completely different than what it chooses to do tomorrow due to changing business circumstances and plans—but the agencies have worked to ensure the timing of redesigns will be roughly correct (especially in the near term), and that the time between redesigns will continue forward for each manufacturer as it has based on recent history. The agencies have also increased the frequency of refreshes in response to comments about the proliferation of some engine and transmission families through manufacturers’ product portfolios.

Also for today’s analysis, the agencies now explicitly model CAFE compliance pathways out through 2050. For the model to work as intended, the agencies must project refresh and redesign schedules out through 2050. The agencies recognize that the accuracy of predictions about the distant future, particularly about refresh and redesign cycles through the 2030–2050 timeframe, are likely to be poor. If historical evolution of the industry continues, many of the nameplates carried forward in the fleet are likely to be out of production, and new nameplates not considered in the analysis are sure to emerge. Still, carrying forward the MY 2017 fleet with the current refresh and redesign cadences is consistent with the current analysis, and imposing an alternative schedule on the fleet, or making up new nameplates and retiring older nameplates without a clear basis, would lack proper foundation.

(6) Defining Technology Adoption Features

In some circumstances, the agencies may reference full vehicle simulation effectiveness data for technology combinations that are not able to be, or are not likely to be applied to all vehicles. In some cases, a specific technology as modeled only exists on paper, and questions remain about the technological feasibility of the efficiency characterization.³⁹⁷ Or, a technology may perform admirably on the test cycle, but fail to meet all functional, or performance requirements for certain vehicles.³⁹⁸ In other cases, the intellectual property landscape may

³⁹⁷ High levels of aerodynamic drag reduction for some body styles, or EPA's previous, speculative characterization of "HCR2" engines, for example.

³⁹⁸ Examples of applications that are unsuitable for certain technologies include low end torque requirements for HCR engines on high load vehicles, or towing and trailering applications, continuously variable transmissions in high torque applications, and low rolling resistance tires on vehicles built for precision cornering and high lateral forces, or instant acceleration from a stand still.

make commercialization of one technology risky for a manufacturer without the consent of the intellectual property owner.³⁹⁹ In such cases, the agencies may not allow a technology to be applied to a certain vehicle. The agencies designate this in the "market data" file with a "SKIP" for the technology and vehicle. The logic is explained technology by technology in this document, as the logic was explained in the PRIA for this rule.

Some commenters argued that the restrictions of technologies on a case-by-case basis required case-by-case explanation (and not objective specification defined cut-offs), and that the use of CBI for performance considerations was unacceptable unless fully disclosed.⁴⁰⁰ As discussed above, the agencies are not able to disclose CBI. Stakeholders have had plenty of opportunities to comment on the applicability of technologies, including

³⁹⁹ Variable compression ratio engines, for example.

⁴⁰⁰ NHTSA-2018-0067-11741, ICCT.

the few that have used SKIP logic restrictions for a portion of the fleet.

Other commenters suggested an optimistic and wholly unfounded approach to manufacturer innovation, arguing that costs would continue to come down (beyond what is currently modeled with cost learning), and the list of fuel-saving technologies would continually regenerate itself (even if the technological mechanism for fuel saving technologies was not yet identified).⁴⁰¹ Therefore, the argument goes that people will figure out new ways to improve fuel saving technologies to increase their applicability, and the current technology characterization should be enabled for selection with no restriction—not because the commenter knows how the technology will be adapted, but that the commenter believes the technology could, eventually, within the timeline of the rulemaking, be adapted, brought to market, and be accepted by consumers. While the agencies recognize the improvements that many manufacturers

⁴⁰¹ NHTSA-2018-0067-12122-33, American Council for an Energy-Efficient Economy.

have achieved in fuel saving technologies, some of which were difficult to foresee, the agencies have an obligation under the law to be judicious and specific about technological feasibility, and to avoid speculative conclusions about technologies to justify the rulemaking.

c) Other Analysis Fleet Data

(1) Safety Classes

The agencies referenced the mass-size-safety analysis to project the effects changes in weight may have on crash fatalities. That analysis, discussed in more detail in Section VI.D.2, considers how weight changes may affect safety for cars, crossover utility vehicles and sport utility vehicles, and pick-up trucks. To consider these effects, the agencies mapped each vehicle in the analysis fleet to the appropriate "Safety Class."

(2) Labor Utilization

The analysis fleet summarizes components of direct labor for each vehicle considered in the analysis. The labor is split into three components: (1) Dealership hours worked on sales functions per vehicle, (2) direct assembly labor for final assembly, engine, and transmission, and (3) percent U.S. content.

In the MY 2016 fleet for the NPRM, the agencies catalogued production locations and plant employment, reviewed annual reports from the North American Dealership Association to estimate dealership employment (27.8 hours per vehicle sold), and estimated the industry average labor hours for final assembly of vehicles (30 hours per vehicle produced), engine machining and assembly (4 hours per engine produced), and transmission production (5 hours per transmission produced).

Today's analysis fleet carries over the estimated labor coefficients for sales and production, but references the most recent Part 583 American Automobile Labeling Act Report for percent U.S. content and for the location of vehicle assembly, engine assembly, and transmission assembly.⁴⁰²

(3) Production Volumes for Sales Analysis

A final important aspect of projecting what vehicles will exist in future model years and potential manufacturer responses to standards is estimating how future sales might change in response to different potential standards. If potential future standards

appear likely to have major effects in terms of shifting production from cars to trucks (or vice versa), or in terms of shifting sales between manufacturers or groups of manufacturers, that is important for the agencies to consider. For previous analyses, the CAFE model used a static forecast contained in the analysis fleet input file, which specified changes in production volumes over time for each vehicle model/configuration. This approach yielded results that, in terms of production volumes, did not change between scenarios or with changes in important model inputs. For example, very stringent standards with very high technology costs would result in the same estimated production volumes as less stringent standards with very low technology costs. For this analysis, as in the proposal, the CAFE model begins with the first-year production volumes (*i.e.*, MY 2017 for today's analysis) and adjusts ensuing sales mix year by year (between cars and trucks, and between manufacturers) endogenously as part of the analysis, rather than using external forecasts of future car/truck split and future manufacturer sales volumes. This leads the model to produce different estimates of future production volumes under different standards and in response to different inputs, reflecting the expectation that regulatory standards and other external factors will, in fact, impact the market.

(4) Comments on Other Analysis Fleet Data

Some commenters suggest that the CAFE model should run as a full consumer choice model (and this idea is discussed in more detail in Section VI.D.1). While this sounds like a reasonable request on the surface, such an approach would place enormous new demands on the data characterized in the fleet (and preceding fleets, which may be needed to calibrate a model properly). For instance, some model concepts may depend on a bevy of product features, such as interior cargo room, artistic appeal of the design, and perceived quality of the vehicle. But product features alone may not be sufficient. Additional information about dealership channels, product awareness and advertising effectiveness, and financing terms also may be required. Such information could dramatically increase the scope of work needed to characterize the analysis fleet for future rulemakings. As described in Section VI.D.1.b)(2)(d) Using Vehicle Choice Models in Rulemaking Analysis. Accordingly, the agencies decided not to develop such a model for this rulemaking.

2. Treatment of Compliance Credit Provisions

Today's final rule involves a variety of provisions regarding "credits" and other compliance flexibilities. Some recently introduced regulatory provisions allow a manufacturer to earn "credits" that will be counted toward a vehicle's rated CO₂ emissions level, or toward a fleet's rated average CO₂ or CAFE level, without reference to required levels for these average levels of performance. Such flexibilities effectively modify emissions and fuel economy test procedures, or methods for calculating fleets' CAFE and average CO₂ levels. Such provisions are discussed below in Section VI.B.2. Other provisions (for CAFE, statutory provisions) allow manufacturers to earn credits by achieving CAFE or average CO₂ levels beyond required levels; these provisions may hence more appropriately be termed "compliance credits."

EPCA has long provided that, by exceeding the CAFE standard applicable to a given fleet in a given model year, a manufacturer may earn corresponding "credits" that the same manufacturer may, within the same regulatory class, apply toward compliance in a different model year. EISA amended these provisions by providing that manufacturers may, subject to specific statutory limitations, transfer compliance credits between regulatory classes, and trade compliance credits with other manufacturers. The CAA provides EPA with broad standard-setting authority for the CO₂ program, with no specific directives regarding either CO₂ standards or CO₂ compliance credits.

EPCA also specifies that NHTSA may not consider the availability of CAFE credits (for transfer, trade, or direct application) toward compliance with new standards when establishing the standards themselves.⁴⁰³ Therefore, this analysis, like that presented in the NPRM, considers 2020 to be the last model year in which carried-forward or transferred credits can be applied for the CAFE program. Beginning in model year 2021, today's "standard setting" analysis for NHTSA's program is conducted assuming each fleet must comply with the CAFE standard separately in every model year.

The "unconstrained" perspective acknowledges that these flexibilities exist as part of the program, and, while not considered by NHTSA in setting standards, are nevertheless important to consider when attempting to estimate the real impact of any alternative. Under

⁴⁰² Part 583 American Automobile Labeling Act Report, available at <https://www.nhtsa.gov/part-583-american-automobile-labeling-act-reports>.

⁴⁰³ 49 U.S.C. 32902(h)(3).

the “unconstrained” perspective, credits may be earned, transferred, and applied to deficits in the CAFE program throughout the full range of model years in the analysis. The Final Environmental Impact Analysis (FEIS) accompanying today’s final rule, like the corresponding Draft EIS analysis, presents results of “unconstrained” modeling. Also, because the CAA provides no direction regarding consideration of any CO₂ credit provisions, today’s analysis, like the NPRM analysis, includes simulation of carried-forward and transferred CO₂ credits in all model years.

Some commenters took issue broadly with this treatment of compliance credits. Michalek and Whitefoot wrote that “we find this requirement problematic because the automakers use these flexibilities as a common means of complying with the regulation, and ignoring them will bias the cost-benefit analysis to overestimate costs.”⁴⁰⁴

Counter to the above general claim, the CAFE model *does* provide means to simulate manufacturers’ potential application of some compliance credits, and both the analysis of CO₂ standards and the NEPA analysis of CAFE standards *do* make use of this aspect of the model. As discussed above, NHTSA does not have the discretion to consider the credit program—in fact, the agency is prohibited by statute from doing so—in establishing maximum feasible standards. Further, as discussed below, the agencies also continue to find it appropriate for the analysis largely to refrain from simulating two of the mechanisms allowing the use of compliance credits.

The model’s approach to simulating compliance decisions accounts for the potential to earn and use CAFE credits as provided by EPCA/EISA. The model similarly accumulates and applies CO₂ credits when simulating compliance with EPA’s standards. Like past versions, the current CAFE model can be used to simulate credit carry-forward (a.k.a. banking) between model years and transfers between the passenger car and light truck fleets but not credit carry-back (a.k.a. borrowing) from future model years or trading between manufacturers.

Regarding the potential to carry back compliance credits, UCS commented that, although past versions of the CAFE model had “considered this flexibility in its approach to multiyear modeling,” NHTSA had, without explanation, “abruptly discontinued support of this method of compliance,” such that

“manufacturers are generally incentivized to over comply, regardless of whether carrying forward a deficit to be compensated by later overcompliance would be a more cost-effective method of compliance.”⁴⁰⁵ Citing the potential that manufacturers could make use of carried back credits in the future, UCS also stated that “NHTSA’s decision to constrain it in the model is unreasonable and arbitrary.”⁴⁰⁶ UCS effectively implies that the agencies should base standards on analysis that presumes manufacturers will take full theoretical advantage of provisions allowing credits to be borrowed.

The agencies have carefully considered these comments, and while EPA’s decisions regarding CO₂ standards can consider the potential to carry back compliance credits from later to earlier model years, and NHTSA’s “unconstrained” evaluation could also do so, past examples of failed attempts to carry back CAFE credits (e.g., a MY2014 carry back default leading to a civil penalty payment) underscore the riskiness of such “borrowing.” Recent evidence indicates manufacturers are disinclined to take such risks,⁴⁰⁷ and both agencies find it reasonable and prudent to refrain from attempting to simulate such “borrowing” in rulemaking analysis.

Unlike past versions, the NPRM and current versions of CAFE model provide a basis to specify (in model inputs) CAFE credits available from model years earlier than those being explicitly simulated. For example, with this analysis representing model years 2017–2050 explicitly, credits earned in model year 2012 are made available for use through model year 2017 (given the current five-year limit on carry-forward of credits). The banked credits are specific to both the model year and fleet in which they were earned.

In addition to the above-mentioned comments, UCS also cited as “errors” that “the model does not accurately reflect the one-time exemption from the EPA 5-year credit life for credits earned in the MY 2010–2015 timeframe” and “NHTSA assumes that there will be absolutely no credit trading between manufacturers.”

As discussed below, in the course of updating the analysis fleet from MY

2016 to MY 2017, the agencies have updated and expanded the manner in which the model accounts for credits earned prior to MY 2017, including credits earned as early as MY 2009. In order to increase the realism with which the model transitions between the early model year (MYs 2017–2020) and the later years that are the subject of this action, the agencies have accounted for the potential that some manufacturers might trade some of these pre-MY 2017 credits to other manufacturers.

However, as with the NPRM, the analysis refrains from simulating the potential that manufacturers might continue to trade credits during and beyond the model years covered by today’s action. The agencies remain concerned that any realistic simulation of such trading would require assumptions regarding which specific pairs of manufacturers might actually trade compliance credits, and the evidence to date makes it clear that the credit market is far from fully “open.” With respect to the FCA comment cited above, the agencies also remain concerned that to set standards based on an analysis that presumes the use of program flexibilities risks making the corresponding actions mandatory. Some flexibilities—credit carry-forward (banking) and transfers between fleets in particular—involve little risk, because they are internal to a manufacturer and known in advance. As discussed above, credit carry-back involves significant risk, because it amounts to borrowing against future improvements, standards, and production volume and mix—and anticipated market demand for fuel efficient vehicles often fail to materialize. Similarly, credit trading also involves significant risk, because the ability of manufacturer A to acquire credits from manufacturer B depends not just on manufacturer B actually earning the expected amount of credit, but also on manufacturer B being willing to trade with manufacturer A, and on potential interest by other manufacturers. Manufacturers’ compliance plans have already evidenced cases of compliance credit trades that were planned and subsequently aborted, reinforcing the agencies’ judgment that, like credit banking, credit trading involves too much risk to be included in an analysis that informs decisions about the stringency of future standards. Nevertheless, recognizing that some manufacturers have actually been trading credits, the agencies have, as in the NPRM, included in the sensitivity analysis a case that simulates “perfect” trading of compliance credits, focusing

⁴⁰⁴ Michalek, J. and Whitefoot, K., NHTSA–2018–0067–11903, at 10–11.

⁴⁰⁵ UCS, NHTSA–2018–0067–12039, Technical Appendix, at 44.

⁴⁰⁶ UCS, *op. cit.*, at 77.

⁴⁰⁷ Section IX, below, reviews data regarding manufacturers’ use of CAFE compliance credit mechanism during MYs 2011–2016, and shows that the use of “carry back” credits is, relative to the use of other compliance credit mechanisms, too small to discern.

on CO₂ standards to illustrate the hypothetical maximum potential impact of trading. The FRIA summarizes results of this and other cases included in the sensitivity analysis.

As discussed in the CAFE model documentation, the model's default logic attempts to maximize credit carry-forward—that is, to “hold on” to credits for as long as possible. If a manufacturer needs to cover a shortfall that occurs when insufficient opportunities exist to add technology in order to achieve compliance with a standard, the model will apply credits. Otherwise the manufacturer carries forward credits until they are about to expire, at which point it will use them before adding technology that is not considered cost-effective. The model attempts to use credits that will expire within the next three years as a means to smooth out technology application over time to avoid both compliance shortfalls and high levels of over-compliance that can result in a surplus of credits. Although it remains impossible precisely to predict manufacturer's actual earning and use of compliance credits, and this aspect of the model may benefit from future refinement as manufacturers and regulators continue to gain experience with these provisions, this approach is generally consistent with manufacturers' observed practices.

NHTSA introduced the CAFE Public Information Center to provide public access to a range of information

regarding the CAFE program,⁴⁰⁸ including manufacturers' credit balances. However, there is a data lag in the information presented on the CAFE PIC that may not capture credit actions across the industry for as much as several months. Furthermore, CAFE credits that are traded between manufacturers are adjusted to preserve the gallons saved that each credit represents.⁴⁰⁹ The adjustment occurs at the time of application rather than at the time the credits are traded. This means that a manufacturer who has acquired credits through trade, but has not yet applied them, may show a credit balance that is either considerably higher or lower than the real value of the credits when they are applied. For example, a manufacturer that buys 40 million credits from Tesla may show a credit balance in excess of 40 million. However, when those credits are applied, they may be worth only 1/10 as much—making that manufacturer's true credit balance closer to 4 million than 40 million.

For the NPRM, the agencies reviewed then-recent credit balances, estimated the potential that some manufacturers could trade credits, and developed inputs that make carried-forward credits

available in each of model years 2011–2015, after subtracting credits assumed to be traded to other manufacturers, adding credits assumed to be acquired from other manufacturers through such trades, and adjusting any traded credits (up or down) to reflect their true value for the fleet and model year into which they were traded.⁴¹⁰ For today's analysis, an additional model year's data was available in mid-2019, and the agencies updated these inputs, as summarized in Table VI–12, Table VI–13, and Table VI–14. While the CAFE model will transfer expiring credits into another fleet (*e.g.*, moving expiring credits from the domestic car credit bank into the light truck fleet), some of these credits were moved into the initial banks to improve the efficiency of application and both to reflect better the projected shortfalls of each manufacturer's regulated fleets and to represent observed behavior. For context, a manufacturer that produces one million vehicles in a given fleet, and experiences a shortfall of 2 mpg, would need 20 million credits, adjusted for fuel savings, to offset the shortfall completely.

BILLING CODE 4910–59–P

⁴⁰⁸ CAFE Public Information Center, http://www.nhtsa.gov/CAFE_PIC/CAFE_PIC_Home.htm (last visited June 22, 2018).

⁴⁰⁹ CO₂ credits for EPA's program are denominated in metric tons of CO₂ rather than gram/mile compliance credits and require no adjustment when traded between manufacturers or fleets.

⁴¹⁰ The adjustments, which are based upon the CAFE standard and model year of both the party originally earning the credits and the party applying them, were implemented assuming the credits would be applied to the model year in which they were set to expire. For example, credits traded into a domestic passenger car fleet for MY 2014 were adjusted assuming they would be applied in the domestic passenger car fleet for MY 2019.

BILLING CODE 4910-59-C

In addition to the inclusion of these existing credit banks, the CAFE model also updated its treatment of credits in the rulemaking analysis. EPCA requires that NHTSA set CAFE standards at maximum feasible levels for each model year without consideration of the program's credit mechanisms. However, as recent NHTSA CAFE/EPA tailpipe CO₂ emissions rulemakings have evaluated effects of standards over longer time periods, the early actions taken by manufacturers required more nuanced representation. Accordingly, the CAFE model now provides for a setting to establish a "last year to consider credits." This adjustment is set at the last year for which new standards are not being considered (MY 2020 in this analysis). This allows the model to replicate the practical application of existing credits toward compliance in early years but also to examine the impact of proposed standards based solely on fuel economy improvements in all years for which new standards are being considered.

Regarding the model's simulation of manufacturers' potential earning and application of compliance credits, UCS commented that the model "inexplicably lets credits expire" because "all technologies which pay for

themselves within the assumed payback period are applied to all manufacturers, regardless of credit status." UCS also claimed that "NHTSA did not accurately reflect unique attributes of EPA's credit bank," that "credits are not traded between manufacturers," and that "NHTSA does not model credit carryback for compliance."⁴¹¹ Relatedly, as discussed above, UCS attributes modeling outcomes to the "effective cost" metric used to select from among available fuel-saving technologies.⁴¹² As discussed in Section VI.B.1, the agencies expect that manufacturers are likely to improve fuel economy voluntarily insofar as doing so "pays back" economically within a short period (30 months), and the agencies note that periods of regulatory stability have, in fact, been marked by CAFE levels exceeding requirements. As discussed above, the agencies have excluded simulation of credit trading (except in MYs prior to those under consideration, aside from an idealized case presented in the sensitivity analysis) and likewise excluded simulation of potential "carryback" provisions. The agencies have excluded

⁴¹¹ UCS, NHTSA-2018-0067-12039, Technical Appendix, at 35-46.

⁴¹² UCS, NHTSA-2018-0067-12039, Technical Appendix, at 28-30.

modeling these scenarios not just because of the analytical complexities involved (and rejecting, for example, the random number generator analysis suggested by UCS), but also because the agencies agree that the actual provisions regarding trading and borrowing of compliance credits create too much risk to be used in the analysis underlying consideration of standards. However, as discussed above, the agencies have revised the "metric" used to prioritize available options to apply fuel-saving technologies. As discussed below, the agencies have revised model inputs to include the large quantity of "legacy" compliance credits EPA has made available under its CO₂ standards.

The CAFE model has also been modified to include a similar representation of existing credit banks in EPA's CO₂ program. While the life of a CO₂ credit, denominated in metric tons of CO₂, has a five-year life, matching the lifespan of CAFE credits, such credits earned in the early MY 2009-2011 years of the EPA program, may be used through MY 2021.⁴¹³ The CAFE model was not modified to allow

⁴¹³ In the 2010 rule, EPA placed limits on credits earned in MY 2009, which expired prior to this rule. However, credits generated in MYs 2010-2011 may be carried forward, or traded, and applied to deficits generated through MY 2021.

exceptions to the life-span of compliance credits, and, to reflect statutory requirements, treated them as if they may be carried forward for no more than five years, so the initial credit banks were modified to anticipate the years in which those credits might be needed. MY 2016 was simulated explicitly in the NPRM analysis to

prohibit the inclusion of banked credits in MY 2016 (which could be carried forward from MY 2016 to MY 2021), and thus underestimated the extent to which individual manufacturers, and the industry as a whole, could rely on these early credits to comply with EPA standards between MY 2016 and MY 2021. However, as indicated in the

NPRM, the final rule's model inputs updated the analysis fleet's basis to MY 2017, such that these additional banked credits *can* be included. The credit banks with which the simulations in this analysis were conducted are presented in the following Tables:

BILLING CODE 4910-59-C

While the CAFE model does not simulate the ability to trade credits between manufacturers, it does simulate the strategic accumulation and application of compliance credits, as well as the ability to transfer credits between fleets to improve the compliance position of a less efficient fleet by leveraging credits earned by a more efficient fleet. The model prefers to hold on to earned compliance credits within a given fleet, carrying them forward into the future to offset potential future deficits. This assumption is consistent with observed strategic manufacturer behavior dating back to 2009.

From 2009 to present, no manufacturer has transferred CAFE credits into a fleet to offset a deficit in the same year in which they were earned. This has occurred with credits acquired from other manufacturers via trade but not with a manufacturer's own credits. Therefore, the current representation of credit transfers between fleets—where the model prefers to transfer expiring, or soon-to-be-expiring credits rather than newly earned credits—is both appropriate and consistent with observed industry behavior.

This may not be the case for CO₂ standards, though it is difficult to be certain at this point. The CO₂ program seeded the industry with a large quantity of early compliance credits (earned in MYs 2009–2011)⁴¹⁴ prior to the existence formal CO₂ standards. Early credits from MYs 2010 and 2011, however, do not expire until 2021. Thus, for manufacturers looking to offset deficits, it is more sensible to exhaust credits that were generated during later model years (which are set to expire within the next five years), rather than relying on the initial bank of credits from MYs 2010 and 2011. The first model year for which earned credits outlive the initial bank is MY 2017, for which final manufacturer CO₂ performance data (and hence, banked credits) has not yet been released. However, considering that under the CO₂ program manufacturers simultaneously comply with passenger car and light truck fleets, to more accurately represent the CO₂ credit system the CAFE model allows (and encourages) intra-year transfers between regulated fleets for the purpose of

⁴¹⁴ In response to public comment, EPA eliminated the possible use of credits earned in MY 2009 for future model years. However, credits earned in MY 2010 and MY 2011 remain available for use.

simulating compliance with the CO₂ standards.

a) Off-Cycle and A/C Efficiency Adjustments to CAFE and Average CO₂ Levels

In addition to more rigorous accounting of CAFE and CO₂ credits, the model now also accounts for air conditioning efficiency and off-cycle adjustments. NHTSA's program considers those adjustments in a manufacturer's compliance calculation starting in MY 2017, and the NPRM version of the model used the adjustments claimed by each manufacturer in MY 2016 as the starting point for all future years. Because air conditioning efficiency and off-cycle adjustments are not credits in NHTSA's program, but rather adjustments to compliance fuel economy (much like the Flexible Fuel Vehicle adjustments due to phase out in MY 2019), they may be included under either a "standard setting" or "unconstrained" analysis perspective.

The manner in which the CAFE model treats the EPA and CAFE A/C efficiency and off-cycle credit programs is similar, but the model also accounts for A/C leakage (which is not part of NHTSA's program). When determining the compliance status of a

manufacturer's fleet (in the case of EPA's program, PC and LT are the only fleet distinctions), the CAFE model weighs future compliance actions against the presence of existing (and expiring) CO₂ credits resulting from over-compliance with earlier years' standards, A/C efficiency credits, A/C leakage credits, and off-cycle credits.

Another aspect of credit accounting, implemented in the NPRM version of the CAFE model, involved credits related to the application of off-cycle and A/C efficiency adjustments, which manufacturers earn by taking actions such as special window glazing or using reflective paints that provide fuel economy improvements in real-world operation but do not produce measurable improvements in fuel consumption on the 2-cycle test.

NHTSA's inclusion of off-cycle and A/C efficiency adjustments began in MY 2017, while EPA has collected several years' worth of submissions from manufacturers about off-cycle and A/C efficiency technology deployment. Currently, the level of deployment can vary considerably by manufacturer, with several claiming extensive Fuel

Consumption Improvement Values (FCIV) for off-cycle and A/C efficiency technologies, and others almost none. The analysis of alternatives presented here (and in the NPRM) does not attempt to project how future off-cycle and A/C efficiency technology use will evolve or speculate about the potential proliferation of FCIV proposals submitted to the agencies. Rather, this analysis uses the off-cycle credits submitted by each manufacturer for MY 2017 compliance, and, with a few exceptions, carries these forward to future years. Several of the technologies described below are associated with A/C efficiency and off-cycle FCIVs. In particular, stop-start systems, integrated starter generators, and full hybrids are assumed to generate off-cycle adjustments when applied to vehicles to improve their fuel economy. Similarly, higher levels of aerodynamic improvements are assumed to include active grille shutters on the vehicle, which also qualify for off-cycle FCIVs.

The NPRM analysis assumed that any off-cycle FCIVs that are associated with actions outside of the technologies discussed in Section VI.C (either chosen

from the pre-approved "pick list," or granted in response to individual manufacturer petitions) remained at the levels claimed by manufacturers in MY 2017. Any additional A/C efficiency and off-cycle adjustments that accrued as the result of explicit technology application calculated dynamically in each model year for each alternative. The NPRM version of the CAFE model also represented manufacturers' credits for off-cycle improvements, A/C efficiency improvements, and A/C leakage reduction in terms of values applicable across all model years.

Recognizing that application of these improvements thus far varies considerably among manufacturers, such that some manufacturers have opportunities to earn significantly more of the corresponding adjustments over time, the agencies have expanded the CAFE model's representation of these credits to provide for year-by-year specification of the amounts of each type of adjustment for each manufacturer, denominated in grams CO₂ per mile,⁴¹⁵ as summarized in the following table:

BILLING CODE 4910-59-P

⁴¹⁵ For estimating their contribution to CAFE compliance, the grams CO₂/mile values in Table VI-1711 are converted to gallons/mile and applied to a manufacturer's 2-cycle CAFE performance. When calculating compliance with EPA's CO₂ program, there is no conversion necessary (as standards are also denominated in grams/mile).

⁴¹⁶ These values are specified in the "market_ref.xlsx" input file's "Credits and Adjustments" worksheet. The file is available with the archive of model inputs and outputs posted at <https://www.nhtsa.gov/corporate-average-fuel-economy/compliance-and-effects-modeling-system>.

CAFE model to apply estimates of the corresponding costs. For today's analysis, the agencies applied estimates

developed previously by EPA, adjusting these values to 2019 dollars. The

following table summarizes inputs through model year 2030:

Table VI-18 – Estimated Costs (\$ per g/mi) for A/C and Off-Cycle Adjustments

| Model Year | A/C Efficiency | A/C Leakage | Off-Cycle |
|-------------------|-----------------------|--------------------|------------------|
| 2017 | 4.57 | 11.43 | 89.59 |
| 2018 | 4.48 | 11.20 | 87.48 |
| 2019 | 4.39 | 10.97 | 85.37 |
| 2020 | 4.30 | 10.76 | 83.79 |
| 2021 | 4.22 | 10.54 | 82.21 |
| 2022 | 4.13 | 10.33 | 81.16 |
| 2023 | 4.05 | 10.12 | 79.58 |
| 2024 | 3.97 | 9.92 | 78.52 |
| 2025 | 3.89 | 9.72 | 77.47 |
| 2026 | 3.81 | 9.53 | 76.31 |
| 2027 | 3.73 | 9.34 | 75.16 |
| 2028 | 3.66 | 9.15 | 74.04 |
| 2029 | 3.59 | 8.97 | 72.92 |
| 2030 | 3.52 | 8.79 | 71.83 |

The model currently accounts for any off-cycle adjustments associated with technologies that are included in the set of fuel-saving technologies explicitly simulated as part of this proposal (for example, start-stop systems that reduce fuel consumption during idle or active grille shutters that improve aerodynamic drag at highway speeds) and accumulates these adjustments up to the 10 g/mi cap. As a practical matter, most of the adjustments for which manufacturers are claiming off-cycle FCIV exist outside of the technology tree, so the cap is rarely reached during compliance simulation. The agencies have considered the potential to model their application explicitly. However, doing so would require data regarding which vehicle models already possess these improvements as well as the cost and expected value of applying them to other models in the future. Such data is currently too limited to support explicit modeling of these technologies and adjustments.

b) Alternative Fuel Vehicles

When establishing maximum feasible fuel economy standards, NHTSA is prohibited from considering the availability of alternatively fueled vehicles,⁴¹⁷ and credit provisions related to AFVs that significantly increase their fuel economy for CAFE compliance purposes. Under the “standard setting” perspective, these technologies (pure battery electric vehicles and fuel cell vehicles)⁴¹⁸ are not available in the compliance simulation to improve fuel economy. Under the “unconstrained” perspective, such as is documented in the DEIS and FEIS, the CAFE model considers these technologies in the same manner as other available technologies, and may apply them if they represent cost-effective compliance pathways. However, under both perspectives, the analysis continues to include dedicated AFVs that already exist in the MY 2017 fleet (and their projected future

volumes). Also, because the CAA provides no direction regarding consideration of alternative fuels, the final rule’s analysis includes simulation of the potential that some manufacturers might introduce new AFVs in response to CO₂ standards. To represent the compliance benefit from such a response fully, NHTSA modified the CAFE model to include the specific provisions related to AFVs under the CO₂ standards. In particular, the CAFE model now carries a full representation of the production multipliers related to electric vehicles, fuel cell vehicles, plug-in hybrids, and CNG vehicles, all of which vary by year through MY 2021.

EPCA also provides that CAFE levels may, subject to limitations, be adjusted upward to reflect the sale of flexible fuel vehicles (FFVs). Although these adjustments end after model year 2020, the final rule’s analysis, like the NPRM’s, includes estimated potential use through MY 2019, as summarized below:

⁴¹⁷ 49 U.S.C. 32902(h).

⁴¹⁸ Dedicated compressed natural gas (CNG) vehicles should also be excluded in this perspective

but are not considered as a compliance strategy under any perspective in this analysis.

Table VI-19 – Estimates of Earned FFV Credit (mpg)

| Manufacturer | Passenger Cars | | | Light Trucks | | |
|----------------|----------------|------|------|--------------|------|------|
| | 2017 | 2018 | 2019 | 2017 | 2018 | 2019 |
| BMW | - | - | - | - | - | - |
| Daimler | 0.6 | 0.4 | 0.2 | 0.6 | 0.4 | 0.2 |
| FCA | 0.6 | 0.4 | 0.2 | 0.6 | 0.4 | 0.2 |
| Ford | 0.6 | 0.4 | 0.2 | 0.6 | 0.4 | 0.2 |
| General Motors | 0.6 | 0.4 | 0.2 | 0.6 | 0.4 | 0.2 |
| Honda | - | - | - | - | - | - |
| Hyundai Kia-H | - | - | - | - | - | - |
| Hyundai Kia-K | - | - | - | - | - | - |
| JLR | - | - | - | - | - | - |
| Mazda | - | - | - | - | - | - |
| Mitsubishi | - | - | - | - | - | - |
| Nissan | - | - | - | - | - | - |
| Subaru | - | - | - | - | - | - |
| Tesla | - | - | - | - | - | - |
| Toyota | - | - | - | 0.6 | 0.4 | 0.2 |
| Volvo | - | - | - | - | - | - |
| VWA | - | - | - | 0.6 | 0.4 | 0.2 |

For its part, EPA has provided that manufacturers selling sufficient numbers of PHEVs, BEVs, and FCVs may, when calculating fleet average CO₂

levels, “count” each unit of production as more than a single unit. The CAFE model accounts for these “multipliers.” As for the NPRM, the final rule’s

analysis applies the following multipliers:

Table VI-20 – Production “Multipliers” for CNG Vehicles, PHEVs, BEVs, and FCVs

| Model Year | CNG or PHEV | BEV or FCV |
|------------|-------------|------------|
| 2017 | 1.60 | 2.00 |
| 2018 | 1.60 | 2.00 |
| 2019 | 1.60 | 2.00 |
| 2020 | 1.45 | 1.75 |
| 2021 | 1.30 | 1.50 |
| 2022 | 1.00 | 1.00 |

For example, under EPA’s current regulation, when calculating the average CO₂ level *achieved* by its MY 2019 passenger car fleet, a manufacturer may treat each 1,000 BEVs as 2,000 BEVs. When calculating the average level *required* of this fleet, the manufacturer must use the actual production volume (in this example, 1,000 units). Similarly, the manufacturer must use the actual production volume when calculating compliance credit balances.

There were no natural gas vehicles in the baseline fleet, and the analysis did

not apply natural gas technology due to cost effectiveness. The application of a 2.0 multiplier for natural gas vehicles for MYs 2022–2026 would have no impact on the analysis because given the state of natural gas vehicle refueling infrastructure, the cost to equip vehicles with natural gas tanks, the outlook for petroleum prices, and the outlook for battery prices, we have little basis to project more than an inconsequential response to this incentive in the foreseeable future.

For the final rule’s analysis, the CAFE model can be exercised in a manner that simulates these current EPA requirements, or that simulates two alternative approaches. The first includes the above-mentioned multipliers in the calculation of average requirements, and the second also includes the multipliers in the calculation of credit balances. The central analysis reflects current regulations. The sensitivity analysis presented in the FRIA includes a case

applying multipliers to the calculation of achieved and required average CO₂ levels, and calculation of credit balances.

c) Civil Penalties

Throughout the history of the CAFE program, some manufacturers have consistently achieved fuel economy levels below applicable standards, electing instead to pay civil penalties as specified by EPCA. As in previous versions of the CAFE model, the current version allows the user to specify inputs identifying such manufacturers and to consider their compliance decisions as if they are willing to pay civil penalties for non-compliance with the CAFE program. As with the NPRM, the civil penalty rate in the current analysis is \$5.50 per 1/10 of a mile per gallon, per vehicle manufactured for sale.

NHTSA notes that treating a manufacturer as if it is willing to pay civil penalties does not necessarily mean that it is expected to pay penalties in reality. Doing so merely implies that the manufacturer will only apply fuel economy technology up to a point, and then stop, regardless of whether or not its corporate average fuel economy is above its standard. In practice, the agencies expect that many of these manufacturers will continue to be active in the credit market, using trades with other manufacturers to transfer credits into specific fleets that are challenged in any given year, rather than paying penalties to resolve CAFE deficits. The CAFE model calculates the amount of penalties paid by each manufacturer, but it does not simulate trades between manufacturers. In practice, some (possibly most) of the total estimated penalties may be a transfer from one OEM to another.

Although EPCA, as amended in 2007 by the Energy Independence and Security Act (EISA), prescribes these specific civil penalty provisions for

CAFE standards, the Clean Air Act (CAA) does not contain similar provisions. Rather, the CAA's provisions regarding noncompliance prohibit sale of a new motor vehicle that is not covered by an EPA certificate of conformity, and in order to receive such a certificate the new motor vehicle must meet EPA's Section 202 regulations, including applicable emissions standards. Therefore, inputs regarding civil penalties—including inputs regarding manufacturers' potential willingness to treat civil penalty payment as an economic choice—apply only to simulation of CAFE standards. On the other hand, some of the same manufacturers recently opting to pay civil penalties instead of complying with CAFE standards have also recently led adoption of lower-GWP refrigerants, and the "A/C leakage" credits count toward compliance only with CO₂ standards, not CAFE standards. The model accounts for this difference between the programs.

When considering technology applications to improve fleet fuel economy, the model will add technology up to the point at which the effective cost of the technology (which includes technology cost, consumer fuel savings, consumer welfare changes, and the cost of penalties for non-compliance with the standard) is less costly than paying civil penalties or purchasing credits. Unlike previous versions of the model, the current implementation further acknowledges that some manufacturers experience transitions between product lines where they rely heavily on credits (either carried forward from earlier model years or acquired from other manufacturers) or simply pay penalties in one or more fleets for some number of years. The model now allows the user to specify, when appropriate for the regulatory program being simulated, on a year-by-

year basis, whether each manufacturer should be considered as willing to pay penalties for non-compliance. This provides additional flexibility, particularly in the early years of the simulation. As discussed above, this assumption is best considered as a method to allow a manufacturer to under-comply with its standard in some model years—treating the civil penalty rate and payment option as a proxy for other actions it may take that are not represented in the CAFE model (*e.g.*, purchasing credits from another manufacturer, carry-back from future model years, or negotiated settlements with NHTSA to resolve deficits).

For the NPRM, NHTSA relied on past compliance behavior and certified transactions in the credit market to designate some manufacturers as willing to pay CAFE penalties in some model years. The full set of NPRM assumptions regarding manufacturer behavior with respect to civil penalties is presented in Table VI–21, which shows all manufacturers were assumed to be willing to pay civil penalties prior to MY 2020. This was largely a reflection of either existing credit balances (which manufacturers will use to offset CAFE deficits until the credits reach their expiration dates) or inter-manufacturer trades assumed likely to happen in the near future, based on previous behavior. The manufacturers in the table whose names appear in bold all had at least one regulated fleet (of three) whose CAFE was below its standard in MY 2016. Because the NPRM analysis began with the MY 2016 fleet, and no technology could be added to vehicles that are already designed and built, all manufacturers could generate civil penalties in MY 2016. However, once a manufacturer is designated as unwilling to pay penalties, the CAFE model will attempt to add technology to the respective fleets to avoid shortfalls.

Table VI-21 – NPRM Assumptions Regarding Manufacturer Willingness to Pay Civil Penalties

| Manufacturer | 2017 | 2018 | 2019 | 2020 | 2021 | 2022 | 2023 | 2024 | 2025 | 2026 |

Several of the manufacturers in Table VI-21 that were presumed to be willing to pay civil penalties in the early years of the program have no history of paying civil penalties. However, several of those manufacturers have either bought or sold credits—or transferred credits from one fleet to another to offset a shortfall in the underperforming fleet. As the CAFE model does not simulate credit trades between manufacturers, providing this additional flexibility in the modeling avoids the outcome where the CAFE model applies more technology than needed in the context of the full set of compliance flexibilities at the industry level. By statute, NHTSA cannot consider credit flexibilities when setting standards, so most manufacturers (those without a history of civil penalty payment) are assumed to comply with their standards through fuel economy improvements for the model years being considered in this analysis. The notable exception to this assumption is Fiat Chrysler Automobiles (FCA), which could still satisfy the requirements of the program through a combination of credit application and civil penalties through MY 2025 before eventually complying exclusively through fuel economy improvements in MY 2026.

As mentioned above, the CAA does not provide civil penalty provisions similar to those provisions specified in EPCA/EISA, and the above-mentioned

corresponding inputs apply only to simulation of compliance with CAFE standards.

Some stakeholders offering comments related to the analytical treatment of civil penalties indicated that NHTSA should tend toward assuming manufacturers will take advantage of this EPCA provision as an economically attractive alternative to compliance. Other commenters implied that NHTSA should tend toward not relying on compliance flexibilities in the analysis used to determine the maximum feasible stringency of CAFE standards. For example, New York University's Institute for Policy Integrity (IPI) offered the following comments:

NHTSA assumes that most manufacturers will be unwilling to pay penalties based in part on the fact that most manufacturers have not paid penalties in recent years. The Proposed Rule cites the statutory prohibition on NHTSA considering credit trading as a reason to assume manufacturers without a history of paying penalties will comply through technology alone, whatever the cost. But this is an arbitrary assumption and is in no way dictated by the statute. NHTSA knows as much, since elsewhere in the proposed rollback, the agency explains "EPCA is very clear as to which flexibilities are not to be considered" and NHTSA is allowed to consider off-cycle adjustments because they are not specifically mentioned. But considering penalties are not mentioned as off-limits for NHTSA in setting the standards either. Instead, the prohibition focuses on credit trading and transferring.

The penalty safety valve has existed in EPCA for decades, and Congress clearly would have known how to add penalties to the list of trading and transferring. The fact that Congress did not bar NHTSA from considering penalties as a safety valve means that NHTSA must consider manufacturer's efficient use of penalties as a cost minimizing compliance option. Besides, NHTSA does consider penalties for some of the manufacturers making its statutory justification even less rational.⁴¹⁹

On the other hand, in more general comments about NHTSA's analytical treatment of program flexibilities, FCA stated that "when flexibilities are considered while setting targets, they cease to be flexibilities and become simply additional technology mandates."⁴²⁰

NHTSA agrees with IPI that EPCA does not expressly prohibit NHTSA, when conducting analysis supporting determinations of the maximum feasible stringency of future CAFE standards, from including manufacturers' potential tendency to pay civil penalties rather than complying with those standards. However, EPCA also does not *require* NHTSA to include this tendency in its analysis. NHTSA also notes, as does IPI, that EPCA *does* prohibit NHTSA from including credit trading, transferring, or the availability of credits in such

⁴¹⁹ Institute for Policy Integrity, NHTSA-2018-0067-12213, at 24.

⁴²⁰ FCA, Docket #NHTSA-2018-0067-11943, at 6.

analysis (although NHTSA interprets this prohibition to apply only to the model years for which standards are being set). This statutory difference is logical based on the way credits and penalties function differently under EPCA. Because credits help manufacturers achieve compliance with CAFE standards, absent the statutory prohibition, credits would be relevant to the feasibility of a standard.⁴²¹ Penalties, on the other hand, do not enable a manufacturer to comply with an applicable standard; penalties are for noncompliance.⁴²² When Congress added credit trading provisions to EPCA in 2007, NHTSA anticipated that competitive considerations would make manufacturers reluctant to engage in such trades. Since that time, manufacturers actually have demonstrated otherwise, although the reliance on trading—especially between specific pairs of OEMs—appears to vary widely. At this time, NHTSA considers it most likely that manufacturers will shift away from paying civil penalties and toward compliance credit trading. Consequently, for NHTSA to include civil penalty payment in its analysis would increasingly amount to using civil penalty payment as an analytical proxy for credit trading. Having further considered the question, NHTSA's current view is, therefore, that including civil penalty payment beyond MY 2020 would effectively subvert EPCA's prohibition against considering credit trading. Therefore, for today's announcement, NHTSA has modified its analysis to assume that BMW, Daimler, FCA, JLR, and Volvo would consider paying civil penalties through MY 2020, and that all manufacturers would apply as much technology as would be needed in order to avoid paying civil penalties after MY 2020.

3. Technology Effectiveness Values

The next input required to simulate manufacturers' decision-making processes for the year-by-year application of technologies to specific vehicles is estimates of how effective each technology would be at reducing fuel consumption. In the NPRM, the agencies used full-vehicle modeling and simulation to estimate the fuel economy improvements manufacturers could make to a fleet of vehicles, considering those vehicles' technical specifications and how combinations of technologies interact. Full-vehicle modeling and simulation uses computer software and

physics-based models to predict how combinations of technologies perform as a full system under defined conditions.

A model is a mathematical representation of a system, and simulation is the behavior of that mathematical representation over time. In this analysis, the model is a mathematical representation of an entire vehicle,⁴²³ including its individual components such as the engine and transmission, overall vehicle characteristics such as mass and aerodynamic drag, and the environmental conditions, such as ambient temperature and barometric pressure. The agencies simulated the model's behavior over test cycles, including the 2-cycle laboratory compliance tests (or 2-cycle tests),⁴²⁴ to determine how the individual components interact. 2-cycle tests are test cycles that are used to measure fuel economy and emissions for CAFE and CO₂ compliance, and therefore are the relevant test cycles for determining technology effectiveness when establishing standards. In the laboratory, 2-cycle testing involves sophisticated test and measurement equipment, carefully controlled environmental conditions, and precise procedures to provide the most repeatable results possible with human drivers. Measurements using these structured procedures serve as a yardstick for fuel economy and CO₂ emissions.

Full-vehicle modeling and simulation was initially developed to avoid the costs of designing and testing prototype parts for every new type of technology. For example, if a truck manufacturer has a concept for a lightweight tailgate and wants to determine the fuel economy impact for the weight reduction, the manufacturer can use physics-based computer modeling to estimate the impact. The vehicle, modeled with the proposed change, can be simulated on a defined test route and under a defined test condition, such as city or highway

driving in warm ambient temperature conditions, and compared against the baseline reference vehicle. Full-vehicle modeling and simulation allows the consideration and evaluation of different designs and concepts before building a single prototype. In addition, full vehicle modeling and simulation is beneficial when considering technologies that provide small incremental improvements. These improvements are difficult to measure in laboratory tests due to variations in how vehicles are driven over the test cycle by human drivers, variations in emissions measurement equipment, and variations in environmental conditions.⁴²⁵

Full-vehicle modeling and simulation requires detailed data describing the individual technologies and performance-related characteristics. Those specifications generally come from design specifications, laboratory measurements, and other subsystem simulations or modeling. One example of data used as an input to the full vehicle simulation are engine maps for each engine technology that define how much fuel is consumed by the engine technology across its operating range.

Using full-vehicle modeling and simulation to estimate technology efficiency improvements has two primary advantages over using single or limited point estimates. An analysis using single or limited point estimates may assume that, for example, one fuel economy improving technology with an effectiveness value of 5 percent by itself and another technology with an effectiveness value of 10 percent by itself, when applied together achieve an additive improvement of 15 percent. Single point estimates generally do not provide accurate effectiveness values because they do not capture complex relationships among technologies. Technology effectiveness often differs significantly depending on the vehicle type (e.g., sedan versus pickup truck) and how the technology interacts with other technologies on the vehicle, as different technologies may provide different incremental levels of fuel economy improvement if implemented alone or in tandem with other technologies. Any oversimplification of these complex interactions leads to less accurate and often overestimated effectiveness estimates.

In addition, because manufacturers often implement several fuel-saving

⁴²³ Our full vehicle model was composed of sub-models, which is why the full vehicle model could also be referred to as a full system model, composed of sub-system models.

⁴²⁴ EPA's compliance test cycles are used to measure the fuel economy of a vehicle. For readers unfamiliar with this process, it is like running a car on a treadmill following a program—or more specifically, two programs. The “programs” are the “urban cycle,” or Federal Test Procedure (abbreviated as “FTP”), and the “highway cycle,” or Highway Fuel Economy Test (abbreviated as “HFET”), and they have not changed substantively since 1975. Each cycle is a designated speed trace (of vehicle speed versus time) that all certified vehicles must follow during testing. The FTP is meant roughly to simulate stop and go city driving, and the HFET is meant roughly to simulate steady flowing highway driving at about 50 mph. For further details on compliance testing, see the discussion in Section VI.B.3.a)(7).

⁴²¹ See 49 U.S.C. 32911(b) (“Compliance is determined after considering credits available to the manufacturer . . .”).

⁴²² See *id.*

⁴²⁵ Difficulty with controlling for such variability is reflected, for example, in 40 CFR 1065.210, Work input and output sensors, which describes complicated instructions and recommendations to help control for variability in real world (non-simulated) test instrumentation set up.

technologies simultaneously when redesigning a vehicle, it is difficult to isolate the effect of individual technologies using laboratory measurement of production vehicles alone. Modeling and simulation offers the opportunity to isolate the effects of individual technologies by using a single or small number of baseline vehicle configurations and incrementally adding technologies to those baseline configurations. This provides a consistent reference point for the incremental effectiveness estimates for each technology and for combinations of technologies for each vehicle type. Vehicle modeling also reduces the potential for overcounting or undercounting technology effectiveness.

An important feature of this analysis is that the *incremental* effectiveness of each technology and combinations of technologies be accurate and relative to a consistent baseline vehicle. The *absolute* fuel economy values of the full vehicle simulations are used only to determine *incremental* effectiveness and are never used directly to assign an absolute fuel economy value to any vehicle model or configuration for the rulemaking analysis.

For this analysis, absolute fuel economy levels are based on the individual fuel economy values from CAFE compliance data for each vehicle in the baseline fleet. The incremental effectiveness from the full vehicle simulations performed in Autonomie, a physics-based full-vehicle modeling and simulation software developed and maintained by the U.S. Department of Energy's Argonne National Laboratory, are applied to baseline fuel economy to determine the absolute fuel economy of applying the first technology change. For subsequent technology changes, incremental effectiveness is applied to the absolute fuel economy level of the previous technology configuration.

For example, if a Ford F150 2-wheel drive crew cab and short bed in the baseline fleet has a fuel economy value of 30 mpg for CAFE compliance, 30 mpg will be considered the reference absolute fuel economy value. A similar full vehicle model in the Autonomie simulation may begin with an average fuel economy value of 32 mpg, and with incremental addition of a specific technology X its fuel economy improves to 35 mpg, a 9.3 percent improvement. In this example, the incremental fuel economy improvement (9.3 percent) from technology X would be applied to the F150's 30 mpg absolute value.

For this analysis, the agencies determined the incremental effectiveness of technologies as applied

to the 2,952 unique vehicle models in the analysis fleet. Although, as mentioned above, full-vehicle modeling and simulation reduces the work and time required to assess the impact of moving a vehicle from one technology state to another, it would be impractical—if not impossible—to build a unique vehicle model for every individual vehicle in the analysis fleet. Therefore, as explained further below, vehicle models are built in a way that maintains similar attributes to the analysis fleet vehicles, which ensures key components are reasonably represented.

We received a wide array of comments regarding the full-vehicle modeling and simulation performed for the NPRM, but there was general agreement that full-vehicle modeling and simulation was the appropriate method to determine technology effectiveness.⁴²⁶ Stakeholders commented on other areas, such as full vehicle simulation tools, inputs, and assumptions, and these comments will be discussed in the following sections. For this final rule, the agencies continued to use the same full-vehicle simulation approach to estimate technology effectiveness for technology adoption in the rulemaking timeframe. The next sections will discuss the details of the explicit input specifications and assumptions used for the final rule analysis.

a) Why This Rulemaking Used Autonomie Full-Vehicle Modeling and Simulation To Determine Technology Effectiveness

The NPRM and final rule analysis use effectiveness estimates for technologies developed using Autonomie, a physics-based full-vehicle modeling and simulation software developed and maintained by the U.S. Department of Energy's Argonne National Laboratory.⁴²⁷ Autonomie was designed to serve as a single tool to meet requirements of automotive engineering throughout the vehicle development process, and has been under continuous improvement by Argonne for over 20 years. Autonomie is commercially available and widely used in the automotive industry by suppliers,

automakers, and academic researchers (who publish findings in peer reviewed academic journals).⁴²⁸ DOE and manufacturers have used Autonomie and its ability to simulate a large number of powertrain configurations, component technologies, and vehicle-level controls over numerous drive cycles to support studies on fuel efficiency, cost-benefit analysis, and carbon dioxide emissions,⁴²⁹ and other topics.

Autonomie has also been used to provide the U.S. government with data to make decisions about future research, and is used by DOE for analysis supporting budget priorities and plans for programs managed by its Vehicle Technologies Office (VTO), and to support decision making among competing vehicle technology research and development projects.⁴³⁰ In addition, Autonomie is the primary vehicle simulation tool used by DOE to support its U.S. DRIVE program, a government-industry partnership focused on advanced automotive and related energy infrastructure technology research and development.⁴³¹

Autonomie is a MathWorks-based software environment and framework for automotive control-system design, simulation, and analysis.⁴³² It is designed for rapid and easy integration of models with varying levels of detail (low to high fidelity), abstraction (from subsystems to systems and entire architectures), and processes (e.g., calibration, validation). By building models automatically, Autonomie allows the quick simulation of many component technologies and powertrain configurations, and, in this case, to assess the energy consumption of advanced powertrain technologies. Autonomie simulates subsystems,

⁴²⁶ See NHTSA–2018–0067–12039; NHTSA–2018–0067–12073. UCS and AAM both agreed that full vehicle simulation can significantly improve the estimates of technology effectiveness.

⁴²⁷ More information about Autonomie is available at <https://www.anl.gov/technology/project/autonomie-automotive-system-design> (last accessed June 21, 2018). As mentioned in the preliminary regulatory impact analysis (PRIA) for this rule, the agencies used Autonomie version R15SP1, the same version used for the 2016 Draft TAR.

systems, or entire vehicles; evaluates and analyzes fuel efficiency and performance; performs analyses and tests for virtual calibration, verification, and validation of hardware models and algorithms; supports system hardware and software requirements; links to optimization algorithms; and supplies libraries of models for propulsion architectures of conventional powertrains as well as hybrid and electric vehicles.

With hundreds of pre-defined powertrain configurations along with vehicle level control strategies developed from dynamometer test data, Autonomie is a highly capable tool for analyzing advantages and drawbacks of applying different technology options within each technology family, including conventional, parallel hybrid, power-split hybrid electric vehicles (HEVs), plug-in hybrid electric vehicles (PHEVs), battery electric vehicles (BEV) and fuel cell vehicles (FCVs). Autonomie also allows users to evaluate the effect of component sizing on fuel consumption for different powertrain technologies as well as to define component requirements (e.g., power, energy) to maximize fuel displacement for a specific application.⁴³³ To evaluate properly any powertrain-configuration or component-sizing influence, vehicle-level control models are critical, especially for electric drive vehicles like hybrids and plug-in hybrids. Argonne has extensive expertise in developing vehicle-level control models based on different approaches, from global optimization to instantaneous optimization, rule-based optimization, and heuristic optimization.⁴³⁴

Autonomie has been developed to consider real-world vehicle metrics like performance, hardware limitations, utility, and drivability metrics (e.g., towing capability, shift busyness, frequency of engine on/off transitions), which are important to producing

realistic estimates of fuel economy and CO₂ emission rates. This increasing realism has, in turn, steadily increased confidence in the appropriateness of using Autonomie to make significant investment decisions. Autonomie has also been validated for a number of powertrain configurations and vehicle classes using Argonne's Advanced Mobility Technology Laboratory (AMTL) (formerly Advanced Powertrain Research Facility, or APRF) vehicle test data.⁴³⁵

Argonne has spent several years developing, applying, and expanding the means to use distributed computing to exercise its Autonomie full-vehicle simulation tool over the scale necessary for realistic analysis to provide data for CAFE and CO₂ standards rulemaking. The NPRM and PRIA detailed how Argonne used Autonomie to estimate the fuel economy impacts for roughly a million combinations of technologies and vehicle types.^{436 437} Argonne developed input parameters for Autonomie to represent every combination of vehicle, powertrain, and component technologies considered in this rulemaking. The sequential

addition of more than 50 fuel economy-improving technologies to ten vehicle types generated more than 140,000 unique technology and vehicle combinations. Running the Autonomie powertrain sizing algorithms to determine the appropriate amount of engine downsizing needed to maintain overall vehicle performance when vehicle mass reduction is applied and for certain engine technology changes (discussed further, below) increased the total number of simulations to more than one million. The result of these simulations is a useful dataset identifying the impacts of combinations of vehicle technologies on energy consumption—a dataset that can be referenced as an input to the CAFE model for assessing regulatory compliance alternatives.

The following sections discuss the full-vehicle modeling and simulation inputs and data assumptions, and comments received on the NPRM analysis. The discussion is necessarily technical, but also important to understand the agencies' decisions to modify (or not) the Autonomie analysis for the final rule.

(1) Full-Vehicle Modeling, Simulation Inputs and Data Assumptions

The agencies provided extensive documentation that quantitatively and qualitatively described the over 50 technologies considered as inputs to the Autonomie modeling.^{438 439} These inputs consisted of engine technologies, transmission technologies, powertrain electrification, light-weighting, aerodynamic improvements, and tire rolling resistance improvements.⁴⁴⁰ The PRIA provided an overview of the sub-models for each technology, including the internal combustion engine model, automatic transmission model, and others.⁴⁴¹ The Argonne NPRM model documentation expanded on these sub-models in detail to show the interaction of each sub-model input and output.⁴⁴²

"Plug-in Vehicle Control Strategy—From Global Optimization to Real Time Application," 22th International Electric Vehicle Symposium (EVS22), Yokohama, (October 2006).

⁴³⁶ As part of the Argonne simulation effort, individual technology combinations simulated in Autonomie were paired with Argonne's BatPAC model to estimate the battery cost associated with each technology combination based on characteristics of the simulated vehicle and its level of electrification. Information regarding Argonne's BatPAC model is available at <http://www.cse.anl.gov/batpac/>.

⁴³⁷ Additionally, the impact of engine technologies on fuel consumption, torque, and other metrics was characterized using GT POWER simulation modeling in combination with other engine modeling that was conducted by IAV Automotive Engineering, Inc. (IAV). The engine characterization "maps" resulting from this analysis were used as inputs for the Autonomie full-vehicle simulation modeling. Information regarding GT Power is available at <https://www.gtisoft.com/gt-suite-applications/propulsion-systems/gt-power-engine-simulation-software>.

For example, as shown in Figure VI-2, the input for Autonomie's driver model (*i.e.*, the model used to approximate the

driving behavior of a real driver) is vehicle speed, and outputs are

accelerator pedal, brake pedal, and torque demand.

Figure VI-2 – Autonomie Driver Sub-Model inputs and outputs

Effectiveness inputs for the NPRM and the final rule analysis were specifically developed to consider many real world and compliance test cycle constraints, to the extent a computer model could capture them. Examples include the advanced engine knock model discussed below, in addition to other constraints like allowing cylinder deactivation to occur in ways that would not negatively impact noise-vibration-harshness (NVH), and similarly optimizing the number of engine on/off events (*e.g.*, from start/stop 12V micro hybrid systems) to balance between effectiveness and NVH.

One major input used in the effectiveness modeling that the agencies provided key specifications for in the PRIA are engine fuel maps that define how an engine equipped with specific technologies operates over a variety of engine load (torque) and engine speed conditions. The engine maps used as inputs to the Autonomie modeling portion of the analysis were developed by starting with a base map and then modifying that base map, incrementally, to model the addition of engine technologies. These engine maps, developed using the GT-Power modeling tool by IAV, were based off real-world engine designs. Simulated operation of these engines included the application of an IAV knock model, also developed from real-world engine data.⁴⁴³ ⁴⁴⁴ Using this process, which incorporated real-world data, ensured

that real-world constraints were considered for each vehicle type. Although the same type of engine map is used for all technology classes, the effectiveness varies based on the characteristics of each vehicle type. For example, a compact car with a turbocharged engine will have different fuel economy and performance values than a pickup truck with the same engine technology type. The engine map specifications are discussed further in Section VI.C.1 of this preamble and Section VI of FRIA.

The agencies also provided key details about input assumptions for various vehicle specifications like transmission gear ratios, tire size, final drive ratios, and individual component weights.⁴⁴⁵ Each of these assumptions, to some extent, varied between the ten technology classes to capture appropriately real-world vehicle specifications like wheel mass or fuel tank mass. These specific input assumptions were developed based on the latest test data and current market fleet information.⁴⁴⁶ The agencies relied on default assumptions developed by the Autonomie team, based on test data and technical publication review, for other model inputs required by Autonomie, such as throttle time response and shifting strategies for different transmission technologies. The Autonomie modeling tool did not simulate vehicle attributes determined to have minimal impacts, like whether

a vehicle had a sun roof or hood scoops, as those attributes would have trivial impact in the overall analysis.

Because the agencies model ten different vehicle types to represent the 2,952 vehicles in the baseline fleet, improper assumptions about an advanced technology could lead to errors in estimating effectiveness. Autonomie is a sophisticated full-vehicle modeling tool that requires extensive technology characteristics based on both physical and intangible data, like proprietary software. With a few technologies, the agencies did not have publicly available data, but had received confidential business information confirming such technologies potential availability in the market during the rulemaking time frame. For such technologies, including advanced cylinder deactivation, the agencies adopted a method in the CAFE model to represent the effectiveness of the technology, and did not explicitly simulate the technologies in the Autonomie model. For this limited set of technologies, the agencies determined that effectiveness could reasonably be represented as a fixed value.⁴⁴⁷ Effectiveness values for technologies not explicitly simulated in Autonomie are discussed further in the individual technology sections of this preamble.

The agencies sought comments on all effectiveness inputs and input assumptions, including the specific data used to characterize the technologies,

Vehicle Simulation Process To Support CAFE Standards 04262018—Report” ANL Autonomie Documentation. Aug 21, 2018.

⁴⁴³ Engine knock in spark ignition engines occurs when combustion of some of the air/fuel mixture in the cylinder does not result from propagation of the flame front ignited by the spark plug, but one or more pockets of air/fuel mixture explodes outside of the envelope of the normal combustion front.

⁴⁴⁶ See further details in Section VI.B.1 Analysis Fleet.

⁴⁴⁷ For final rule, 9 out of 50 plus technologies use fixed offset effectiveness values. The total effectiveness of these technologies cannot be captured on the 2-cycle test or, like ADEAC, they are a new technology where robust data that could be used as an input to the technology effectiveness modeling does not yet exist. Specifically, these nine technologies are LDB, SAX, EPS, IACC, EFR, ADEAC, DSLI, DSLIAD and TURBOAD.

such as data to build the technology input, data representing operating range of technologies, and data for variation among technology inputs. The agencies also sought comment on the effectiveness values used for technologies not explicitly defined in Autonomie.

Meszler Engineering Services, commenting on behalf of the Natural Resources Defense Council, and ICCT questioned the accuracy of the effectiveness estimates in the Argonne database, and as an example Meszler analyzed the fuel economy impacts of a 10-speed automatic transmission relative to a baseline 8-speed automatic transmission, concluding that the widely ranging effectiveness estimates were unexpected. ICCT questioned the accuracy of the IAV engine maps that serve as an input to the Autonomie effectiveness modeling, and asked whether those could “reasonably stand as a foundation for automotive developments and technology combinations” discussed elsewhere in their comments. ICCT also questioned whether Autonomie realistically and validly modeled synergies between technologies, using the effectiveness values from CEGR and transmissions as an example. Meszler stated that the agencies have an obligation to validate the Autonomie estimates before using them to support the NPRM or any other rulemaking. The agencies also received comments on the specific effectiveness estimates generated by Autonomie; however, those comments will be discussed in each individual technology section, below.

Despite these criticisms, Meszler stated that the critiques of the Autonomie technology database were not meant to imply that the Autonomie vehicle simulation model used to develop the database was fundamentally flawed, or that the model could not be used to derive accurate fuel economy impact estimates. Meszler noted that, as with any model, estimates derived with Autonomie are only valid for a given set of modeling parameters and if those parameters are well defined, the estimates should be accurate and reliable. Conversely, if those parameters are not well defined, the estimates would be inaccurate and unreliable. Meszler stated that the agencies must make the full set of modeling assumptions used for the Autonomie database available for review and comment.

We agree with Meszler that, in general, when inputs to a model are inaccurate, output effectiveness results may be too high or too low. The technology effectiveness estimates from

modeling results often vary with the type of vehicle and the other technologies that are on that vehicle.⁴⁴⁸ The Autonomie output database consists of permutations of over 50 technologies for each of the ten technology classes simulated by the CAFE model. A wide range of effectiveness is expected when going from a baseline technology to an advanced technology across different technology classes because there are significant differences in how much power is required from the powertrain during 2-cycle testing across the ten vehicle types. This impacts powertrain operating conditions (e.g., engine speed and load) during 2-cycle testing. Fuel economy improving technologies have different effectiveness at each of those operating conditions so vehicles that have higher average power demands will have different effectiveness than vehicles with lower average power demands. Further, the differences in effectiveness at higher power and lower power vary by technology so the overall relationship is complex. Large-scale full-vehicle modeling and simulation account for these interactions and complexities.

Before conducting any full-vehicle modeling and simulation, the agencies spent a considerable amount of time and effort developing the specific inputs used for the Autonomie analysis. The agencies believe that these technology inputs provide reasonable estimates for the light-duty vehicle technologies the agencies expect to be available in the market in the rulemaking timeframe. As discussed earlier, these inputs vary in effectiveness due to how different vehicles, like compact cars and pickup trucks, operate on the 2-cycle test and in the real world. Some technologies, such as 10-speed automatic transmissions (AT10) relative to 8-speed automatic transmissions (AT8), can and should have different effectiveness results in the analysis between two different technology classes.⁴⁴⁹ These unique synergistic effects can only be taken into account through conducting full-vehicle modeling and simulation, which the agencies did here.

With regards to Meszler’s comment that the agencies have an obligation to validate the Autonomie estimates before using them to support the NPRM or any

other rulemaking, the agencies would like to point Meszler to the description of the Argonne Autonomie team’s robust process for vehicle model validation that was contained in the PRIA.⁴⁵⁰ To summarize, the NPRM and final rule analysis leveraged extensive vehicle test data collected by Argonne National Laboratory.⁴⁵¹ Over the past 20 years, the Argonne team has developed specific instrumentation lists and test procedures for collecting sufficient information to develop and validate full vehicle models. In addition, the agencies described the Argonne team’s efforts to validate specific component models as well, such as the advanced automatic transmission and dual clutch transmission models.⁴⁵²

The agencies also described the process for validating inputs used to develop the IAV engine maps,^{453 454} another input to the Autonomie simulations. As discussed in the PRIA, IAV’s engine model development relied on a collection of sub-models that controlled independent combustion characteristics such as heat release, combustion knock, friction, heat flow, and other combustion optimization tools. These sub-models and other

⁴⁴⁸ The PRIA Chapter 6.2.2.1, Table 6–2 and Table 6–3 defined the characteristics of the reference technology classes that representative of the analysis fleet.

⁴⁴⁹ Separately, the agencies modified specific transmission modeling parameters for the final rule after additional review, including a thorough review of public comments, and this review is discussed in detail in Section VI.C.2.

computational fluid dynamics models were utilized to convert test data for use in the IAV engine map development. Specific combustion parameters, like from test data for the coefficient of variation for the indicated mean effective pressure (COV of IMEP), which is a common variable for combustion stability in a spark ignited engine, was used to assure final engine models were reasonable. The assumptions and inputs used in the modeling and validation of engine model results leveraged IAV's global engine database, which included benchmarking data, engine test data, single cylinder test data and prior modeling studies, and also technical publications and information presented at conferences. The agencies referenced in the PRIA that engine maps were validated with engine dynamometer test data to the maximum extent possible.⁴⁵⁵ Because the NPRM and the final rule analysis considered some technologies not yet in production, the agencies relied on technical publications and engine modeling by IAV to develop and corroborate inputs and input assumptions where engine dynamometer test data was not available.

In addition, as described earlier in this section, the full set of NPRM modeling assumptions used for the Autonomie database were available for review and comment in the docket for this rulemaking.⁴⁵⁶ The full set of modeling assumptions used for the final rule are also available in the docket.⁴⁵⁷

Both ICCT and Meszler also commented on the availability of technologies within the Autonomie database, with Meszler stating that with limited exceptions, technologies were not included in the NPRM CAFE model if they were not included in the simulation modeling that underlay the Argonne database, and accordingly if a combination of technologies was not modeled during the development of the Argonne database, that package (or

combination) of technologies was not available for adoption in the CAFE model. Meszler stated that these constraints limited the slate of technologies available to respond to fuel economy standards, and independently expanding the model to include additional technologies or technology combinations is not trivial.

ICCT gave specific examples of key efficiency technologies that it stated Autonomie did not include, like advanced DEAC, VCR, Miller Cycle, e-boost, and HCCI. ICCT argued that this was especially problematic as the agencies appeared to have available engine maps from IAV on advanced DEAC, VCR, Miller Cycle, E-boost (and from advanced DEAC, VCR, Miller Cycle, E-boost, HCCI from EPA) that Argonne or the agencies have been unable to or opted not to include in their modeling. ICCT stated that the agencies must disclose how Autonomie had been updated to incorporate "cutting edge" 2020–2025 automotive technologies to ensure they reflect available improvements.⁴⁵⁸

The agencies have updated the final rule analysis to include additional technologies. In the NPRM, the agencies presented the engine maps for all of the technologies that ICCT listed, except HCCI, and sought comment on the engine maps, technical assumptions and the potential use of the technologies for the final rule analysis. Based on the available technical information and the ICCT and Meszler comments, for the final rule analysis, VCR, Miller Cycle (VTG), and e-boost (VTGe with 48V BISG) technologies have been added and included in the Autonomie modeling and simulations, and advanced DEAC technology has been added using fixed point effectiveness estimates in the CAFE model analysis. The agencies disagree with ICCT's assessment of HCCI and do not believe it will be available for wide-scale application in the rulemaking timeframe, and therefore have not included it as a technology. HCCI technology has been in the research phase for several decades, and the only production applications to date use a highly-limited version that restricts HCCI combustion to a very narrow range of engine operating conditions.^{459 460 461}

Additional discussion of how Autonomie-modeled and non-modeled technologies are incorporated into the CAFE Model is located in Section VI.B.3.c), below.

ICCT and Meszler also commented that the agencies overly limited the availability of several technologies in the NPRM analysis. In response, the agencies reconsidered the restrictions that were applied in the NPRM analysis, and agree with the commenters for several technologies and technology classes. Many technologies identified by the commenters are now in production for the MY2017 as well as MY2018 and MY2019. The agencies also think that the baseline fleet compliance data reflects adoption of many of these technologies. For the final rule analysis, the agencies have expanded the availability of several technologies. In the CAFE model, the agencies are now allowing parallel hybrids (SHEVP2) to be adopted with high compression Atkinson mode engines (HCR0 and HCR1). In addition, as mentioned above, the Autonomie full-vehicle modeling included Variable Compression Ratio engine (VCR), Miller Cycle Engine (VTG), E-boost (VTGe) technologies, and cylinder deactivation technologies (DEAC) to be applied to turbocharged engines (TURBO1). As these changes relate to the technology effectiveness modeling, the CAFE model analysis now includes effectiveness estimates based on full vehicle simulations for all of these technology combinations.

We disagree with comments stating the agencies should allow every technology to be available to every vehicle class.⁴⁶² Discussed earlier in this section, Autonomie models key aspects of vehicle operation that are most relevant to assessing fuel economy, vehicle performance and certain aspects of drivability (like EPA 2-cycle tests, EPA US06 cycle tests, gradability, low speed acceleration time from 0-to-60 mph, passing acceleration time from 50 to 80 mph, and number of transmission shifts). However, there are other critical aspects of vehicle functionality and operation that the agencies considered beyond those criteria, that cannot necessarily be reflected in the Autonomie modeling. For example, a pickup truck can be modeled with a

continuously variable transmission (CVT) and show improvements on the 2-cycle tests. However, pickup trucks are designed to provide high load towing utility.⁴⁶³ CVTs lack the torque levels needed to provide that towing utility, and would fail mechanically if subject to high load towing.⁴⁶⁴ The agencies provided discussions of some of these technical considerations in the PRIA, and explained why the agencies had limited technologies for certain vehicle classes, such as limiting CVTs on pickups as in the example above. These and other limitations are discussed further in the individual technology sections.

The agencies also received a variety of comments that conflated aspects of the Autonomie models with technology inputs and input assumptions. For example, commenters expressed concern about the transmission gear set and final drive values used for the NPRM analysis, or more specifically, that the gear ratios were held constant across applications.⁴⁶⁵ In this case, both the inputs (gear set and final drive ratio) and input assumption (ratios held constant) were discussed by the commenters. Because these comments are actually about technology inputs to the Autonomie model, for these and similar cases, the agencies are addressing the comments in the individual technology sections which discuss the technology inputs and input assumptions that impact the effectiveness values for those technologies.

For the NPRM analysis, the agencies prioritized using inputs that were based on data for identifiable technology configurations and that reflected practical real world constraints. The agencies provided detailed information on the NPRM analysis inputs and input assumptions in the NPRM Preamble, PRIA and Argonne model documentation for engine technologies, transmission technologies, powertrain electrification, light-weighting, aerodynamic improvements, tire rolling resistance improvements, and other vehicle technologies. Comments and the agencies' assessment of comments for each technology are discussed in the individual technology sections below. Through careful consideration of the comments, the agencies have updated

analytical inputs associated with several technologies, and as discussed above, have included several advanced technologies for which technical information was included in the NPRM. However, for most technologies, the agencies have determined that the technology inputs and input assumptions that were used in the NPRM analysis remain reasonable and the best available for the final rule analysis.

(2) How The Agencies Defined Different Vehicle Types in Autonomie

As described in the NPRM, Argonne produced full-vehicle models and ran simulations for many combinations of technologies, on many types of vehicles, but it did not simulate literally every single vehicle model/configuration in the analysis fleet because it would be impractical to assemble the requisite detailed information—much of which would likely only be provided on a confidential basis—specific to each vehicle model/configuration and because the scale of the simulation effort would correspondingly increase by orders of magnitude. Instead, Argonne simulated 10 different vehicle types, corresponding to the five “technology classes” generally used in CAFE analysis over the past several rulemakings, each with two performance levels and corresponding vehicle technical specifications (e.g., small car, small performance car, pickup truck, performance pickup truck, etc.).

Technology classes are a means of specifying common technology input assumptions for vehicles that share similar characteristics. Because each vehicle technology class has unique characteristics, the effectiveness of technologies and combinations of technologies is different for each technology class. Conducting Autonomie simulations uniquely for each technology class provides a specific set of simulations and effectiveness data for each technology class. Like the Draft TAR analysis, there are separate technology classes for compact cars, midsize cars, small SUVs, large SUVs, and pickup trucks. However, new for the NPRM analysis and carried into this final rule analysis, each of those vehicle types has been split into “low” (or “standard”) performance and a “high” performance versions, which represent two classes with similar body styles but different levels of performance attributes (for a total of 10 technology classes). The separate technology classes for high performance and low performance

vehicles better account for performance diversity across the fleet.

NHTSA directed Argonne to develop a vehicle assumptions database to capture vehicle attributes that would comprise the full vehicle models. For each vehicle technology class, representative vehicle attributes and characteristics were identified from publicly available information and automotive benchmarking databases like A2Mac1,⁴⁶⁶ Argonne's Downloadable Dynamometer Database (D³),⁴⁶⁷ and EPA compliance and fuel economy data,⁴⁶⁸ EPA's guidance on the cold start penalty on 2-cycle tests.⁴⁶⁹ The resulting vehicle assumptions database consists of over 100 different attributes like vehicle frontal area, drag coefficient, fuel tank weight, transmission housing weight, transmission clutch weight, hybrid vehicle component weights, and weights for components that comprise engines and electric machines, tire rolling resistance, transmission gear ratios and final drive ratio. Each of the 10 different vehicle types was assigned a set of these baseline attributes and characteristics, to which combinations of fuel-saving technologies were added as inputs for the Autonomie simulations. For example, the characteristics of the MY 2016 Honda Fit were considered along with a wide range of other compact cars to identify representative characteristics for the Autonomie simulations for the base compact car technology class. The simulations determined the fuel economy achieved when applying each combination of technologies to that vehicle type, given its baseline characteristics.

For each vehicle technology class and for each vehicle attribute, Argonne estimated the attribute value using statistical distribution analysis of publicly available data and data obtained from the A2Mac1 benchmarking database.⁴⁷⁰ Some

vehicle attributes were also based on test data and vehicle benchmarking, like the cold-start penalty for the FTP test cycle and vehicle electrical accessories load. The analysis of vehicle attributes used in the NPRM was discussed in the Argonne model documentation,⁴⁷¹ and values for each vehicle technology class were provided with the NPRM for public review.⁴⁷²

The agencies did not believe it was appropriate to assign one single engine mass for each vehicle technology class in the NPRM analysis. To account for the difference in weight for different engine types, Argonne performed a regression analysis of engine peak power versus weight, based on attribute data taken from the A2Mac1 benchmarking database. For example, to account for weight of different engine sizes like 4-cylinder versus 8-cylinder, Argonne developed a relationship curve between peak power and engine weight based on the A2Mac1 benchmarking data. For the NPRM analysis, this relationship was used to estimate mass for all engine types regardless of technology type (*e.g.*, variable valve lift and direct injection). Secondary weight reduction associated with changes in engine technology was applied by using this linear relationship between engine power and engine weight from the A2Mac1 benchmarking database. When a vehicle in the analysis fleet with an 8-cylinder engine adopted a more fuel efficient 6-cylinder engine, the total vehicle weight would reflect the updated engine weight with two less cylinders based on the peak power versus engine weight relationship. The impact of engine mass reduction on effectiveness is accounted for directly in the Autonomie simulation data through the application of the above relationship. Engine mass reduction through downsizing is, therefore, appropriately not included as part of vehicle mass reduction technology that is discussed in Section VI.C.4 because doing so would result in double counting the impacts. As discussed further below, for the final rule the agencies improved upon the precision of engine weights by creating two curves to separately represent naturally aspirated engine designs and turbocharged engine designs.

In addition, certain attributes were held at constant levels within each technology class to maintain vehicle functionality, performance and utility including noise, vibration, and harshness (NVH), safety, performance and other utilities important for customer satisfaction. For example, in addition to the vehicle performance constraints discussed in Section VI.B.3.a)(6), the analysis does not allow the frontal area of the vehicle to change, in order to maintain utility like ground clearance, head-room space, and cargo space, and a cold-start penalty is used to account for fuel economy degradation for heater performance and emissions system catalyst light-off.⁴⁷³ This allows us to capture the discrete improvement in technology effectiveness while maintaining vehicle attributes that are important vehicle utility, consumer acceptance and compliance with criteria emission standards, and considering these constraints similar to how manufacturers do in the real world.

The agencies sought comment on the analytical approach used to determine vehicle attributes and characteristics for the Autonomie modeling. In response, the agencies received a wide variety of comments on vehicle attributes ranging from discussions of performance increase from technology adoption (*e.g.*, if a vehicle adopting an electrified powertrain improved its time to accelerate from 0–60 mph), to comments on vehicle attributes *not* modeled in Autonomie, like heated seats and cargo space.

Toyota and the Alliance commented that the inclusion of performance vehicle classes addressed the market reality that some consumers will purchase vehicles for their performance attributes and will accept the corresponding reduction in fuel economy. Furthermore, Toyota commented that some gain in performance is more realistic, and that “dedicating all powertrain improvements to fuel efficiency is inconsistent with market reality.” Toyota “supports the agencies’ inclusion of performance classes in compliance modeling where a subset of certain models is defined to have higher performance and a commensurate reduction in fuel efficiency.”⁴⁷⁴ Also, in support of the addition of performance vehicle classes, the Alliance commented that “vehicle categories have been increased to 10 to better recognize the

range of 0–60 performance characteristics within each of the 5 previous categories, in recognition of the fact that many vehicles in the baseline fleet significantly exceeded the previously assumed 0–60 performance metrics. This provides better resolution of the baseline fleet and more accurate estimates of the benefits of technology.”⁴⁷⁵

UCS commented that the CAFE model incorporates technology improvements to each vehicle by applying the effectiveness improvement of the average vehicle in the technology class, leading to discrete “stepped” effectiveness levels for technologies across the different vehicle types. UCS stated that in contrast, the OMEGA model takes into account a vehicle’s performance characteristics through response-surface modeling based on relative deviation from the class average modeled in ALPHA.⁴⁷⁶

Although differences between the ALPHA and Autonomie models are discussed in more detail below, for the NPRM vehicle simulation analysis the agencies expanded the number of vehicle classes from the five classes used in the Draft TAR to ten classes, to represent better the diversity of vehicle characteristics across the fleet. Each of these ten vehicle technology classes are empirically built from benchmarking data and other information from various sources, amounting to hundreds of vehicle characteristics data points to develop each vehicle class. The agencies expand on these vehicle classes and characteristics in Section VI.B.3.(a)(2) Vehicle Types in Autonomie and Section VI.B.3.(a)(3) How Vehicle Models are Built in Autonomie and Optimized for Simulation. The agencies believe that the real-world data used to define vehicle characteristics for each of the ten vehicle classes, in addition to the ten vehicle technology classes themselves, ensures the analysis reasonably accounts for the diversity in vehicle characteristics across the fleet.

The agencies believe that UCS’s characterization of how technology improvements are applied in the analysis is a misleading oversimplification. While the analysis approach in the final rule uses a representative effectiveness value, the value is not linked solely to the vehicle technology class, as the UCS implies. The entire technology combination, or technology key, which includes the vehicle technology class, is used to

key specifications which is then available to their subscribers.

determine the value for the platform being considered. Within each vehicle class, the interactions between the added technology and the full vehicle system (including other technologies and substantial road load characteristics) are considered in the effectiveness values calculated for each technology during compliance modeling. As discussed under each of the technology pathways sections, the effectiveness for most technologies is reported as a range rather than a single value. The range exists because the effectiveness for each technology is adjusted based on the technologies it is coupled with and the major road load characteristics of the full vehicle system. This approach, in combination with using the baseline vehicle's initial performance values as a starting point for performance improvement, results in a widely variable level of improvement for the system, dependent on individual vehicle platform characteristics. As a result, the application of a response-surface approach would likely result in minimal improvement in accuracy for the Autonomie and CAFE model analysis approach.

For the final rule analysis, the agencies used the same process to obtain the vehicle attributes and characteristics for the vehicle technology classes. Data was acquired from publicly available sources, Argonne D³, EPA compliance and fuel economy data, and A2mac1 benchmarking data. Accordingly, the attributes and characteristics of the modeled vehicles reflect actual vehicles that meet customer expectations and automakers' capabilities to manufacture the vehicles. In addition, for the final rule, the agencies improved the NPRM analysis by updating some of the attribute values to account for changes in the fleet. For example, the agencies have updated vehicle electrical accessory load on the test cycle to reflect higher electrical loads associated with contemporary vehicle features.

(3) How This Rulemaking Builds Vehicle Models for Autonomie and Optimize Them for Simulation

Before any simulation is initiated in Autonomie, Argonne must "build" a vehicle by assigning reference technologies and initial attributes to the components of the vehicle model representing each technology class.⁴⁷⁷ The reference technologies are baseline technologies that represent the first step on each technology pathway used in the analysis. For example, a compact car is built by assigning it a baseline engine, a baseline 6-speed automatic transmission (AT6), a baseline level of aerodynamic improvement (AERO0), a baseline level of rolling resistance improvement (ROLL0), a baseline level of mass reduction technology (MR0), and corresponding attributes from the Argonne vehicle assumptions database like individual component weights.⁴⁷⁸ A baseline vehicle will have a unique starting point for the simulation and a unique set of assigned inputs and attributes, based on its technology class.

The next step in the process is to run a powertrain sizing algorithm that ensures the built vehicle meets or exceeds defined performance metrics, including low-speed acceleration (*i.e.*, time required to accelerate from 0–60 mph), high-speed passing acceleration (time required to accelerate from 50–80 mph), gradeability (*e.g.* the ability of the vehicle to maintain constant 65 miles per hour speed on a six percent upgrade), and towing capacity. Together, these performance criteria are widely used by industry as metrics to quantify vehicle performance attributes that consumers observe and that are important for vehicle utility and customer satisfaction.

In the compact car example used above, the agencies assigned an initial specific engine design and engine power, transmission, AERO, ROLL, and MR technologies, and other attributes like vehicle weight. If the built vehicle

does not meet all the performance criteria in the first iteration, then the engine power is increased to meet the performance requirement. This increase in power is from higher engine displacement, which could involve an increase in number of cylinders, leading to an increase in the engine weight. The iterative process continues to check whether the compact car with updated engine power, and corresponding updated engine weight, meets its defined performance metrics. The loop stops once all the metrics are met, and at this point, a compact car technology class vehicle model becomes ready for simulation. For further discussion of the vehicle performance metrics, see Section VI.B.3.(a).

Autonomie then adopts a single fuel saving technology to the baseline vehicle model, keeping everything else the same except for that one technology and the attributes associated with it. For example, the model would apply an 8-speed automatic transmission in place of the baseline 6-speed automatic transmission, which would lead to either an increase or decrease in the total weight of the vehicle based on the technology class assumptions. At this point, Autonomie confirms whether performance metrics are met for this new vehicle model through the previously discussed sizing algorithm. Once a technology has been assigned to the vehicle model and the resulting vehicle meets its performance metrics, those vehicle models will be used as inputs to the full vehicle simulations. So, in the example of the 6-speed to 8-speed automatic transmission technology update, the agencies now have the initial ten vehicle models (one for each technology class), plus the ten new vehicle models with the updated 8-speed automatic transmission, which adds up to 20 different vehicle models for simulation. This permutation process is conducted for each of the over 50 technologies considered, and for all ten technology classes, which results in more than one million optimized vehicle models.

Figure VI–3 shows the process for building vehicles in Autonomie for simulation.

⁴⁷⁷ For the NPRM analysis, Chapter 8 Vehicle-Sizing Process in the ANL Model Documentation had discussed this process in detail. Further discussion of this process is located in Chapter 8 of the ANL Model Documentation for this final rule.

⁴⁷⁸ See Section VI.A.7.

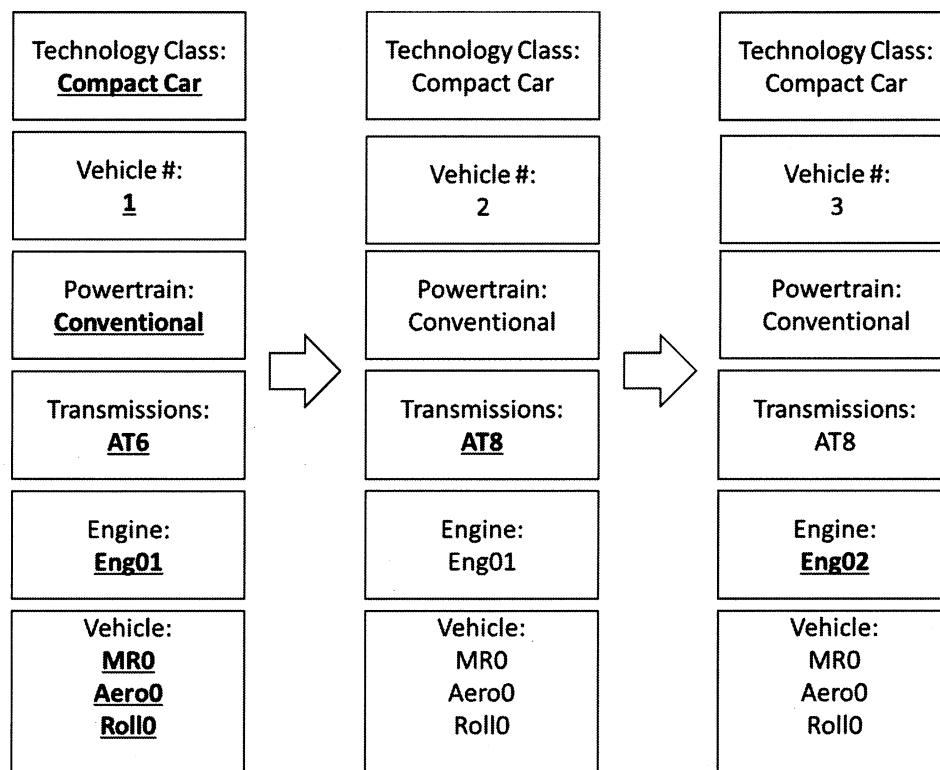

Figure VI-3 – Autonomie Technology Adoption Process for Vehicle building with compact car technology class as an example

Some of the technologies require extra steps for optimization before the vehicle models are built for simulation; for example, the sizing and optimization process is more complex for the electrified vehicles (*i.e.*, HEVs, PHEVs) compared to vehicles with internal combustion engines, as discussed further, below. Throughout the vehicle building process, the following items are considered for optimization:

- Vehicle weight is decreased or increased in response to switching from one type of technology to another for the technologies for which the agencies consider weight, such as different engine and transmission types;
- Vehicle performance is decreased or increased in response to the addition of mass reduction technologies when switching from one vehicle model to another vehicle model for the same engine;
- Vehicle performance is decreased or increased in response to the addition of a new technology when switching from one vehicle model to another vehicle

model for the same hybrid electric machine; and

- Electric vehicle battery size is decreased or increased in response to the addition of mass, aero and/or tire rolling resistance technologies when switching from one vehicle model to another vehicle model.

Every time a vehicle adopts a new technology, the vehicle weight is updated to reflect the new component weight. For some technologies, the direct weight change is easy to assess. For example, in the NPRM the agencies designated weights for transmissions so, when a vehicle is updated to a higher geared transmission, the weight of the original transmission is replaced with the corresponding transmission weight (*e.g.*, the weight of a vehicle moving from a 5-speed automatic transmission to an 8-speed automatic transmission will be updated based on the 8-speed transmission weight).

For other technologies, like engine technologies, assessing the updated vehicle weight is much more complex. Discussed earlier, modeling a change in

engine technology involves both the new technology adoption and a change in power (because the reduction in vehicle weight leads to lower engine loads, and a resized engine). When a new engine technology is adopted on a vehicle the agencies account for the associated weight change to the vehicle based on the earlier discussed regression analysis of weight versus power. For the NPRM engine weight regression analysis, the agencies considered 19 different engine technologies that consisted of unique components to achieve fuel economy improvements. This regression analysis is technology agnostic by taking the approach of using engine peak power versus engine weight because it removed biases to any specific engine technology in the analysis. Although the agencies do not estimate the specific weight for each individual engine technology, such as VVT and SGDI, this process provides a reasonable estimate of the weight differences among engine technologies.

Figure VI-4 – Engine weight determination as function of power and type of air induction (naturally aspirated vs turbocharged)

For the final rule analysis, the agencies used the same process to assign initial weights to the original 19 engines, plus the added engines. However, the agencies improved upon precision of the weights by creating two separate curves separately to represent naturally aspirated engine designs and turbocharged engine designs.⁴⁷⁹ This update resulted in two benefits. First, small naturally aspirated 4-cylinder engines that adopted turbocharging technology reflected the increased weight of associated components like ducting, clamps, the turbocharger itself, a charged air cooler, wiring, fasteners, and a modified exhaust manifold. Second, larger cylinder count engines like naturally aspirated 8-cylinder and 6-cylinder engines that adopted turbocharging and downsized technologies would have lower weight due to having fewer engine cylinders. For example, a naturally aspirated 8-cylinder engine that adopts turbocharging technology when downsized to a 6-cylinder turbocharged engine appropriately reflects the added weight of turbocharging components, and the lower weight of fewer cylinders.

As with conventional vehicle models, electrified vehicle models were built from the ground up. For the NPRM analysis, Argonne used data from the A2mac1 database and vehicle test data to define different attributes like weights and power. Argonne used one

electric motor specific power for each type of hybrid and electric vehicle.⁴⁸⁰ For MY2017, the U.S. market has an expanded number of available hybrid and electric vehicle models. To capture appropriately the improvements for electrified vehicles for the final rule analysis, the agencies applied the same regression analysis process that considers electric motor weight versus electric motor power for vehicle models that have adopted electric motors. Benchmarking data for hybrid and electric vehicles from the A2Mac1 database was analyzed to develop a regression curve of electric motor peak power versus electric motor weight.⁴⁸¹

(4) How Autonomie Sizes Powertrains for Full Vehicle Simulation

The agencies maintain performance neutrality of the full vehicle simulation analysis by resizing engines, electric machines, and hybrid electric vehicle battery packs at specific incremental technology steps. To address product complexity and economies of scale, engine resizing is limited to specific incremental technology changes that would typically be associated with a major vehicle or engine redesign.⁴⁸²

⁴⁸⁰ NHTSA–2018–0067–0005. ANL Autonomie Model Assumptions Summary. Aug 21, 2018. Non_Vehicle_Attributes tab. Specific power for PS and P2 HEVs was set to 2750 watts/kg, plug-in HEVs were set to 375 watts/kg, and electric vehicles were set to 1400 watts/kg.

⁴⁸¹ ANL Model Documentation for the final rule analysis, Chapter 5.2.10 Electric Machines System Weight.

⁴⁸² See 83 FR 43027 (Aug. 24, 2018).

Manufacturers have repeatedly told the agencies that the high costs for redesign and the increased manufacturing complexity that would result from resizing engines for small technology changes preclude them from doing so. It would be unreasonable and unaffordable to resize powertrains for every unique combination of technologies, and exceedingly so for every unique combination of technologies across every vehicle model due to the extreme manufacturing complexity that would be required to do so. The agencies reiterated in the NPRM that the analysis should not include engine resizing with the application of every technology or for combinations of technologies that drive small performance changes so that the analysis better reflects what is feasible for manufacturers.⁴⁸³

When a powertrain does need to be resized, Autonomie attempts to mimic manufacturers' development approaches to the extent possible. Discussed earlier, the Autonomie vehicle building process is initiated by building a baseline vehicle model with a baseline engine, transmission, and other baseline vehicle technologies. This baseline vehicle model (for each technology class) is sized to meet a specific set of

⁴⁸³ For instance, a vehicle would not get a modestly bigger engine if the vehicle comes with floor mats, nor would the vehicle get a modestly smaller engine without floor mats. This example demonstrates small levels of mass reduction. If manufacturers resized engines for small changes, manufacturers would have dramatically more part complexity, potentially losing economies of scale.

⁴⁷⁹ ANL Model Documentation for the final rule analysis, Chapter 5.2.9 Engine Weight Determination.

performance criteria, including acceleration and gradeability.

The modeling also accounts for the industry practice of platform, engine, and transmission sharing to manage component complexity and the associated costs.⁴⁸⁴ At a vehicle refresh cycle, a vehicle may inherit an already resized powertrain from another vehicle within the same engine-sharing platform that adopted the powertrain in an earlier model year. In the Autonomie modeling, when a new vehicle adopts fuel saving technologies that are inherited, the engine is not resized (the properties from the baseline reference vehicle are used directly and unchanged) and there may be a small change in vehicle performance. For example, in Figure VI-3, Vehicle 2 inherits Eng01 from Vehicle 1 while updating the transmission. Inheritance of the engine with new transmission may change performance. This example illustrates how manufacturers generally manage manufacturing complexity for engines, transmissions, and electrification technologies.

Autonomie implements different powertrain sizing algorithms depending on the type of powertrain being considered because different types of powertrains contain different components that must be optimized.⁴⁸⁵

For example, the conventional powertrain resizing considers the reference power of the conventional engine (e.g., Eng01, a basic VVT engine, is rated at 108 kilowatts and this is the starting reference power for all technology classes) against the power-split hybrid (SHEVPS) resizing algorithm that must separately optimize engine power, battery size (energy and power), and electric motor power. An engine's reference power rating can either increase or decrease depending on the architecture, vehicle technology class, and whether it includes other advanced technologies.

Performance requirements also differ depending on the type of powertrain because vehicles with different powertrain types may need to meet different criteria. For example, a plug-in hybrid electric vehicle (PHEV) powertrain that is capable of traveling a certain number of miles on its battery energy alone (referred to as all-electric range, or AER, or as performing in electric-only mode) is also sized to ensure that it can meet the performance requirements of a US06 cycle in electric-only mode.

The powertrain sizing algorithm is an iterative process that attempts to optimize individual powertrain components at each step. For example, the sizing algorithm for conventional powertrains estimates required power to meet gradeability and acceleration performance and compares it to the reference engine power for the technology class. If the power required to meet gradeability and acceleration performance exceeds the reference

engine power, the engine power is updated to the new value. Similarly, if the reference engine power exceeds the gradeability and acceleration performance power, it will be decreased to the lower power rating. As the change in power requires a change design of the engine, like increasing displacement (e.g., going from a 5.2-liter to 5.6-liter engine, or vice versa) or increasing cylinder count (e.g., going from an I4 to a V6 or vice versa), the engine weight will also change. The new engine power is used to update the weight of the engine.

Next, the conventional powertrain sizing algorithm enters an acceleration algorithm loop to verify low-speed acceleration performance (time it takes to go from 0 mph to 60 mph). In this step, Autonomie adjusts engine power to maintain a performance attribute for the given technology class and updates engine weight accordingly. Once the performance criteria are met, Autonomie ends the low-speed acceleration performance algorithm loop and enters a high-speed acceleration (time it takes to go from 50 mph to 80 mph) algorithm loop. Again, Autonomie might need to adjust engine power to maintain a performance attribute for the given technology, and it exits this loop once the performance criteria have been met. At this point, the sizing algorithm is complete for the conventional powertrain based on the designation for engine type, transmissions type, aero type, mass reduction technology and low rolling resistance technology.

Figure VI-5 below shows the sizing algorithm for conventional powertrains.

⁴⁸⁴ Ford EcoBoost Engines are shared across ten different models in MY2019. <https://www.ford.com/powertrains/ecoboost/>. Last accessed Nov. 05, 2019.

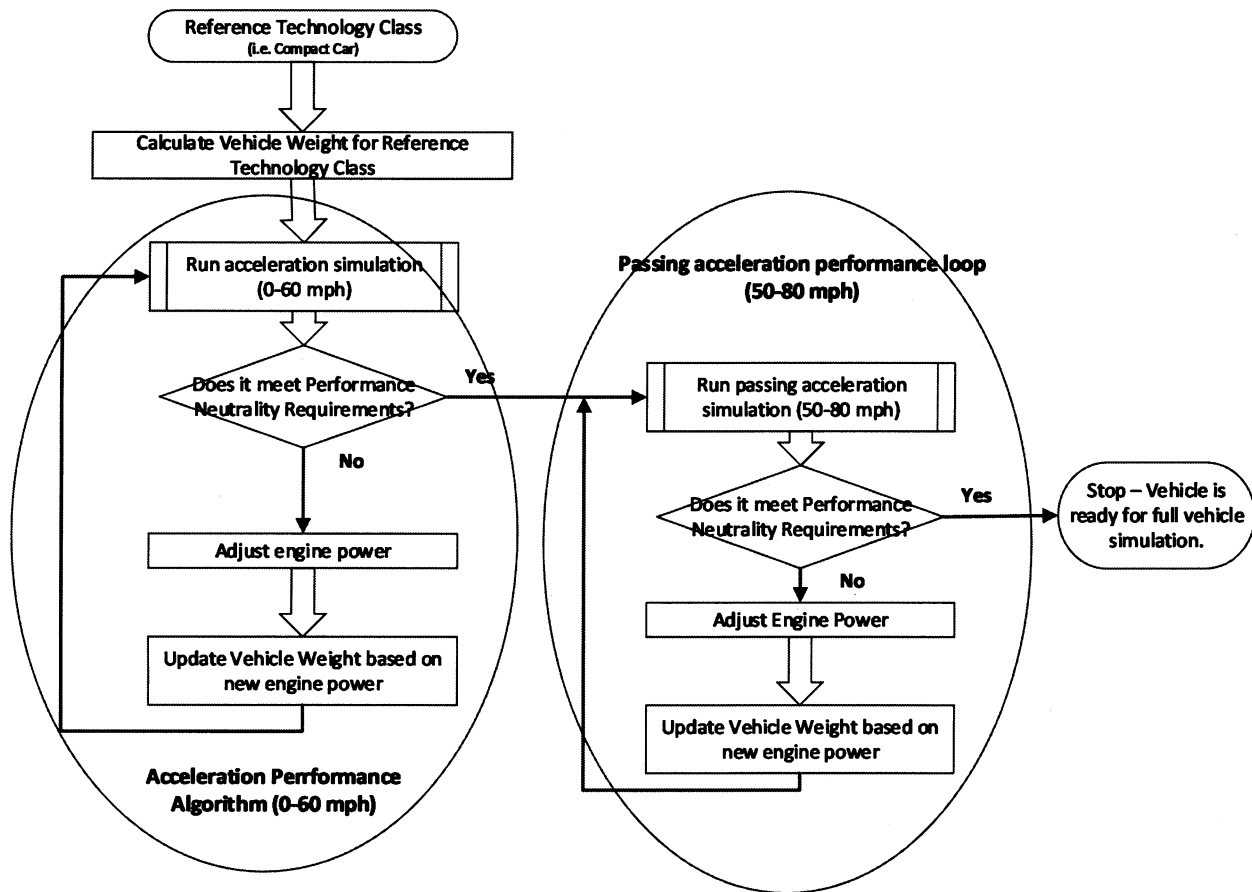

Figure VI-5 – Conventional powertrain sizing algorithm

Depending on the type of powertrain considered, the sizing algorithms may also size to meet different performance criteria in different order. The powertrain sizing algorithms for electrified vehicles are considerably more complex, and are discussed in further detail in Section VI.C.3, below.

(5) How the Agencies Considered Maintaining Vehicle Attributes

For this rulemaking analysis, consistent with past CAFE and CO₂

rulemakings, the agencies have analyzed technology pathways manufacturers could use for compliance that attempt to maintain vehicle attributes, utility, and performance. Using this approach allows the agencies to assess costs and benefits of potential standards under a scenario where consumers continue to get the similar vehicle attributes and features, other than changes in fuel economy. The purpose of constraining vehicle attributes is to simplify the analysis and reduce variance in other

attributes that consumers value across the analyzed regulatory alternatives. This allows for a more streamlined accounting of costs and benefits by not requiring the values of other vehicle attributes that trade off with fuel economy.

Several examples of vehicle attributes, utility and performance that could be impacted by adoption of fuel economy improving technology include the following.

Table VI-22 – Vehicle Attributes that Could be Impacted by Fuel Economy Improving Technologies

| Vehicle Attribute | Impacted by Fuel Economy Improving Technologies |
|-------------------------------------|--|
| Interior volume | Electrification, aerodynamics |
| Cargo/trunk space | Electrification, aerodynamics |
| Heater/defroster performance | Engine, transmission, start-stop |
| Air conditioning system performance | Air conditioning system, start-stop |
| Drivability | Engine, transmission |
| Idle quality | Engine, transmission |
| Noise | Engine, transmission, mass reduction |
| Vibration | Engine, transmission, mass reduction |
| Harshness | Engine, transmission, mass reduction, tires |
| Ride quality | Mass reduction, tires |
| Handling | Mass reduction, tires |
| Braking | Brake drag, tires |
| Steering feel | Electric power steering, tires |
| Turning circle | Footprint |
| 0 - 60 mph acceleration | Engine, transmission, electrification, mass reduction, aero, tires |
| Passing acceleration | Engine, transmission, electrification, mass reduction, aero, tires |
| Gradeability | Engine, transmission, electrification, mass reduction, aero, tires |
| Towing capacity | Engine, transmission, electrification, mass reduction, aero |
| Launch acceleration feel | Engine, transmission, electrification, mass reduction |
| Styling | Aero, engine, transmission, electrification |
| Driving range | Electrification, fuel economy/tank size (mass) |
| Refueling time | Fuel economy/tank size |

Consequences for the agencies not fully considering or accounting for potential changes in vehicle attributes, utility, and performance are degradation in vehicle attributes, utility, and performance that lead to consumer acceptance issues without accounting for the corresponding costs and/or not accounting for the costs of technology designs that maintain vehicle attributes, utility, and performance. The agencies incorporated changes in the NPRM analysis and that are carried into this final rule that address deficiencies in past analyses, including the Draft TAR and Proposed Determination analyses. These changes were discussed in the NPRM and are repeated in the discussion of individual technologies in

this Preamble, the FRIA, and supporting documents. The following are several examples of technologies that did not maintain vehicle attributes, utility, and performance in the Draft TAR and Proposed Determination analyses.

For the EPA Draft TAR and Proposed Determination analyses, HCR engine and downsized and turbocharged engine technologies effectiveness was estimated using Tier 2 certification fuel, which has a higher octane rating compared to regular octane fuel.^{486 487} This does not maintain functionality

⁴⁸⁶ Tier 2 fuel has an octane rating of 93. Typical regular grade fuel has an octane rating of 87 ((R+M)/2 octane).

⁴⁸⁷ EPA Proposed Determination at 2–209 to 2–212.

because consumers would incur higher costs for using premium fuel in order to achieve the modeled fuel economy improvements, compared to baseline engines that were replaced, which operated on lower cost regular octane fuel. By not maintaining the fuel octane functionality and vehicle attributes, the EPA Draft TAR and Proposed Determination analyses applied higher effectiveness for these technologies than could be achieved had regular octane fuel been assumed for the HCR and downsized turbocharged engines. The Draft TAR and Proposed Determination analyses also did not account for the higher costs that would be incurred by consumers to pay for high octane fuel. These issues were addressed in the

NPRM and this final rule analysis, and account for some of the effectiveness and cost differences between the Draft TAR/Proposed Determination and the NPRM/final rule.⁴⁸⁸

Another example is mass reduction technology. As background, the agencies characterize mass reduction as either primary mass reduction or secondary mass reduction. Primary mass reduction involves reducing mass of components that can be done independently of the mass of other components. For example, the mass of a hood (*e.g.*, replacing a steel hood with an aluminum hood) or reducing the mass of a seat are examples of primary mass reduction because each can be implemented independently. When there is a significant level of primary mass reduction, other components that are designed based on the mass of primary components, may be redesigned and have lower mass. An example of secondary mass reduction is the brake system. If the mass of primary components is reduced sufficiently, the resulting lighter weight vehicle could maintain braking performance and attributes, and safety with a lighter weight brake system. Mass reduction in the brake system is secondary mass reduction because it requires primary mass reduction before it can be incorporated. For the EPA Draft TAR and Proposed Determination analyses, secondary mass reduction was applied exclusively based on cost, with no regard to whether sufficient primary mass reduction was applied concurrently. The analyses did not account for the degraded functionality of the secondary components and systems and also understated the costs for lower levels of mass reduction.⁴⁸⁹ These issues were addressed in the NPRM and this final rule analysis, and account for some of the cost differences between the Draft TAR/Proposed Determination and the NPRM/final rule.

The agencies note that for some technologies it is not reasonable or practicable to match exactly the baseline vehicle's attributes, utility, and performance. For example, when engines are resized to maintain acceleration performance, if the agencies applied a criterion that allowed no shift in performance whatsoever, there would be an extreme proliferation of unique engine displacements. Manufacturers have repeatedly and consistently told the agencies that the high costs for redesign and the increased manufacturing complexity

that would result from resizing engines for small technology changes preclude them from doing so. It would be unreasonable and unaffordable to resize powertrains for every unique combination of technologies, and exceedingly so for every unique combination technologies across every vehicle model due to the extreme manufacturing complexity that would be required to do so.⁴⁹⁰ For the NPRM and final rule analyses, engine resizing is limited to specific incremental technology changes that would typically be associated with a major vehicle or engine redesign to address product complexity and economies of scale considerations. The EPA Draft TAR and Proposed Determination analyses adjusted the effectiveness of every technology combination assuming performance could be held constant for every combination, and the analysis did not recognize or account for the extreme complexity nor the associated costs for that impractical assumption. The NPRM and final rule analyses account for these real-world practicalities and constraints, and doing so explains some of the effectiveness and cost differences between the Draft TAR/Proposed Determination and the NPRM/final rule.

The subsections for individual technologies discuss the technology assumptions and constraints that were considered to maintain vehicle attributes, utility, and performance as closely as possible. The agencies believe that any minimal remaining differences, which may directionally either improve or degrade vehicle attributes, utility and performance are small enough to have *de minimis* impact on the analysis.

(6) How the Agencies Considered Performance Neutrality

The CAFE model examines technologies that can improve fuel economy and reduce CO₂ emissions. An improvement in efficiency can be realized by improving the powertrain that propels the vehicle (*e.g.*, replacing a 6-cylinder engine with a smaller, turbocharged 4-cylinder engine), or by reducing the vehicle's loads or burdens (*e.g.*, lowering aerodynamic drag, reducing vehicle mass and/or rolling resistance). Either way, these changes reduce energy consumption and create a range of choices for automobile manufacturers. At the two ends of the range, the manufacturer can choose either:

(A) *To design a vehicle that does same the amount of work as before but uses less fuel.*

For example, a redesigned pickup truck would receive a turbocharged V6 engine in place of the outgoing V8. The pickup would offer no additional towing capacity, acceleration, larger wheels and tires, expanded infotainment packages, or customer convenience features, but would achieve a higher fuel economy rating (and correspondingly lower CO₂ emissions).

(B) *To design a vehicle that does more work and uses the same amount of fuel as before.*

For example, a redesigned pickup truck would receive a turbocharged V6 engine in place of the outgoing V8, but with engine efficiency improvements that allow the same amount of fuel to do more work. The pickup would offer improved towing capacity, improved acceleration, larger wheels and tires, an expanded (heavier) infotainment package, and more convenience features, while maintaining (not improving) the fuel economy rating of the previous year's model.

In other words, automakers weigh the trade-offs between vehicle performance/utility and fuel economy, and they choose a blend of these attributes to balance meeting fuel economy and emissions standards and suiting the demands of their customers.

Historically, vehicle performance has improved over the years. The average horsepower is the highest that it has ever been; all vehicle types have improved horsepower by at least 49 percent compared to the 1975 model year, and pickup trucks have improved by 141 percent.⁴⁹¹ Since 1978, the 0–60 acceleration time of vehicles has improved by 39–47 percent depending on vehicle type.⁴⁹² Also, to gain consumer acceptance of downsized turbocharged engines, manufacturers have stated they often offer an *increase* in performance.⁴⁹³ Fuel economy has also improved, but the horsepower and acceleration trends show that not 100 percent of technological improvements have been applied to fuel savings. While future trends are uncertain, the past trends suggest vehicle performance is unlikely to *decrease*, as it seems reasonable to assume that customers

⁴⁹⁰ For more details, see Section VI.B.3.a)(6) Performance Neutrality.

will at a minimum demand vehicles that offer the same utility as today's fleet.

For this rulemaking analysis, consistent with past CAFE and CO₂ rulemakings, the agencies have analyzed technology pathways manufacturers could use for compliance that attempt to maintain vehicle attributes, utility and performance. NHTSA's analysis in the Draft TAR used the same approach for performance neutrality as was used for the NPRM and is being carried into this final rule. This approach is described throughout this section and further in FRIA Section VI. For the Draft TAR and Proposed Determination, the EPA analyses used an approach that maintained 0–60 mph acceleration time for every technology package. However, that approach did not account for the added development, manufacturing, assembly and service parts complexity and associated costs that would be incurred by manufacturers to produce the substantial number of engine variants that would be required to achieve those CO₂ improvements.⁴⁹⁴ Using the NPRM approach, which is carried into this final rule, allows the agencies to assess costs and benefits of potential standards under a scenario where consumers continue to get the same vehicle attributes and features, other than changes in fuel economy (approaching the scenario in example “A” above). This approach also eliminates the need to assess the value of changes in vehicle attributes and features. As discussed later in this section, while some small level of performance increase is unavoidable when conducting this type of analysis, the added technology results almost exclusively in improved fuel economy. This allows the cost of these technologies to reflect almost entirely the cost of compliance with standards with nearly neutral vehicle performance.

The CAFE model maintains the initial performance and utility levels of the analysis vehicle fleet, while considering real world constraints faced by manufacturers.

To maintain performance neutrality when applying fuel economy technologies, it is first necessary to characterize the performance levels of each of the nearly 3000 vehicle models in the MY 2017 baseline fleet. As discussed in Section VI.B.1.b) Assigning Vehicle Technology Classes, above, each individual vehicle model in the analysis fleet was assigned to one of ten vehicle

“technology classes”—the class that is most similar to the vehicle model. The technology classes include five standard class vehicles (compact car, midsize car, small SUV, midsize SUV, pickup) plus five “performance” versions of these same body styles.⁴⁹⁵ Each vehicle class has a unique set of attributes and characteristics, including vehicle performance metrics, that describe the typical characteristics of the vehicles in that class.

The analysis used four criteria to characterize vehicle performance attributes and utility:

- Low-speed acceleration (time required to accelerate from 0–60 mph)
- High-speed acceleration (time required to accelerate from 50–80 mph)
- Gradeability (the ability of the vehicle to maintain constant 65 miles per hour speed on a six percent upgrade)
- Towing capacity

Low-speed and high-speed acceleration target times are typical of current production vehicles and range from 6 to 10 seconds depending on the vehicle class; for example, the midsize SUV performance class has a low- and high-speed acceleration target of 7 seconds.⁴⁹⁶ The gradeability criterion requires that the vehicle, given its attributes of weight, engine power, and transmission gearing, be capable of maintaining a minimum of 65 mph while going up a six percent grade. The towing criterion, which is applicable only to the pickup truck and performance pickup truck vehicle technology classes, is the same as the gradeability requirement but adds an additional payload/towing mass (3,000 lbs. for pickups, or 4,350 lbs for performance pickups) to the vehicle, essentially making the vehicle heavier.

In addition, to maintain the capabilities of certain electrified vehicles in the 2017 baseline fleet, the analysis required that those vehicles be capable of achieving the accelerations and speeds of certain standard driving cycles. The agencies use the US06 “aggressive driving” cycle and the UDDS “city driving” cycle to ensure that core capabilities of BEVs and PHEVs, such as driving certain speeds and/or distances in electric-only mode, are maintained. In addition to the four criteria discussed above, the following

⁴⁹⁵ Separate technology classes were created for high performance and low performance vehicles to better account for performance diversity across the fleet.

⁴⁹⁶ Note, for all vehicle classes, the low and high-speed acceleration targets use the same value. See section VI.B.1.b)(1) Assigning Vehicle Technology Classes for a list of low-speed acceleration target by vehicle technology class.

performance criteria are applied to these electrified vehicles:

- Battery electric vehicles (BEV) are sized to be capable of completing the US06 “aggressive driving” cycle.

- Plug-in hybrid vehicles with 50 mile all-electric range (PHEV50) are sized to be capable of completing the US06 “aggressive driving” cycle in electric-only mode.

- Plug-in hybrid vehicles with 20 mile all-electric range (PHEV20) are sized to be capable of completing the UDDS “city driving” cycle in electric-only (charge depleting) mode.⁴⁹⁷

Together, these performance criteria are widely used by industry as metrics to quantify vehicle performance attributes that consumers observe and that are important for vehicle utility and customer satisfaction.⁴⁹⁸

When certain fuel-saving technologies are applied that affect vehicle performance to a significant extent, such as replacing a pickup truck's V8 engine with a turbocharged V6 engine, iterative resizing of the vehicle powertrain (engine, electric motors, and/or battery) is performed in the Autonomie simulation such that the above performance criteria is maintained. For example, if the aforementioned engine replacement caused an improvement in acceleration, the engine may be iteratively resized until vehicle acceleration performance is shifted back to the initial target time for that vehicle technology class. For the low and high-speed acceleration criteria, engine resizing iterations continued until the acceleration time was within plus or minus 0.2 seconds of the target time,^{499 500} which is judged to balance

⁴⁹⁷ PHEV20's are blended-type plug-in hybrid vehicles, which are capable of completing the UDDS cycle in charge depleting mode without assistance from the engine. However, under higher loads, this charge depleting mode may use supplemental power from the engine.

Rousseau, 2018a, An Extensive Study on Vehicle Sizing, Energy Consumption and Cost of Advance Vehicle Technologies, Report No. ANL/ESD-17/17, Argonne National Laboratory, Lemont, Ill., Oct 2018.

⁴⁹⁹ For example, if a vehicle has a target 0–60 acceleration time of 6 seconds, a time within 5.8–6.2 seconds was accepted.

⁵⁰⁰ With the exception of a few performance electrified vehicle types which, based on observations in the marketplace, use different criteria to maintain vehicle performance without battery assist. Performance PHEV20, and Performance PHEV50 resize to the performance of a conventional six-speed automatic (CONV 6AU).

Continued

⁴⁹⁴ Each variant would require a unique engine displacement, requiring unique internal engine components, such as crankshaft, connecting rods and others.

reasonably the precision of engine resizing with the number of simulation iterations needed to achieve performance within the 0.2 second window, and the associated computer resources and time required to perform the iterative simulations. Engine resizing is explained further in Section VI.B.3.a)(4) How Autonomie Sizes Powertrains for Full Vehicle Simulation and the Argonne Model Documentation for the final rule analysis.

The Autonomie simulation resizes until the least capable of the performance criteria is met, to ensure the pathways do not degrade any of the vehicle performance metrics. It is possible that as one criterion target is reached after the application of a specific technology or technology package, other criteria may be better than their target values. For example, if the engine size is decreased until the low speed acceleration target is just met, it is possible that the resulting engine size would cause high speed acceleration performance to be better than its target.⁵⁰¹ Or, a PHEV50 may have an electric motor and battery appropriately sized to operate in all electric mode through the repeated accelerations and high speeds in the US06 driving cycle, but the resulting motor and battery size enables the PHEV50 slightly to over-perform in 0–60 acceleration, which utilizes the power of both the electric motor and combustion engine.

To address product complexity and economies of scale, engine resizing is limited to specific incremental technology changes that would typically be associated with a major vehicle or engine redesign.⁵⁰² Manufacturers have repeatedly and consistently told the agencies that the high costs for redesign and the increased manufacturing complexity that would result from resizing engines for small technology changes preclude them from doing so. It would be unreasonable and unaffordable to resize powertrains for every unique combination of technologies, and exceedingly so for every unique combination technologies across every vehicle model due to the extreme manufacturing complexity that would be required to do so. Engine displacements are further described in Section VI.C.1 Engine Paths.

Performance SHEVP2, engines/electric-motors were resized if the 0–60 acceleration time was worse than the target, but not resized if the acceleration time was better than the target time.

⁵⁰¹ The Autonomie simulation databases include all of the estimated performance metrics for each combination of technology as modeled.

⁵⁰² See 83 FR 43027 (Aug. 24, 2018).

To address this issue, and consistent with past rulemakings, the NPRM simulation allowed engine resizing when mass reductions of 7.1 percent, 10.7 percent, 14.2 percent (and 20 percent for the final rule analysis) were applied to the vehicle curb weight,⁵⁰³ and when one powertrain architecture was replaced with another architecture during a redesign cycle.⁵⁰⁴ At its refresh cycle, a vehicle may also inherit an already resized powertrain from another vehicle within the same engine-sharing platform. The analysis did not re-size the engine in response to adding technologies that have smaller effects on vehicle performance. For instance, if a vehicle's curb weight is reduced by 3.6 percent (MR1), causing the 0–60 mile per hour time to improve slightly, the analysis would not resize the engine. The criteria for resizing used for the analysis better reflects what is feasible for manufacturers to do.⁵⁰⁵

Automotive manufacturers have commented that the CAFE model's consideration of the constraints faced in relation to vehicle performance and economies of scale are realistic.

Industry associations and individual manufacturers widely supported the use of the performance metrics used in the NPRM analysis, the use of standard and higher performance technology classes, and the representation in the analysis of the real-world manufacturing complexity constraints and criteria for powertrain redesign.

The Alliance of Automobile Manufacturers (Alliance), Ford, and Toyota stated that the inclusion of additional performance metrics such as gradeability are appropriate. Specifically in support of the gradeability performance criteria, the Alliance commented that “performance metrics related to vehicle operation in top gear are just as critical to customer acceptance as are performance metrics

⁵⁰³ These correspond, respectively, to reductions of 10%, 15%, 20%, and 28.2% of the vehicle glider mass. For more detail on glider mass calculation, see section VI.C.4 Mass Reduction.

⁵⁰⁴ Some engine and accessory technologies may be added to an engine without an engine architecture change. For instance, manufacturers may adapt, but not replace engine architectures to include cylinder deactivation, variable valve lift, belt-integrated starter generators, and other basic technologies. However, switching from a naturally aspirated engine to a turbo-downsized engine is an engine architecture change typically associated with a major redesign and radical change in engine displacement.

⁵⁰⁵ For instance, a vehicle would not get a modestly bigger engine if the vehicle comes with floor mats, nor would the vehicle get a modestly smaller engine without floor mats. This example demonstrates small levels of mass reduction. If manufacturers resized engines for small changes, manufacturers would have dramatically more part complexity, potentially losing economies of scale.

such as 0–60 mph times that focus on performance in low-gear ranges.”⁵⁰⁶ The Alliance also commented specifically on the relationship between gradeability and downsized engines, stating that as “engine downsizing levels increase, top-gear gradeability becomes more and more important,” and further that the consideration of gradeability “helps prevent the inclusion of small displacement engines that are not commercially viable and that would artificially inflate fuel savings.”⁵⁰⁷

Ford and Toyota similarly commented in support of the CAFE model's consideration of multiple performance criteria. Ford stated that this model “takes a more realistic approach to performance modeling” and “better replicates OEM attribute-balancing practices.” Ford stated furthermore that “OEMs must ensure that each individual performance measure—and not an overall average—meets its customer's requirements,” and that, in contrast, previous analyses did “not align with product planning realities.”⁵⁰⁸ Toyota commented in support of including gradeability as a performance metric “to avoid underpowered engines and overestimated fuel savings.”⁵⁰⁹

Toyota and the Alliance commented that the inclusion of performance vehicle classes addressed the market reality that some consumers will purchase vehicles for their performance attributes and will accept the corresponding reduction in fuel economy. Furthermore, Toyota commented that most consumers consider more than just fuel economy when purchasing a vehicle, and that “dedicating all powertrain improvements to fuel efficiency is inconsistent with market reality.” Toyota “supports the agencies’ inclusion of performance classes in compliance modeling where a subset of certain models is defined to have higher performance and a commensurate reduction in fuel efficiency.”⁵¹⁰ Also in support of the addition of performance vehicle classes, the Alliance commented that “vehicle categories have been increased to 10 to better recognize the range of 0–60 performance

⁵⁰⁶ Alliance of Automobile Manufacturers, Attachment “Full Comment Set,” Docket No. NHTSA–2018–0067–12073, at 139.

⁵⁰⁹ Toyota, Attachment 1, Docket No. NHTSA–2018–0067–12098, at 6.

⁵¹⁰ Toyota, Attachment 1, Docket No. NHTSA–2018–0067–12098, at 6.

characteristics within each of the 5 previous categories, in recognition of the fact that many vehicles in the baseline fleet significantly exceeded the previously assumed 0–60 performance metrics. This provides better resolution of the baseline fleet and more accurate estimates of the benefits of technology.”⁵¹¹

Toyota also commented in support of various real-world manufacturing complexity constraints employed in the analysis for powertrain redesigns. Toyota commented that model parameters such as redesign cycles and engine sharing across vehicle models place a more realistic limit on the number of engines and transmissions that a manufacturer is capable of introducing. Toyota also commented in support of the constraints that the CAFE model placed on engine resizing, stating that “there are now more realistic limits placed on the number of engines and transmissions in a powertrain portfolio which better recognizes [how] manufacturers must manage limited engineering resources and control supplier, production, and service costs. Technology sharing and inheritance between vehicle models tends to limit the rate of improvement in a manufacturer’s fleet.” Toyota pointed out that this is in contrast to previous analyses in which resizing was too unconstrained, which created an “unmanageable number of engine configurations within a vehicle platform” and spawned cases where “engine downsizing and power reduction sometimes exceeded limits beyond basic acceleration requirements needed for vehicle safety and customer satisfaction.”⁵¹²

The above comments from the Alliance, Ford, and Toyota support the methodologies the agencies employed to conduct a performance neutral analysis. These methodologies helped to ensure that multiple performance criteria, including gradeability, are all individually accounted for and maintained when a vehicle powertrain is resized, and that real-world manufacturing complexity constraints are factored in to the agencies’ analysis of feasible pathways manufacturers could take to achieve compliance with CAFE standards. The agencies continue to believe this is a reasonable approach for the aforementioned reasons.

Environmental advocacy groups and CARB criticized the CAFE model’s

⁵¹¹ Alliance of Automobile Manufacturers, Attachment “Full Comment Set,” Docket No. NHTSA–2018–0067–12073, at 135.

⁵¹² Toyota, Attachment 1, Docket No. NHTSA–2018–0067–12098, at 6.

engine resizing constraints and how they affected the acceleration performance criteria.

CARB, The International Council on Clean Transportation (ICCT), the Union of Concerned Scientists (UCS), and the American Council for an Energy-Efficient Economy (ACEEE) commented that the CAFE model was not performance neutral, allowing an improvement in performance which reduced the effectiveness of applied fuel-saving technologies and/or increased the cost of compliance. Specifically, ACEEE stated that there appeared to be a shortfall in the fuel economy effectiveness of technology packages, potentially resulting from the effectiveness being “consumed” by additional vehicle performance rather than improvement of fuel economy. Several of these same commenters conducted analyses attempting to quantify the magnitude of these changes in vehicle performance for various vehicle technology classes.

CARB commented on the performance shift of several vehicle types. Analyzing the 0–60 acceleration for the medium car non-performance technology class and looking at all cases with resized engines, CARB claimed that “effectively half of the simulations resulted in improved performance.”⁵¹³ Focusing on electrified vehicles in that same technology class, CARB stated that “the data from the Argonne simulations shows that 76 of the 88 strong electrified packages (including P2HPV, SHEVPS, BEV, FCEV, PHEV), where Argonne purposely resized the system to maintain performance neutrality, resulted in notably faster 0 to 60 mph acceleration times and passing times.” Specifically regarding parallel hybrid electric vehicles (SHEVP2), CARB stated that all modeled packages resulted in improved performance.⁵¹⁴ UCS commented that the NPRM analysis allowed too much change in vehicle performance, stating that “while some performance creep may be reasonable” many performance values show “an overlap between performance and non-performance vehicles” within the compact car technology class.⁵¹⁵

The agencies carefully considered these comments. For the NPRM analysis, the SHEVP2 engines/electric-

motors were resized if the 0–60 acceleration time was worse than the target, but not resized if the acceleration time was better than the target. This approach maintained vehicle performance with a depleted battery (without electric assist) in order to maintain fully the performance and utility characteristics under all conditions, and improved performance when electric assist was available (when the battery is not depleted), such as during the 0–60 mph acceleration. The agencies found that this resulted in some parallel hybrid vehicles having improved 0–60 acceleration times. This approach was initially chosen for the NPRM because the resulting level of improved performance was consistent with observations of how industry had applied SHEVP2 technology. However, in assessing the CARB comment, the agencies balanced the NPRM approach for SHEVP2 performance with the agencies’ criteria of maintaining vehicle functionality and performance when technology is applied. Both could not be fully achieved under all conditions for the case of the SHEVP2.

The agencies concluded it is reasonable to maintain performance including electric assist when SHEVP2 technology is applied to a standard (non-performance) vehicle, and therefore the analysis for the final rule allows upsizing *and* downsizing of the parallel hybrid powertrain (SHEVP2) using the 0.2 seconds window around the target.⁵¹⁶ For performance vehicles, the agencies concluded that it remains reasonable to maintain vehicle performance with a depleted battery (without electric assist) in order to maintain fully the performance characteristics under all conditions, and continued to use the NPRM methodology.

The refinement for the standard performance SHEVP2 resolved the electrified packages issue identified by CARB, and also addressed most of the change in performance in the overall fleet, including with compact cars as mentioned by UCS. As explained further below, the agencies assessed performance among the alternatives for the final rule analysis. That assessment showed that, with the final rule refinements, 245 out of 255 total resized vehicles (96 percent of vehicles) in the medium non-performance class (same

⁵¹³ California Air Resources Board, Attachment 2, Docket No. NHTSA–2018–0067–11873, at 180. Note that the target acceleration time for medium car non-performance is in fact 9.0 seconds, as indicated in ANL documentation, but was incorrectly reported as 9.4s in NPRM table II–7 in the NPRM.

⁵¹⁴ California Air Resources Board, Attachment 2, Docket No. NHTSA–2018–0067–11873, at 186.

⁵¹⁵ Union of Concerned Scientists, Attachment 2, Docket No. NHTSA–2018–0067–12039, at 24.

⁵¹⁶ To represent marketplace trends better, the performance class of SHEVP2’s allow acceleration time below 0.2 seconds less than the target, and PHEV20’s and PHEV50’s inherit combustion engine size from the conventional powertrain they are replacing. Further discussion of resizing targets can be found in Chapter 8 of the ANL Model Documentation for the final rule analysis.

class focused on by CARB), had 0–60 mph acceleration times within the plus-or-minus 0.2 second window (8.8 to 9.2 seconds).⁵¹⁷ The only vehicles outside the window were certain strong electrified vehicles which exceeded 0–60 the acceleration target as a result of achieving other performance criteria, such as the US06 driving cycles in all-electric-mode.⁵¹⁸

The assessment also showed that for the small car class (mentioned by UCS) the acceleration times of performance and non-performance vehicles do not go beyond each other's targets. For example, the vehicle in the small car class with the very best 0–60 mph time and a conventional powertrain achieves an 8.38 second 0–60 mph time, which is slower than the performance small car baseline of 8 seconds. This vehicle had multiple incremental technologies applied, including for example aerodynamic improvements, and has not reached the threshold for engine resizing.⁵¹⁹ After engine resizing, the “fastest” conventional small car has a 0–60 mph time of 9.9 seconds, only 0.1 seconds from the target of 10 seconds.⁵²⁰

CARB also commented on the improvement of “passing times,” or 50–80 mph high-speed acceleration times. As stated above, an improvement in one or more of the performance criteria is an expected outcome when using the rulemaking analysis methodology that resizes powertrains such that there is no degradation in any of the performance metrics. Consistent with past rulemakings, the agencies do not believe it is appropriate for the rulemaking analysis to show pathways that degrade vehicle performance or utility for one or more of the performance criteria, as doing so would adversely impact functional capability of the vehicle and could lead to customer dissatisfaction. The agencies agree there is very small increase in passing performance for some technology combinations, and believe this is an appropriate outcome. High-speed acceleration is rarely the least-capable performance criteria.

CARB, ICCT, UCS, and H-D Systems (HDS), in an attempt to identify a potential cause for changes in performance, commented that the CAFE model should have placed fewer

constraints on engine resizing. CARB and ICCT commented that engine resizing should have been allowed even at low levels of mass reduction. Comments from CARB, UCS, HDS, and ICCT stated that engine resizing should also have been allowed for other incremental technologies, and within their comments they conducted performance analysis of non-resized cases.

CARB claimed that requiring a minimum of 7.1 percent curb weight reduction before engine resizing is a constraint that “limits the optimization of the technologies being applied.”⁵²¹ UCS stated that “a significant share of the benefit of a few percent reduction in mass has gone towards improved performance rather than improved fuel economy, leaving a substantial benefit of mass reduction underutilized and/or uncounted.”⁵²² ICCT also commented that “when vehicle lightweighting is deployed at up to a 7 percent mass reduction, the engine is not resized even though less power would be needed for the lighter vehicle, meaning any such vehicles inherently are higher performance.”⁵²³

UCS and HDS commented on the lack of resizing for technologies other than mass reduction, with HDS stating that “the Agencies incorrectly limited the efficacy of technologies that reduce tractive load because their modeling does not re-optimize engine performance after applying these technologies.”⁵²⁴ CARB also commented that the lack of resizing when a BISG or CISC system is added “results in a less than optimized system that does not take full advantage of the mild hybrid system.” Similarly, ICCT noted a case in which a Dodge RAM “did not apply engine downsizing with the BISG system on that truck, so there are also significant performance benefits that should be accounted for, meaning that for constant-performance the fuel

consumption reduction would be even greater.”⁵²⁵

CARB further commented on the performance improvement in cases without engine resizing by stating that “94 percent of the packages modeled result in improved performance,” and that for these non-resized cases that were actually adopted by a vehicle in the simulation, “fewer than 20 percent maintained baseline performance with gains of 2 percent or less in acceleration time.”⁵²⁶ Referring specifically to non-resized electrified vehicles, CARB also stated that “44,878 of the 53,818 packages, or greater than 83 percent, result in improved performance.”⁵²⁷ CARB also commented that engine sharing across different vehicles within a platform, which in some cases may constrain resizing for a member of that platform, should not dictate that these engines must remain identical in all aspects, and that “this overly restrictive sharing of identical engines newly imposed in the CAFE Model is not consistent with today's industry practices and results in less optimal engine sizing and causes a systematic overestimation of technology costs to meet the existing standards.”⁵²⁸

The agencies note broadly, in response to these comments, that when conducting an analysis which balances performance neutrality against the realities faced by manufacturers, such as manufacturing complexity, economies of scale, and maintaining the full range of performance criteria, it is inevitable to observe at least some minor shift in vehicle performance. For example, if a new transmission is applied to a vehicle, the greater number of gear ratios helps the engine run in its most efficient range which improves fuel economy, but also helps the engine to run in the optimal “power band” which improves performance. Thus, the technology can provide both improved fuel economy and performance. Another example is applying a small amount of mass reduction that improves both fuel economy and performance by a small amount. Resizing the engine to maintain performance in these examples would require a unique engine displacement that is only slightly different than the baseline engine. While engine resizing in these incremental cases could have some small benefit to fuel economy, the

⁵²¹ California Air Resources Board, Attachment 2, Docket No. NHTSA–2018–0067–11873, at 178. Note, a 7.1% curb weight reduction equates to the agencies' third level of mass reduction (MR3); additional discussion of engine resizing for mass reduction can be found in Section VI.B.3.a)(4) Autonomie Sizes Powertrains for Full Vehicle Simulation] and in the ANL Model Documentation for the final rule analysis.

⁵²² Union of Concerned Scientists, Attachment 2, Docket No. NHTSA–2018–0067–12039, at 11.

⁵²⁴ H-D Systems, Attachment 1, Docket No. NHTSA–2018–0067–12395, at 4. For reference, technologies that reduce tractive road load include mass reduction, aerodynamic drag reduction, and tire rolling resistance reduction.

⁵²⁵ International Council on Clean Transportation, Attachment 3, Docket No. NHTSA–2018–0067–11741, at I–24.

⁵²⁶ California Air Resources Board, Attachment 2, Docket No. NHTSA–2018–0067–11873, at 183.

⁵²⁷ California Air Resources Board, Attachment 2, Docket No. NHTSA–2018–0067–11873, at 187.

⁵²⁸ California Air Resources Board, Attachment 2, Docket No. NHTSA–2018–0067–11873, at 185.

⁵¹⁷ This includes 135 strong electrified vehicles.

⁵¹⁸ As noted earlier, electrified vehicles had to be capable of successfully completing UDDS or US06 driving cycles in all-electric mode, and in some cases the resulting motor size produced improved acceleration times.

⁵¹⁹ Discussion of engine resizing can be found in Section VI.B.3.a)(5).

⁵²⁰ See NPRM Autonomie simulation database for Small cars, Docket ID NHTSA–2018–0067–1855.

gains may not justify the costs of producing unique niche engines for each combination of technologies. If manufacturers were to produce marginally downsized engines to complement every small increment of mass reduction or technology, the resulting large number of engine variants that would need to be manufactured would cause a substantial increase in manufacturing complexity, and require significant changes to manufacturing and assembly plants and equipment.⁵²⁹ The high costs would be economically infeasible.

Also, as noted in the NPRM, the 2015 NAS report stated that “[f]or small (under 5 percent [of curb weight]) changes in mass, resizing the engine may not be justified, but as the reduction in mass increases (greater than 10 percent [of curb weight]), it becomes more important for certain vehicles to resize the engine and seek secondary mass reduction opportunities.”⁵³⁰ In consideration of both the NAS report and comments received from manufacturers, the agencies determined it would be reasonable to allow allows engine resizing upon adoption of 7.1 percent, 10.7 percent, 14.2 percent, and 20 percent curb weight reduction, but not at 3.6 percent and 5.3 percent.⁵³¹ Resizing is also allowed upon changes in powertrain type or the inheritance of a powertrain from another vehicle in the same platform. The increments of these higher levels of mass reduction, or complete powertrain changes, more appropriately match the typical engine displacement increments that are available in a manufacturer’s engine portfolio.

The agencies point to the comments from manufacturers, discussed further above, which support the agencies’ assertion that the CAFE model’s resizing constraints are appropriate. As discussed previously, Toyota commented that this approach better considers the constraints of engineering

resources and manufacturing costs and results in a more realistic number of engines and transmissions.⁵³² The Alliance also commented on the benefit of constraining engine resizing, stating that “the platform and engine sharing methodology in the model better replicates reality by making available to each manufacturer only a finite number of engine displacements, helping to prevent unrealistically ‘over-optimized’ engine sizing.”⁵³³

Another comment from CARB stated that engine resizing “was only simulated for cases where those levels of mass reduction were applied, *in the absence of virtually all other technology or efficiency improvements.*”⁵³⁴ The agencies do not agree that resizing should be simulated in all cases which involve small incremental technologies. In the final rule analysis, vehicles can have engines resized at four (out of six) levels of mass reduction technology, during a vehicle redesign cycle which changes powertrain architecture, and by inheritance during a vehicle refresh cycle. As discussed previously, the application of small incremental technologies such as reductions in aerodynamic drag or rolling resistance does not justify the high cost and complexity of producing additional varieties of engine sizes. Accordingly, for each curb weight reduction level of 7.1 percent or above and for each vehicle technology class, Autonomie sized a baseline engine by running a simulation of a vehicle without incremental technologies applied; then, those baseline engines were inherited by all other simulations using the same levels of curb weight reduction, which also added any variety of incremental technologies.⁵³⁵ For further clarification, in any case in which a vehicle adopts a 7.1 percent or more curb weight reduction, no matter what other technologies were already present or are added to the vehicle in conjunction with the mass reduction, that vehicle will receive an engine which has been appropriately sized for the newly applied mass reduction

level.⁵³⁶ This can be observed in the Autonomie simulation databases by tracking the “EngineMaxPower” column (not the “VehicleSized” column).

Finally, ICCT claimed that the agencies did not sufficiently report performance-related vehicle information. ICCT commented that the output files did not show data on “engine displacement, the maximum power of each engine, the maximum torque of each engine, the initial and final curb weight of each vehicle (in absolute terms), and estimated 0–60 mph acceleration.” ICCT claimed that because this data was not found, the agencies are “showing that they have not even attempted to analyze accurately the future year fleet for their performance” and that “the agencies are intentionally burying a critical assumption, whereby their future fleet has not been appropriately downsized, and it therefore has greatly increased utility and performance characteristics.”⁵³⁷

In fact, for the NPRM, and again for this final rule, the agencies did analyze vehicle performance and have made the data available to the public. An indication of the actual engine displacement change is available by noting the displacements used in Autonomie simulation database for each of the technology states. The displacements reported in Autonomie are used by the full-vehicle-simulation within the Autonomie model, and while they do not directly represent each specific vehicle’s actual engine sizes, they do fully reflect the relative change in engine size that is applied to each vehicle. It is the relative change in engine size that is relevant for the analysis. Similarly, the vehicle power and torque used by the full vehicle simulations are reported in the Autonomie simulation databases; their values and relative change across an engine resizing event can be observed. Initial and final curb weights for the analysis fleet are reported in Vehicles Report output file column titled “CW Initial” and “CW,” respectively. The time required for 0–60 mph acceleration is reported in the Autonomie simulation database files. A detailed description of the engine resizing methodology is available in the Argonne Model

⁵²⁹ For example, each unique engine would require unique internal components such as crankshafts, pistons, and connecting rods, as well as unique engine calibrations for each displacement. Assembly plants would need to stock and feed additional unique engines to the stations where engines are dressed and inserted into vehicles.

⁵³⁰ National Research Council. 2011. Assessment of Fuel Economy Technologies for Light-Duty Vehicles. Washington, DC—The National Academies Press. <http://nap.edu/12924>.

⁵³¹ These curb weight reductions equate to the following levels of mass reduction as defined in the analysis: MR3, MR4, MR5 and MR6, but not MR1 and MR2; additional discussion of engine resizing for mass reduction can be found in Section VI.B.3.a)(6) Autonomie Sizes Powertrains for Full Vehicle Simulation.

⁵³² Toyota, Attachment 1, Docket No. NHTSA–2018–0067–12098, at 6.

⁵³³ Alliance of Automobile Manufacturers, Attachment “Full Comment Set,” Docket No. NHTSA–2018–0067–12073, at 140.

⁵³⁴ California Air Resources Board, Attachment 2, Docket No. NHTSA–2018–0067–11873, at 178.

⁵³⁵ In the Autonomie simulation database files, the simulations which establish baseline sized engines are marked “yes” in the “VehicleSized” column, and the subsequent simulations which use this engine and add other incremental technologies are marked “inherited.” For a list of Autonomie simulation database files, see Table VI–4 Autonomie Simulation Database Output Files in Section VI.A.7 Structure of Model Inputs and Outputs.

⁵³⁶ For example, if a vehicle possesses MR2, AERO1, and ROLL1 and subsequently adopts MR3, AERO1, ROLL2, the vehicle will adopt the lower engine power level associated with MR3. As a counter example, if a vehicle possesses MR3, ROLL1, and AERO1 and subsequently adopts MR3, ROLL1, AERO2, the engine will not be resized and it will retain the power level associated with MR3.

⁵³⁷ International Council on Clean Transportation, Attachment 3, Docket No. NHTSA–2018–0067–11741, at I–74.

Documentation, which explains how vehicle characteristics are used to calculate powertrain size.⁵³⁸ These data and information that are available in the Autonomie and CAFE model documentation provide the information needed to analyze performance, and in fact, this is evidenced by the statements of numerous commenters discussed in this section. The agencies have conducted their own performance analysis, which is discussed further below, using the same data documentation mentioned here.

Updates to the CAFE model have minimized performance shift over the simulated model years, and have eliminated performance differences between simulated standards.

The Autonomie simulation updates, discussed previously, were included in the final rule analysis, and have resulted in average performance that is similar across the regulatory alternatives. Because the regulatory analysis compares differences in impacts among the alternatives, the agencies believe that having consistent performance across the alternatives is an important aspect of performance neutrality. If the vehicle fleet had performance gains which varied significantly depending on the alternative, performance differences would impact the comparability of the simulations. Using the NPRM CAFE model data, the agencies analyzed the sales-weighted average 0–60 performance of the entire simulated vehicle fleet for MYs 2016 and 2029, and identified that the Augural standards had 4.7 percent better 0–60 mph acceleration time compared to the NPRM preferred alternative, which had no changes in standards in MYs 2021–2026.⁵³⁹ This assessment confirmed the observations of the various commenters. With the refinements that were incorporated for the final rule, similar analysis showed that the Augural standards had a negligible 0.1 percent difference in 0–60 mph acceleration

time compared to the NPRM preferred alternative.⁵⁴⁰

The updates applied to the final rule Autonomie simulations also resulted in further minimizing the performance change across model years. As the agencies attempted to minimize this performance shift occurring “over time,” it was also acknowledged that a small increase would be expected and would be reasonable. This increase is attributed to the analysis recognizing the practical constraints on the number of unique engine displacements manufacturers can implement, and therefore not resizing powertrains for every individual technology and every combination of technologies when the performance impacts are small. Perfectly equal performance with 0 percent change would not be achievable while accounting for these real world resizing constraints. The performance analysis in the 2011 NAS report shared a similar view on performance changes, stating that “truly equal performance involves nearly equal values . . . within 5 percent.”⁵⁴¹ In response to comments, using NPRM CAFE model data, the agencies analyzed the sales-weighted average 0–60 performance of the entire simulated vehicle fleet, and identified that the performance increase from MYs 2016 and 2029 was 7.5 percent under Augural Standards and 3.1 percent under the NPRM preferred alternative standards. The agencies conducted a similar analysis using final rule data and found the performance increase over time from MYs 2017 to 2029 was 3.9 percent for Augural Standards and 4.0 percent for the NPRM preferred alternative standards. The agencies determined this change in performance is reasonable and note it is within the 5 percent bound in discussed by NAS in its 2011 report.

This assessment shows that for the final rule analysis, performance is neutral across regulatory alternatives and across the simulated model years allowing for fair, direct comparison among the alternatives.

(7) How the Agencies Simulated Vehicle Models on Test Cycles

After vehicle models are built for every combination of technologies and vehicle classes represented in the analysis, Autonomie simulates their

performance on test cycles to calculate the effectiveness improvement of the fuel-economy-improving technologies that have been added to the vehicle. Discussed earlier, the agencies minimize the impact of potential variation in determining effectiveness by using a series of tests and procedures specified by federal law and regulations under controlled conditions.

Autonomie simulates vehicles in a very similar process as the test procedures and energy consumption calculations that manufacturers must use for CAFE and CO₂ compliance.^{542 543 544} Argonne simulated each vehicle model on several test procedures to evaluate effectiveness. For vehicles with conventional powertrains and micro hybrids, Autonomie simulates the vehicles on EPA 2-cycle test procedures and guidelines.⁵⁴⁵ For mild and full hybrid electric vehicles and FCVs, Autonomie simulates the vehicles using the same EPA 2-cycle test procedure and guidelines, and the drive cycles are repeated until the initial and final state of charge are within a SAE J1711 tolerance. For PHEVs, Autonomie simulates vehicles in similar procedures and guidelines as SAE J1711.⁵⁴⁶ For BEVs Autonomie simulates vehicles in similar procedures and guidelines as SAE J1634.⁵⁴⁷

b) Selection of One Full-Vehicle Modeling and Simulation Tool

The NPRM described tools that the agencies previously used to estimate technology effectiveness. For the analysis supporting the 2012 final rule for MYs 2017 and beyond, the agencies used technology effectiveness estimates from EPA’s lumped parameter model (LPM). The LPM was calibrated using data from vehicle simulation work performed by Ricardo Engineering.⁵⁴⁸

⁵³⁸ See Chapter 8 of the ANL Model documentation for the final rule analysis.

⁵³⁹ The agencies’ analysis matched all MY 2016 and MY 2029 vehicles in the NPRM Vehicles Report output file, under both the Augural standards and preferred alternative, with the appropriate 0–60 mph acceleration time from the NPRM Autonomie simulation databases. This was done by examining each vehicle’s assigned technologies, finding the Autonomie simulation with the corresponding set of technologies, and extracting that simulation’s 0–60 mph acceleration time. This process effectively assigned a 0–60 time to every vehicle in the fleet for four scenarios: (1) MY 2016 under augural standards, (2) MY 2016 under the preferred alternative, (3) MY 2029 under augural standards, and (4) MY 2029 under the preferred alternative. For each scenario, an overall fleet-wide weighted average 0–60 time was calculated, using each vehicle’s MY2016 sales volumes as the weight. For more information, see the FRIA Section VI.

⁵⁴⁰ This updated analysis used the FRM CAFE Model Vehicles Report output file and the FRM Autonomie simulation databases. The final rule analysis introduced an updated MY 2017 fleet as a starting point, replacing the NPRM 2016MY fleet. For more information, see the FRIA Chapter VI.

⁵⁴¹ National Research Council. 2011. Assessment of Fuel Economy Technologies for Light-Duty Vehicles. Washington, DC—The National Academies Press, at 62. <http://nap.edu/12924>.

The agencies also used full vehicle simulation modeling data from Autonomie vehicle simulations performed by Argonne for mild hybrid and advanced transmission effectiveness estimates.^{549 550}

For the 2016 Draft TAR analysis, EPA and NHTSA used two different full system simulation programs for complementary but separate analyses. NHTSA used Argonne's Autonomie tool, described in detail above, with engine map inputs developed by IAV using GT-Power in 2014, and updated in 2016.^{551 552 553} Argonne, in coordination with NHTSA, developed a methodology for large scale simulation using Autonomie and distributed computing, thus overcoming one of the challenges to full vehicle simulation that the NAS committee outlined in its 2015 report and implementing a recommendation that the agencies use full-vehicle simulation to improve the analysis method of estimating technology effectiveness.⁵⁵⁴ EPA used a limited number of full-vehicle simulations performed using its ALPHA model, an EPA-developed full-vehicle simulation model,⁵⁵⁵ to calibrate the LPM, used to

estimate technology effectiveness. EPA also used the same modeling approach for its Proposed Determination analysis.⁵⁵⁶

In the subsequent August 2017 Request for Comment on Reconsideration of the Final Determination of the Mid-Term Evaluation of Greenhouse Gas Emissions Standards for MY 2022–2025 Light-Duty Vehicles, the agencies requested comments on whether EPA should use alternative methodologies and modeling, including the Autonomie full-vehicle simulation tool and DOT's CAFE model, for the analysis that would accompany its revised Final Determination.⁵⁵⁷ As discussed in the NPRM, stakeholders questioned the efficacy of the combined outputs and assumptions of the LPM and ALPHA,⁵⁵⁸ especially as the tools were used to evaluate increasingly heterogeneous combinations of technologies in the vehicle fleet.⁵⁵⁹

More specifically, the Auto Alliance noted that their previous comments to the midterm evaluation, in addition to comments from individual manufacturers, highlighted multiple concerns with EPA's ALPHA model that were unresolved, but addressed in Autonomie.⁵⁶⁰ First, the Alliance expressed concern over ALPHA modeling errors related to road load reductions, stating that an error derived from how mass and coast-down coefficients were updated when mass, tire and aero improvements were made resulted in benefits overstated by 3 percent to 11 percent for all vehicle types. Next, the Alliance repeated its concern that EPA should consider top-gear gradeability as one of its performance metrics to maintain

functionality, noting that EPA had acknowledged the industry's comments in the Proposed Determination, "but generally dismissed the auto industry concerns." Additional analysis by EPA in its Response to Comments document did not allay the Alliance's concerns,⁵⁶¹ as the Alliance concluded that "[c]onsistent with the National Academy of Sciences recommendation from 2011, EPA should monitor gradeability to ensure minimum performance."

Furthermore, the Alliance stated that ALPHA vehicle technology walks provided in response to manufacturer comments on the Proposed Determination did not correctly predict cumulative effectiveness when compared to technologies in real world applications. The Alliance stated that many of the individual technologies and assumptions used by ALPHA overestimated technology effectiveness and were derived from questionable sources. As an example, the Alliance referenced an engine map used by EPA to represent the Honda L15B7 engine, where the engine map data was collected by "(1) taking a picture of an SAE document containing an image of the engine map, and then (2) 'digitizing' the image by 'tracing image contours'" (citing EPA's ALPHA documentation). The Alliance could not definitively state whether the "digitization" process, lack of detail in the source image, or another factor were the reasons that some regions of overestimated efficiency were observed in the engine map, but concluded that "the use of this map should be discontinued within ALPHA," and "any analysis conducted with it is highly questionable." Based on these concerns and others, the Alliance recommended that Autonomie be used to inform the downstream cost optimization models (*i.e.*, the CAFE model and/or OMEGA).

Global Automakers argued that NHTSA's CAFE model, which incorporates data from Autonomie simulations, provided a more transparent and discrete step through each of the modeling scenarios.⁵⁶² Global pointed out that the LPM is "of particular concern due to its simplified technology projection processes," and it "propagates fundamentally flawed

⁵⁶⁰ EPA–HQ–OAR–2015–0827–9194, at p. 36–44.

⁵⁶¹ The Alliance noted that in higher-gear-count transmissions, like 8-speed automatics, modeled by ALPHA with an expanded ratio spread to achieve fuel economy, are concerning for gradeability. Additionally, infinite engine downsizing along with expanded ratio spread transmission, in real world gradeability may cause further deteriorate as modeled in ALPHA, which leads to inflated effectiveness values for powertrains that would not meet customer demands.

⁵⁶² EPA–HQ–OAR–2015–0827–9728, at 14.

content into the ALPHA and OMEGA models and therefore cannot accurately assess the efficacy of fuel economy technologies.” Global did note that EPA “plans to abandon its reliance on LPM in favor of another modeling approach,” referring to the RSE,⁵⁶³ but stated that “EPA must provide stakeholders with adequate time to evaluate the updated modeling approach, ensure it is analytically robust, and provide meaningful feedback.” Global Automakers concluded that EPA’s engine mapping and tear-down analyses have played an important role in generating publicly-available information, and stated that the data should be integrated into the Autonomie model.

On the other hand, other stakeholders commented that EPA’s ALPHA modeling should continue to be used, for procedural reasons like, “[i]t would appear arbitrary for EPA now, after five years of modeling based on ALPHA, to declare it can no longer use its internally developed modeling tools and must rely solely on the Autonomie model,” and “[t]he ALPHA model is inextricably built into the regulatory and technical process. It will require years of new analysis to replace the many ALPHA and OMEGA modeling inputs and outputs that permeate the entire rulemaking process, should EPA suddenly decide to change its models.”⁵⁶⁴ Commenters also cited technical reasons to use ALPHA, like EPA’s progress benchmarking and validating the ALPHA model to over fifteen various MY 2013–2015 vehicles,⁵⁶⁵ and that technologies like the “Atkinson 2” engine technology were not considered in NHTSA’s compliance modeling.⁵⁶⁶ Commenters also cited that ALPHA was created to be publicly available, open-sourced, and peer-reviewed, “to allow for transparency to both automakers and public stakeholders, without hidden and proprietary aspects that are present in commercial modeling products.”⁵⁶⁷

The agencies described in the NPRM that after having reviewed comments about whether EPA should use

alternative methodologies and modeling, and after having considered the matter fully, the agencies determined it was reasonable and appropriate to use Autonomie for full-vehicle simulation.⁵⁶⁸ The agencies stated that nothing in Section 202(a) of the Clean Air Act (CAA) mandated that EPA use any specific model or set of models for analysis of potential CO₂ standards for light duty vehicles. The agencies also distinguished the models and the inputs used to populate them; specifically, comments presented as criticisms of the models, such as “Atkinson 2” engine technology not considered in the compliance modeling, actually concerned model inputs.⁵⁶⁹

With regards to modeling technology effectiveness, the agencies concluded that, although the CAFE model requires no specific approach to developing effectiveness inputs, the National Academy of Sciences recommended, and stakeholders have commented, that full-vehicle simulation provides the best balance between realism and practicality. As stated above, Argonne has spent several years developing, applying, and expanding means to use distributed computing to exercise its Autonomie full-vehicle simulation tool at the scale necessary for realistic analysis of technologies that could be used to comply with CAFE and CO₂ standards, and this scalability and related flexibility (in terms of expanding the set of technologies to be simulated) makes Autonomie well-suited for developing inputs to the CAFE model.

In response to the NPRM, the Auto Alliance commented that NHTSA’s modeling and analysis tools are superior to EPA’s, noting that NHTSA’s tools have had a significant lead in their development.⁵⁷⁰ The Alliance pointed out that Autonomie was developed from the beginning to address the complex task of combining two power sources in a hybrid powertrain, while EPA’s ALPHA model had not been validated or used to simulate hybrid powertrains. While both models are physics-based forward looking vehicle simulators, the Alliance commented that Autonomie is fully documented with available training, while ALPHA “has not been documented with any instructions making it difficult for users outside of EPA to run and interpret the model.” The Alliance also mentioned specific improvements in the Autonomie simulations since the Draft TAR, including expanded performance classes to better consider vehicle

performance characteristics, the inclusion of gradeability as a performance metric, as recommended by the NAS, the inclusion of new fuel economy technologies, and the removal of unproven technologies.

The Alliance, Global Automakers, and other automakers writing separately all stated that the agencies should use one simulation and modeling tool for analysis.^{571 572} The Alliance stated that since both the Autonomie and ALPHA modeling systems answer essentially the same questions, using both systems leads to inconsistencies and conflicts, and is inefficient and counterproductive.

The agencies agree with the Alliance that the fully developed and validated Autonomie model fulfills the agencies’ analytical needs for full-vehicle modeling and simulation. The agencies also agree that it is counterintuitive to have two separate models conducting the same work.

Some commenters stated that broadly, EPA was required to conduct its own technical analysis and rely on its own models to do so.⁵⁷³ Those comments are addressed in Section IV.

Regarding the merits of EPA’s models, and based on previous inputs and assumptions used to populate those models, ICCT commented that “[b]ased on the ICCT’s global analysis of vehicle regulations, the EPA’s physics-based ALPHA modeling offers the most sophisticated and thorough modeling of the applicable technologies that has ever been conducted.” ICCT listed several reasons for this, including that the EPA modeling is based on systematic modeling of technologies and their synergies; it was built and improved upon by extensive modeling by and with Ricardo (an engineering consulting firm); it incorporated National Academies input at multiple stages; it has included many peer reviews at many stages of the modeling and the associated technical reports published by engineers in many technical journal articles and conference proceedings; and EPA’s Draft TAR analysis, which used ALPHA, used state-of-the-art engine maps based on benchmarked high-efficiency engines. ICCT concluded

⁵⁶³ See Moskalik, A., Bolon, K., Newman, K., and Cherry, J. “Representing GHG Reduction Technologies in the Future Fleet with Full Vehicle Simulation,” SAE Technical Paper 2018-01-1273, 2018, doi:10.4271/2018-01-1273. Since 2018, EPA has employed vehicle-class-specific response surface equations automatically generated from a large number of ALPHA runs to more readily apply large-scale simulation results, which eliminated the need for manual calibration of effectiveness values between ALPHA and the LPM.

that “[d]espite these rigorous advances in vehicle simulation modeling, it appears that the agencies have inexplicably abandoned this approach, expressly disregarding the EPA benchmarked engines, ALPHA modeling, and all its enhancements since the last rulemaking.”

The hallmarks ICCT lists regarding the ALPHA modeling are equally applicable to Autonomie.⁵⁷⁴ Autonomie is also based on systematic modeling of technologies and their synergies when combined as packages. The U.S. Department of Energy created Autonomie, and over the past two decades, helped to develop and mature the processes and inputs used to represent real-world vehicles using continuous feedback from the tool’s worldwide user base of vehicle manufacturers, suppliers, government agencies, and other organizations. Moreover, using Autonomie brings the agencies closer to the NAS Committee’s stated goal of “full system simulation modeling for every important technology pathway and for every vehicle class.”⁵⁷⁵ While the NAS Committee originally thought that full vehicle simulation modeling would not be feasible for the thousands of vehicles in the analysis fleets because the technologies present on the vehicles might differ from the configurations used in the simulation modeling,⁵⁷⁶ Argonne has developed a process to simulate explicitly every important technology pathway for every vehicle class. Moreover, although separate from the Autonomie model itself, the Autonomie modeling for this rulemaking incorporated other NAS committee recommendations regarding full vehicle simulation inputs and input assumptions, including using engine-model-generated maps derived from a validated baseline map in which all parameters except the new technology of interest are held constant.⁵⁷⁷

As discussed further below and in VI.C.1 Engine Paths, this is one reason why the IAV maps were used instead of the EPA maps, and the agencies instead referenced EPA’s engine maps to corroborate the Autonomie effectiveness results. The IAV maps are engine-model-generated maps derived from a validated baseline map in which all parameters except the new technology of interest are held constant. While EPA’s engine maps benchmarking specific vehicles’ engines incorporate

multiple technologies, for example including improvements in engine friction and reduction in accessory parasitic loads, comparisons presented in Section VI.C.1 showed that engine maps developed by IAV, while not exactly the same, are representative of EPA’s engine benchmarking data.

In addition, both ALPHA and Autonomie have been used to support analyses that have been published in technical journal articles and conference proceedings, but those analyses differ fundamentally because of the nature of the tools. ALPHA was developed as a tool to be used by EPA’s in-house experts.⁵⁷⁸ As EPA stated in the ALPHA model peer review,⁵⁷⁹ “ALPHA is not intended to be a commercial product or supported for wide external usage as a development tool.”⁵⁸⁰ Accordingly, EPA experts have published several peer-reviewed journal articles using ALPHA and have presented the results of those papers at conference proceedings.⁵⁸¹

To explore ICCT’s comments on the importance of peer review further, it is important to take the actual substantive content of the ALPHA peer review into account.⁵⁸² One reviewer raised significant questions over the availability of ALPHA documentation, stating “[t]here is an overall lack of detail on key technical features that are new in the model,” and “[w]e were not able to find any information on how the model handles component weight changes.” Reviewers also raised questions related to model readiness, stating “[a]ccording to the documentation review, ALPHA’s stop/start modeling appears to be very simplistic.” Moreover, when running ALPHA simulations, the reviewer noted the results “strongly suggest that the model has errors in the underlying equations or coding with respect to all of the load reductions.” Also, one reviewer said the following of ALPHA: “A specific simulation runtime is

significantly high, more than 10 mins. without providing any indication to the user progress made so far. A fairly more complicated model such as Autonomie available even with enhanced capabilities is significantly faster today.”⁵⁸³

The peer reviewer’s assessment of Autonomie as a more complicated model with enhanced capabilities is not surprising, given Autonomie’s history of development. Autonomie is a commercial tool with more than 275 worldwide organizational users, including vehicle manufacturers, suppliers, government agencies, and nonprofit organizations having licensed and used Autonomie. Both Autonomie’s creators and user base unaffiliated with Argonne have published over 100 papers, including peer-reviewed papers in journals, related to Autonomie validation and other studies.⁵⁸⁴ One could even argue that the tool has been continuously peer reviewed by these thousands of experts over the past two decades.

In fact, in responding to a peer review comment on the ALPHA model’s underlying equations and coding with respect to road load reductions, EPA noted that Autonomie had been used as a reference system simulation tool to validate ALPHA model results.⁵⁸⁶

Outside of formal peer-reviewed studies, Autonomie has been used by organizations like ICCT to support policy documents, position briefs, and white papers assessing the potential of future efficiency technologies to meet potential regulatory requirements.⁵⁸⁷

⁵⁷⁷ NAS Recommendation 2.1.

just as the agencies did in this rulemaking.

Similarly to ICCT, UCS stated that in contrast to Autonomie, ALPHA had been thoroughly peer-reviewed and is constantly being updated to reflect the latest technology developments based on work performed by the National Vehicle and Fuel Emissions Laboratory.⁵⁸⁸ UCS also stated that because EPA has direct control over the model and its interface to OMEGA, EPA can better ensure that the inputs into OMEGA reflect the most up-to-date data, unlike the Autonomie work, which effectively has to be “locked in” before it can be deployed in the CAFE model. UCS also stated that ALPHA is based on the GEM model (used to simulate compliance with heavy-duty vehicle regulations) which was been updated with feedback from heavy-duty vehicle manufacturers and suppliers, and in fact, “NHTSA has such confidence in the GEM model that they accept its simulation-based results as compliance with the heavy-duty fuel economy regulations.”

Again, the agencies believe that it is important to note that Autonomie not only meets, but also exceeds, UCS’ listed metrics. Autonomie’s models, sub-models, and controls are constantly being updated to reflect the latest technology developments based on work performed by Argonne National Laboratory’s Advanced Mobility Technology Laboratory (AMTL) (formerly Advanced Powertrain Research Facility, or ARPF).⁵⁸⁹ ⁵⁹⁰ The

Autonomie validation has included nine validation studies with accompanying reports for software, six validation studies and reports for powertrains, nine validation studies and reports for advanced components, ten validation studies and reports for advanced controls, and overall model validation using test data from over 50 vehicles.⁵⁹¹

In fact, using Autonomie, which has validated data based on test data from over 50 vehicles, alleviates other stakeholder concerns about the level of model validation in past analyses. For example, Global Automakers expressed concerns about whether the effectiveness values used in past EPA analysis, generated from ALPHA full-vehicle model simulations, were properly validated, stating that “[a]lthough EPA claims that the LPM was calibrated based on thorough testing and modeling with the ALPHA model, the materials provided with the Proposed and Final Determination only cover 18 percent of the projected vehicle fleet with regards to specific combinations of powertrain technology presented by EPA in the MY 2025 OMEGA pathway. It is unclear how EPA calibrated the LPM for the remaining 82 percent of the projected vehicles. EPA’s failure to publicly share the data for such a large percentage of vehicles raises questions about the quality of data.”⁵⁹² While simple modeled parameters like single dimensional linear systems, such as engine dynamometer torque measurements can be validated through other models,⁵⁹³ full vehicle systems are complex multi-dimensional non-linear systems that need to be developed with multiple data sets, and validated with other fully independent data sets. Autonomie’s models and sub-models have undergone extensive validation that has proven the

models’ agreement with empirical data and the principles of physics.

In addition, the agencies disagree with UCS’ comment that EPA’s direct control over its effectiveness modeling and interface to OMEGA results in a more up-to-date analysis. Argonne’s participation in developing inputs for the rulemaking analysis allowed the agencies access to vehicle benchmarking data from more vehicles than if the agencies were limited by their own resources, and access to the Argonne staff’s extensive experience based on direct coordination with vehicle manufacturers, suppliers, and researchers that all actively use Autonomie for their own work. In addition to Autonomie’s continuous updates to incorporate the latest fuel-economy-improving technologies, discussed throughout this section, the data supplied to and generated by Autonomie for use in the CAFE model was continuously updated during the analysis process. This is just one part of the iterative quality assurance (QA) and quality check (QC) process that the agencies developed when Argonne’s large-scale simulation modeling based in Autonomie was first used for the Draft TAR.

In addition to Argonne’s team constantly updating Autonomie, Argonne’s use of high performance computing (HPC) allowed for constant update of the analysis during the rulemaking process. Argonne’s HPC platform allows a full set of simulations—over 750,000 modeled vehicles that incorporate over 50 different fuel-economy-improving technologies—to be simulated in one week. Subsets of the simulations can be re-run should issues come up during QA/QC in a day or less. Tools like the internet and high performance computers have allowed the agencies to evaluate technology effectiveness with up-to-date inputs without the proximity of the computers and the people running them working as a detriment to the analysis.

Finally, GEM, ALPHA, and Autonomie were all developed in the MATLAB computational environment as forward-looking physics-based vehicle models. Just as ALPHA has roots in GEM, created in 2010 to accompany the agencies’ heavy-duty vehicle CO₂ emissions and fuel consumption standards, Autonomie has its origins in the software PSAT, developed over 20 years ago. While this information is useful, as implied by UCS’ comment, the origin of the software was less important than the capabilities the software could provide for today’s analysis. NHTSA’s acceptance of GEM

⁵⁹² Docket ID EPA–HQ–OAR–2015–0827–9728. Global later repeated that “only 18% of all vehicle data used as inputs to the ALPHA modeling was made available in the EPA’s public sources. Additional data had to be specifically requested subsequent to the publication of the Draft TAR and Proposed Determination. This lack of publicly available data highlights transparency concerns, which Global Automakers has raised on several previous occasions.”

⁵⁹³ Section 89.307 Dynamometer calibration.

results for compliance with heavy-duty fuel economy regulations had no bearing on the decision to use Autonomie to assess the effectiveness of light-duty fuel economy and CO₂ improving technologies. GEM was developed to serve as the compliance model for heavy-duty vehicles,⁵⁹⁴ and GEM serves that limited scope very well.

UCS did comment that full vehicle simulation could significantly improve the estimates of technology effectiveness, but thought it critical that the process be as open and transparent as possible. UCS pointed to ALPHA results published in peer-reviewed journals as an example of how transparency has provided the ALPHA modeling effort with significant and valuable feedback, and contrasted what they characterized as Autonomie's "black box" approach, which they stated "does not lend itself to similar dialog, nor does it make it easy to assess the validity of the results." Specifically, UCS stated that it is "impossible to verify, replicate, or alter the work done by Autonomie due to the expensive nature of the tools used and lack of open source or peer-reviewed output." In contrast, UCS stated that EPA's ALPHA model has been thoroughly peer reviewed, and is readily "downloadable, editable, and accessible to anyone with a MATLAB license."

The agencies responses on the merits of how ALPHA and Autonomie were peer-reviewed are discussed above. Regarding UCS' comment that it is impossible to verify, replicate, or alter the work done by Autonomie, the agencies disagree. All inputs, assumptions, model documentation—including of component models and individual control algorithms—and outputs for the NPRM Autonomie modeling were submitted to the docket for review.⁵⁹⁵ Commenters were able to

provide a robust analysis of Autonomie's technology effectiveness inputs, input assumptions, and outputs, as shown by their comments on specific vehicle technology effectiveness assumptions, discussed throughout this section and in the individual technology sections below.

The agencies also disagree with UCS' assessment of Autonomie as "expensive." While Autonomie is a commercial product, the biggest financial barrier to entry for both ALPHA and Autonomie is the same: A MathWorks license.⁵⁹⁶ Regardless, Argonne has made the version of Autonomie used for this final rule analysis available upon request, including the individual runs used to generate each technology effectiveness estimate.⁵⁹⁸

Next, ICCT supplanted its statement that the agencies "inexplicably" abandoned ALPHA, commenting that the agencies' explanation and justification for relying on Autonomie rather than ALPHA failed to discuss ALPHA in detail, and the agencies did not compare and contrast the two models. ICCT continued, "the EPA cannot select its modeling tool arbitrarily, yet it appeared that the EPA has whimsically shifted from an extremely well-vetted, up-to-date, industry-grade modeling tool to a less-vetted, academic-grade framework with outdated inputs without even attempt to scrutinize the change." ICCT also stated that the agencies are legally obligated to acknowledge and explain when they change position, and "cannot simply ignore that EPA previously concluded

that the ALPHA modeling accurately projected real-world effects of technologies and technology packages."

The agencies disagree that a more in-depth discussion of ALPHA was required in the NPRM. In acknowledging the transition to using Autonomie for effectiveness modeling and the CAFE model for analysis of regulatory alternatives,⁵⁹⁹ the agencies described several analytical needs that using a single analysis from the CAFE model—with inputs from the Autonomie tool—addressed. These included that Autonomie produced realistic estimates of fuel economy levels and CO₂ emission rates through consideration of real-world constraints, such as the estimation and consideration of performance, utility, and drivability metrics (e.g., towing capability, shift busyness, frequency of engine on/off transitions).⁶⁰⁰ That EPA previously concluded the ALPHA modeling accurately projected real-world effects of technologies and technology packages has no bearing on Autonomie's ability to fulfill the analytical needs that the agencies articulated in the NPRM, including that Autonomie also accurately projects real-world effects of technologies and technology packages.

The agencies also disagree with ICCT's characterization of ALPHA as "an extremely well-vetted, up-to-date, industry-grade modeling tool" and Autonomie as a "less-vetted, academic-grade framework with outdated inputs." Again, Autonomie has been used by government agencies, vehicle manufacturers (and by agencies and manufacturers together in the collaborative government-industry partnership U.S. DRIVE program), suppliers, and other organizations because of its ability to simulate many powertrain configurations, component technologies, and vehicle-level controls over numerous drive cycles. Characterizing ALPHA as an "industry-grade modeling tool" contravenes EPA's own description of its tool—an in-house vehicle simulation model used by EPA, not intended to be a commercial product.⁶⁰¹

⁶⁰⁰ 83 FR 43001 (Aug. 24, 2018).

⁶⁰¹ See, e.g., Overview of ALPHA Model, <https://www.epa.gov/regulations-emissions-vehicles-and-engines/advanced-light-duty-powertrain-and-hybrid-analysis-alpha>; ALPHA Effectiveness Modeling: Current and Future Light-Duty Vehicle & Powertrain Technologies (Jan. 20, 2016), available at <https://www.epa.gov/sites/production/files/2016-10/documents/alpha-model-sae-govt-ind-mtg-2016-01-20.pdf> ("ALPHA is not a commercial product (e.g. there are no user manuals, tech support hotlines, graphical user interfaces, or full libraries

That characterization also contravenes documentation from the automotive industry indicating that manufacturers consider ALPHA to generate overly optimistic effectiveness values, to be unrepresentative of real-world constraints, and a difficult tool to use.^{602 603} The Alliance commented to the MTE reconsideration that “[p]revious comments from the Alliance and individual manufacturers to the MTE docket have highlighted multiple concerns with EPA’s ALPHA model. Many of these concerns remain unresolved.”⁶⁰⁴ Furthermore, the Alliance commented that ALPHA “has not been documented with any instructions making it difficult for users outside of EPA to run and interpret the model.”⁶⁰⁵ Global Automakers further stated that the “lack of publicly available data [related to inputs used in the ALPHA modeling] highlights transparency concerns, which Global Automakers has raised on several previous occasions.”⁶⁰⁶ In fact, both the Alliance of Automobile Manufacturers and Global Automakers, the two trade organizations that represent the automotive industry, concluded that Autonomie should be used to generate effectiveness inputs for the CAFE model.⁶⁰⁷

of components).”). See also Peer Review of ALPHA Full Vehicle Simulation Model, available at <https://nepis.epa.gov/Exe/ZyPdf.cgi?Dockey=P100PUKT.pdf>. While ALPHA peer reviewers found the model to be a “fairly simple transparent model . . . [t]he model execution requires an expert MatLab/Simulink user since no user-friendly interface currently exists.” Indeed, EPA noted in response to this comment that “[a]s with any internal tool, EPA does not have the need for a “user-friendly interface” like one that would normally accompany a commercial product which is available for purchase and fully supported for wide external usage.”

⁶⁰² See EPA–HQ–OAR–2015–0827–10125, at 7. As part of their assessment that known technologies could not meet the original MY 2022–2025 standards, Toyota noted that the ALPHA conversion of Toyota’s MY 2015 to MY 2025 performance “appears to yield overly optimistic results because the powertrain efficiency curves represent best-case targets and not the average vehicle, the imposed performance constraints are unmarketable, and the generated credits are out of sync with product cadence and design cycles.” See also NHTSA–2018–0067–12431, at 7. More recently, Toyota stated in their comments to the NPRM that “Toyota’s position [on the efficacy of the OMEGA and LPM models] has been clearly represented by comments previously submitted by the Alliance of Automobile Manufacturers, Global Automakers, and Novation Analytics. Those comments identify the LPM and OMEGA models as sources of inaccuracy in EPA technology evaluations and provide suggested improvements. Neither model is transparent, intuitive, or user friendly.”

In addition, Autonomie contains up-to-date sub-models to represent the latest electrification and advanced transmission and advanced engine technologies. As summarized by the Alliance, “Autonomie was developed from the start to address the complex task of combining 2 power sources in a hybrid powertrain.”⁶⁰⁸ Autonomie has continuously improved over the years by adopting new technologies into its modeling framework. Even a small sampling of SAE papers shows how Autonomie has been validated to simulate the latest fuel-economy-improving technologies like hybrid vehicles and PHEVs.⁶⁰⁹

Moreover, Autonomie effectively considers other real-world constraints faced by the automotive industry. Vehicle manufacturers and suppliers spend significant time and effort to ensure technologies are incorporated into vehicles in ways that will balance consumer acceptance for attributes such as driving quality,⁶¹⁰ noise-vibration-harshness (NVH), and meeting other regulatory mandates, like EPA’s and CARB’s On-Board Diagnostics (OBD) requirements,⁶¹¹ and EPA’s and CARB’s criteria exhaust emissions standards.⁶¹² The implementation of new fuel economy improving technologies have at times raised consumer acceptance issues.⁶¹³ As discussed earlier, there are

instead use NHTSA’s Autonomie and Volpe models to support the Revised Final Determination.”). See also EPA–HQ–OAR–2015–0827–9728 at 15 (stating the EPA’s engine mapping and tear down analyses “should be integrated into the Autonomie model, which then feeds into the Volpe modeling process.”); EPA–HQ–OAR–2015–0827–9194 at 33.

⁶⁰⁸ Alliance, Docket ID NHTSA–2018–0067–12073 at 135.

⁶¹⁰ An example of a design requirement is accommodating the “lag” in torque delivery due to the spooling of a turbine in a turbocharged downsized engine. This affects real-world vehicle performance, as well as the vehicle’s ability to shift during normal driving and test cycles.

⁶¹¹ EPA adopted and incorporated by reference current OBD regulations by the California ARB, effective for MY 2017, that cover all vehicles except those in the heavier fraction of the heavy-duty vehicle class.

⁶¹² Tier 3 emission standards for light-duty vehicles were proposed in March 2013 78 FR 29815 (May 21, 2013) and signed into law on March 3, 2014 79 FR 23413 (June 27, 2014). The Tier 3 standards—closely aligned with California LEV III standards—are phased-in over the period from MY2017 through MY2025. The regulation also tightens sulfur limits for gasoline.

⁶¹³ Atiyeh, C. “What you need to know about Ford’s PowerShift Transmission Problems” Car and Driver. July 11, 2019. <https://www.caranddriver.com/news/a27438193/ford-powershift-transmission-problems/>.

diminishing returns for modeling every vehicle attribute and tradeoff, as each takes time and incurs cost; however, Autonomie sub-models are designed to account for a number of the key attributes and tradeoffs, so the resulting effectiveness estimates reflect these real world constraints.

Furthermore, aside from the fact that Autonomie represents the structural state-of-the-art in full-vehicle modeling and simulation, Autonomie can be populated with any inputs that could be populated in the ALPHA model.⁶¹⁴ The agencies chose to use specific inputs for this rulemaking because, as discussed further in Sections VI.C below, they best represent the technologies that manufacturers could incorporate in the rulemaking timeframe, in a way that balanced important concerns like consumer acceptance. Some other examples of how Autonomie inputs have been updated with the latest vehicle technology data specifically for this analysis include test data incorporated from both Argonne and NHTSA-sponsored vehicle benchmarking, including an updated automatic transmission skip-shifting feature,⁶¹⁵ additional application of cylinder deactivation for turbocharged downsized engines, and as discussed above, new modeling and simulation that includes variable compression ratio and Miller Cycle engines.

Finally, ICCT commented that the agencies must conduct a systematic comparison of the Autonomie modeling system and ALPHA modeling in several respects, including the differences in technical inputs and resulting efficiency estimates, to explain how the choice of model altered the regulatory technology penetration and compliance cost estimations, and the differences in modeling methodologies, including regarding the relative level of experience of the teams conducting the effectiveness modeling, to demonstrate that the choice to use Autonomie was not “due to convenience and easier access by the NHTSA research team, rather than for any technical improvement.” ICCT stated that without performing this comparison, “it otherwise appears that the agencies switched from a better-vetted model and system of inputs with more recent input data to a less-vetted model and system of inputs as a way to bury many dozens of changes without transparency or expert assessment (as illustrated in the

⁶¹⁴ For example, Autonomie used the HCR1 and HCR2 engine maps used as inputs to ALPHA in the Draft TAR and Proposed Determination.

⁶¹⁵ NHTSA Benchmarking, “Laboratory Testing of a 2017 Ford F–150 3.5 V6 EcoBoost with a 10-speed transmission.” DOT HS 812 520.

above errors and invalidated data on individual technologies).” Each issue is discussed below in turn.

First, regarding technical inputs, technology pathways, and resulting outputs, ICCT stated that the agencies must compare (1) whether the models have been routinely strengthened by incorporating cutting edge 2020–2025 automotive technologies to ensure they reflect the available improvements; (2) every efficiency technology in the 2016 Draft TAR and original EPA TSD and Proposed and Final Determination analysis against the NPRM; (3) all the major technology package pathways (*i.e.*, all combinations with high uptake in the Adopted and Augural 2025 standards) in the current NPRM versus the 2016 Draft TAR and the 2016 TSD and original Final Determination analysis; (4) each of the major 2025 technology package synergies; (5) the modeling work of EPA’s, Ricardo’s, and Argonne’s 2014–2018 model year engine benchmarking and modeling of top engine and transmission models; and “defend why they appear to have chosen to dismiss the superior and better vetted technology modeling approach.”

ICCT stated that the agencies must make these comparisons because, “[o]therwise, it seems obvious that the agencies have subjectively decided to use the modeling that increases the modeled cost, providing further evidence of a high degree of bias without an objective accounting of the methodological differences and the sensitivity of the results to their new decision.” Moreover, ICCT stated that “[b]ecause ALPHA is the dominant, preferred, and better-vetted modeling and was used in the original Proposed and Final Determination, the agencies are responsible for assessing and describing how the use of the ALPHA modeling would result in a different regulatory result for their analysis of the 2017–2025 adopted [CO₂] and Augural CAFE standards.”

The agencies do not believe that it is necessary to conduct a retrospective comparison of ALPHA/LPM and Autonomie effectiveness for every technology in the Draft TAR and Proposed Determination to the NPRM and final rule analyses, between the two models for technologies and packages used in the NPRM and final rule analysis, or to explain where and why Autonomie provided different results from ALPHA and the LPM, to assess and describe how the use of the ALPHA modeling would result in a different regulatory result of CAFE and CO₂ standards, per ICCT’s request. While it is anticipated that different values will

be produced using different tools in an analysis, it is not appropriate to select the tool for use based on preferred results. The selection of an analysis tool should be based on an evaluation of the tool’s capabilities and appropriateness for the analysis task. The analysis tool should support the full extent of the analysis and support the level of input and output resolution required. To compare the output of the two models for the purpose of selecting a tool for the analysis would likely be biased and disingenuous to the purpose of the analysis. In this case, Autonomie was selected for this analysis for the reasons discussed throughout this section, and accordingly the agencies believe that it was reasonable to consider effectiveness estimates developed with Autonomie.

That said, comparison of how the tools *behave* is discussed here to further support the agencies’ decision process. To demonstrate, in addition to everything discussed previously in this section, differences in how each model handles powertrain systems modeling with specific examples are discussed below as a reference, and differences between the agencies’ approaches to effectiveness modeling for specific technologies is discussed in Section VI.C where appropriate. While the improved approach to estimating technology effectiveness estimates certainly impacted the regulatory technology penetration, compliance cost estimates, and “major 2025 technology packages and synergies,” how technologies are applied in the compliance modeling and the associated costs of the technologies is equally as important to consider when examining factors that might impact the regulatory analysis; that consideration goes beyond the scope of simply considering which full vehicle simulation model better performs the functions required of this analysis.

The agencies have discussed updates to the technologies considered in the Autonomie modeling throughout this section, in addition to Autonomie’s models and sub-models that control advanced technologies like hybrid and electrified powertrains. Autonomie’s explicit models, sub-models, and controls for hybrid and electric vehicles have been continuously validated over the past several years,⁶¹⁶ as Autonomie

was developed from the beginning to address the complex task of combining two power sources in a hybrid powertrain.

Also regarding the inputs to both models, as highlighted in Section VI.C.3.a), and discussed above, inputs and assumptions for the ALPHA modeling used for the EPA Draft TAR and Proposed Determination analysis were projected from benchmarking testing. While it is straightforward to measure engine fuel consumption and create an engine fuel map, it is extremely challenging to identify the specific technologies and levels of technologies present on a benchmarking engine. Attributing changes in the overall engine fuel consumption to the individual engine technologies that make up the complete engine involves significant uncertainty.

The fixed-point model approach used by the ALPHA model does not develop an effectiveness function and assigns a single value to a technology. The single value is derived from benchmark testing, which often does not isolate the effect of a single technology from the effects of other technologies on the tested vehicle. To isolate a single technology’s effect for use in fixed point modeling properly, the agencies would need to benchmark multiple versions of a single vehicle, carefully controlling changes to the vehicles’ fuel efficiency technologies. This process would need to be repeated for a large portion of the vehicle fleet and would require significant funding and thousands of lab hours to complete. Without this level of data, fixed-point effectiveness estimates tend to be too high, as they are unable to account for synergetic effects of multiple technologies. Specifically, when EPA benchmarks vehicles like the 2018 Toyota Camry, the resulting fuel map captures the benefits of many

technologies associated with that engine. This data can be helpful when developing controls and validating component operations in modeling, but it is inaccurate to conclude that fuel consumption is directly related to individual engine technologies, such as lubrication and friction reduction, and geometric improvements in efficiency.

Contrasted, the NPRM and final rule Autonomie analyses selected specific base engine maps and applied technologies incrementally, both individually and in known combinations, to better isolate the impacts of the technologies. As discussed above, this also implemented NAS Recommendation 2.1, to use engine-model-generated maps in the full vehicle simulations derived from a validated baseline map in which all parameters except the new technology of interest are held constant.⁶¹⁷ While the different methods are valid for different purposes, the method selected for the analysis presented today was more useful for measuring the

incremental effectiveness *increments* as opposed to the *absolute* values of technology effectiveness, *e.g.*, that could be measured by benchmarking a technology package.

To provide an example of another difference in behavior between the simulation tools, a comparison between ALPHA and Autonomie transmissions shifting behavior was conducted. The comparison highlighted the differences in how each simulation tool approaches transmission shift logic. The ALPHA simulation tool used ALPHAShift. ALPHAShift is an optimization algorithm that uses numerous vehicle characteristics to find a best shifting strategy. The primary inputs for the algorithm includes the fuel consumption (or cost) map for the vehicle engine.⁶¹⁸ Although a public version of ALPHA is available for evaluation, the ALPHAShift algorithm used by the tool is hard coded with fixed values.^{619 620} This is an issue, because despite peer reviewed documentation on how to tune the

algorithm,⁶²¹ no documentation of how the algorithm logic works is available for review. This is confounding for the use of the software, particularly when the observed behavior of the model departs from expected behavior. Figure VI-6 below shows simulated gear shift (left) versus actual gear shift (right), demonstrating an unexpected shift to neutral before shifting to the requested gear.

By contrast, and discussed further in VI.C.2 Transmission Paths, Autonomie uses a fully documented algorithm to develop a best shifting strategy for each unique vehicle configuration. The algorithm develops shifting strategies unique to each individual vehicle based on gear ratio, final drive ratio, engine BSFC and other vehicle characteristics. This is one example of model behavior, in addition to the availability of more transparency on this behavior for greater stakeholder review, that led the agencies to determine it was reasonable and appropriate to use Autonomie for this analysis.

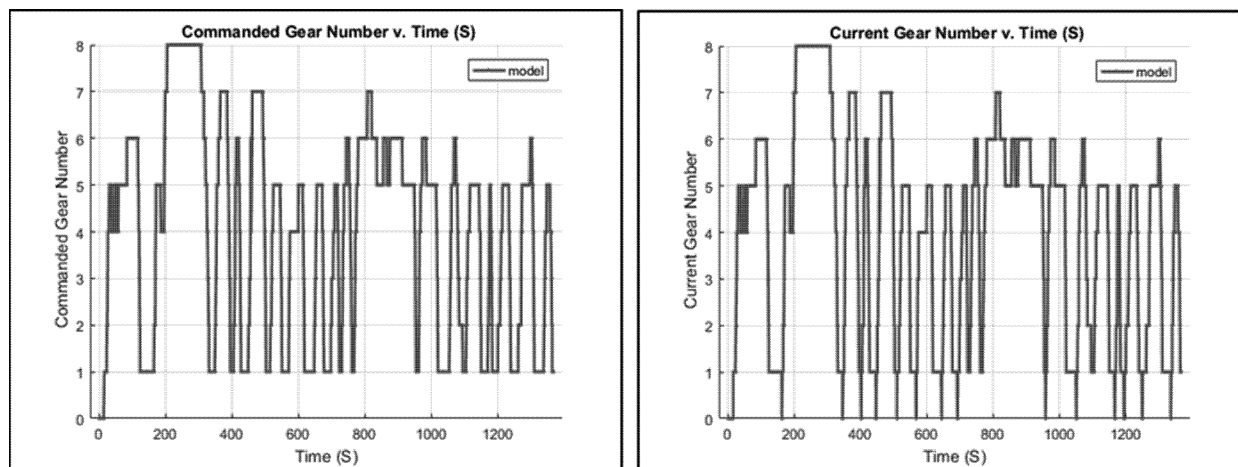

Figure VI-6 – Comparison of Commanded Gear Shift versus Actual Gear Shift for the UDDS⁶²²

Regarding the technical expertise of the team conducting the effectiveness modeling, ICCT commented:

[T]he agencies should also disclose how much commercial business is conducted by

the Ricardo, IAV, and Argonne Autonomie teams that underpin the modeling of EPA and NHTSA, respectively, including how much related research they have done for auto industry clients over the past ten years. We mention this because we strongly suspect

that Ricardo, upon which EPA built its ALPHA model, has done at least an order of magnitude (in number of projects, person-hours, and budget) more work with and for the automotive industry than the IAV and Autonomie teams have in direct work for

⁶¹⁷ 2015 NAS Report at p. 82.

automotive industry clients. A conventional government procurement effort that competitively vets potential research expert teams would presumably have selected for such automotive industry credentials and experience, yet it appears that the agencies are wholly deferring to Autonomie's less rigorous research-grade modeling framework and data due to convenience and easier access by the NHTSA research team, rather than for any technical improvement, and this is to the detriment of showing clear understanding of real-world automotive engineering developments (as demonstrated by many erroneous technology combination results throughout these comments).

First, NHTSA follows Federal Acquisition Regulation (FAR) to award contracts and Interagency Agreements (IAAs),⁶²³ and any awarded contracts and IAAs must follow the FAR requirements. Importantly, FAR 3.101–1 includes key aspects of conduct and ethics that NHTSA must follow in awarding a contract or IAA:

Government business shall be conducted in a manner above reproach and, except as authorized by statute or regulation, with complete impartiality and with preferential treatment for none. Transactions relating to the expenditure of public funds require the highest degree of public trust and an impeccable standard of conduct. The general rule is to avoid strictly any conflict of interest or even the appearance of a conflict of interest in Government-contractor relationships. While many Federal laws and regulations place restrictions on the actions of Government personnel, their official conduct must, in addition, be such that they would have no reluctance to make a full public disclosure of their actions.⁶²⁴

While some factors are more relevant than others in considering whether to award a contract or enter into an IAA, the amount of work that an organization has performed, characterized by projects, person-hours, and budget, is only one of a multitude of factors that is considered (if it is even considered at all—an agency might not request this information and an organization might decline to provide it because of contractual clauses or to protect commercial business interests) when assessing whether an organization meets the agency's needs for a specific task. Other factors, such as the federal budget, also set boundaries for the scope of work that can be performed under any competitive government procurement effort.

As discussed throughout this section, the team at Argonne National Laboratory behind Autonomie has developed and refined a state-of-the-art tool that is used by the automotive

industry, government agencies, and research or other nongovernmental institutions around the world. The tool has been and continues to be validated to production vehicles, and updated to include models, sub-models, and controls representing the state-of-the-art in fuel economy improving technology. To the extent that ICCT believes that “research done for auto industry clients,” “work with and for the automotive industry,” and “automotive industry credentials and experience,” are metrics upon which to base this type of important decision, the agencies point ICCT to the statements from the automotive industry, above, recommending Autonomie be used for technology effectiveness modeling.

ICCT concluded that “[w]hile the agencies are in their process of conducting a proper vetting of their NPRM's foundational Autonomie-based modeling, we recommend that they rely on what appears to be the superior and better vetted technology modeling approach with more thorough and state-of-the-art advanced powertrain systems modeling and engine maps from the EPA ALPHA modeling.”

The agencies properly vetted the Autonomie modeling and decided that Autonomie represented a reasonable and appropriate tool to provide technology effectiveness estimates for this rulemaking. To the extent that commenters' concerns were more about the effectiveness results than the tools used to model technology effectiveness, modeling updates detailed in the Section VI.B.3.c), below, address those comments. While some commenters may still be dissatisfied with Autonomie's technology effectiveness estimates, the agencies believe that the refinement of inputs and input assumptions, and associated explanation of why those refinements are appropriate and reasonable, have appropriately addressed comments on these issues. Importantly, none of these refinements have led either agency to reconsider using Autonomie for this rulemaking analysis.

Additional discussion of the agencies' decision to rely on one set of modeling tools for this rulemaking is located in Section VI.A of this preamble.

c) Technology Effectiveness Values Implementation in the CAFE Model

While the Autonomie model produces a large amount of information about each simulation run—for a single technology combination, in a single technology class—the CAFE model only uses two elements of that information: Battery costs and fuel consumption on the city and highway cycles. The

agencies combine the fuel economy information from the two cycles to produce a composite fuel economy for each vehicle, on each fuel. Plug-in hybrids, being the only dual-fuel vehicles in the Autonomie simulation, require efficiency estimates of operation on both gasoline and electricity—as well as an estimate of the utility factor, or the number of miles driven on each fuel. The fuel economy information for each technology combination, for each technology class, is converted into a single number for use in the CAFE model.

As described in greater detail below, each Autonomie simulation record represents a unique combination of technologies, and the agencies create a technology “key” or technology state vector that describes all the technology content associated with a record. The 2-cycle fuel economy of each combination is converted into fuel consumption (gallons per mile) and then normalized relative to the starting point for the simulations. In each technology class, the combination with the lowest technology content is the VVT (only) engine, with a 5-speed transmission, no electrification, and no body-level improvements (mass reduction, aerodynamic improvements, or low rolling resistance tires). This is the reference point (for each technology class) for all the effectiveness estimates in the CAFE model. The improvement factors that the model uses are a given combination's fuel consumption improvement relative to the reference vehicle in its technology class.

For the majority of the technologies analyzed within the CAFE Model, the fuel economy improvements were derived from the database of Autonomie's detailed full-vehicle modeling and simulation results. In addition to the technologies found in the Autonomie simulation database, the CAFE modeling system also incorporated a handful of technologies that were required for CAFE modeling, but were not explicitly simulated in Autonomie. The total effectiveness of these technologies either could not be captured on the 2-cycle test, or there was no robust data that could be used as an input to the full-vehicle modeling and simulation, like with emerging technologies such as advanced cylinder deactivation (ADEAC). These additional technologies are discussed further in Sections VI.B.3 Technology Effectiveness and individual technologies sections. For calculating fuel economy improvements attributable to these additional technologies, the model used defined fuel consumption improvement factors that are constant

⁶²³ Federal Acquisition Regulation (FAR). <https://www.acquisition.gov/>.

⁶²⁴ FAR 3.101–1.

across all technology combinations in the database and scale multiplicatively when applied together. The Autonomie-simulated and additional technologies were then externally combined, forming a single dataset of simulation results (referred to as the vehicle simulation database, or simply, database), which may then be utilized by the CAFE modeling system.

To incorporate the results of the combined database of Autonomie-simulated and additional technologies, while still preserving the basic structure of the CAFE Model's technology subsystem, it was necessary to translate the points in this database into corresponding locations defined by the technology pathways. By recognizing that most of the pathways are unrelated, and are only logically linked to designate the direction in which technologies are allowed to progress, it is possible to condense the paths into a smaller number of groups based on the specific technology. In addition, to allow for technologies present on the Basic Engine and Dynamic Road Load (DLR—*i.e.*, MASS, AERO, and ROLL) paths to be evaluated and applied in any given combination, a unique group was established for each of these technologies.

As such, the following technology groups are defined within the modeling system: Engine cam configuration (CONFIG), VVT engine technology (VVT), VVL engine technology (VVL), SGDI engine technology (SGDI), DEAC engine technology (DEAC), non-basic engine technologies (ADVENG), transmission technologies (TRANS), electrification and hybridization (ELEC), low rolling resistance tires (ROLL), aerodynamic improvements (AERO), mass reduction levels (MR), EFR engine technology (EFR), electric accessory improvement technologies (ELECACC), LDB technology (LDB), and SAX technology (SAX). The combination of technologies along each of these groups forms a unique technology state vector and defines a unique technology combination that corresponds to a single point in the database for each technology class evaluated within the modeling system.

As an example, a technology state vector describing a vehicle with a SOHC engine, variable valve timing (only), a 6-speed automatic transmission, a belt-integrated starter generator, rolling resistance (level 1), aerodynamic improvements (level 2), mass reduction (level 1), electric power steering, and low drag brakes, would be specified as “SOHC; VVT; AT6; BISG; ROLL10;

AERO20; MR1; EPS; LDB.”⁶²⁵ By assigning each unique technology combination a state vector such as the one in the example, the CAFE Model can then assign each vehicle in the analysis fleet an initial state that corresponds to a point in the database.

Once a vehicle is assigned (or mapped) to an appropriate technology state vector (from one of approximately three million unique combinations, which are defined in the vehicle simulation database as CONFIG; VVT; VVL; SGDI; DEAC; ADVENG; TRANS; ELEC; ROLL; AERO; MR; EFR; ELECACC; LDB; SAX), adding a new technology to the vehicle simply represents progress from a previous state vector to a new state vector. The previous state vector simply refers to the technologies that are currently in use on a vehicle. The new state vector, however, is computed within the modeling system by adding a new technology to the combination of technologies represented by the previous state vector, while simultaneously removing any other technologies that are superseded by the newly added one.

For example, consider the vehicle with the state vector described as: SOHC; VVT; AT6; BISG; ROLL10; AERO20; MR1; EPS; LDB. Assume the system is evaluating PHEV20 as a candidate technology for application on this vehicle. The new state vector for this vehicle is computed by removing SOHC, VVT, AT6, and BISG technologies from the previous state vector,⁶²⁶ while also adding PHEV20, resulting in the following: PHEV20; ROLL10; AERO20; MR1; EPS; LDB.

From here, it is relatively simple to obtain a fuel economy improvement factor for any new combination of technologies and apply that factor to the fuel economy of a vehicle in the analysis fleet. The formula for calculating a vehicle's fuel economy after application of each successive technology represented within the database is defined, simply put, as the difference between the fuel economy improvement factor associated with the technology state vector before application of a candidate technology, and after the application of a candidate

technology.⁶²⁷ This is applied to the original compliance fuel economy value for a discrete vehicle in the MY 2017 analysis fleet, as discussed previously in Section VI.B.3 Technology Effectiveness.

The fuel economy improvement factor is defined in a way that captures the incremental improvement of moving between points in the database, where each point is defined uniquely as a combination of up to 15 distinct technologies describing, as mentioned above, the engine's cam configuration, multiple distinct combinations of engine technologies, transmission, electrification type, and various vehicle body level technologies.

Unlike the preceding versions of the modeling system, the current version of the CAFE Model relies entirely on the vehicle simulation database for calculating fuel economy improvements resulting from all technologies available to the system. The fuel economy improvements are derived from the factors defined for each unique technology combination or state vector. Each time the improvement factor for a new state vector is added to a vehicle's existing fuel economy, the factor associated with the old technology combination is entirely removed. In that sense, application of technologies obtained from the Autonomie database is “self-correcting” within the model. As such, special-case adjustments defined by the previous version of the model are not applicable to this one.

Meszler Engineering Services, commenting on behalf of Natural Resources Defense Council, commented that “[w]ith very limited exception, technology is not included in the NPRM CAFE model if it was not included in the simulation modeling that underlies the Argonne database,” citing the “add-on” technologies and technologies with fixed effectiveness values.⁶²⁸ Meszler continued, “[t]his same limitation controls the coupling of technologies, and by extension the definition of the CAFE model technology pathways. If a combination of technologies were not modeled during the development of the Argonne database, that package (or combination) of technologies is not available for adoption in the CAFE model. Both of these design constraints serve to limit the slate of technologies available to respond to fuel economy

⁶²⁵ In the example technology state vector, the series of semicolons between VVT and AT6 correspond to the engine technologies which are not included as part of the combination, while the gap between MR1 and EPS corresponds to EFR and the omitted technology after LDB is SAX. The extra semicolons for omitted technologies are preserved in this example for clarity and emphasis, and will not be included in future examples.

⁶²⁶ For more discussion of how the CAFE Model handles technology supersession, see Section VI.A.7.

⁶²⁷ For more discussion of how the CAFE Model calculates a vehicle's fuel economy where the vehicle switches from one type of fuel to another, for example, from gasoline operation to diesel operation or from gasoline operation to plug-in hybrid/electric vehicle operation, see Section VI.A CAFE Model.

⁶²⁸ NHTSA–2018–0067–11723, at 4–5.

standards. The slate of available technologies is basically constrained to those included in NHTSA's research activity. If a technology or technology combination was not in the NHTSA research planning process, it is not available in the model." Finally, Meszler stated that "because of the constrained model architecture and the reliance on the Argonne database for impact estimates, independently expanding the model to include additional technologies or technology combinations is not trivial."

We agree that expanding the database to include new technologies is not trivial. However, it is possible. The set of available technologies is part of the model code, and the code is made public upon each release of the model. Many commenters made modifications to the model code, conducted additional tests of their own, and presented their results to the agencies in the form of public comments before the end of the public comment period. A user could add the new technology, identify the associated engineering restrictions that determine combinations for which that technology should not be considered, and add the relevant rows (representing possible technology combinations that include the new technology) in the database (which exists locally on every computer that runs the model). An enterprising user could also take an existing technology along a given path and replace the efficiency values with new values—presumably from their own full vehicle simulations for each technology combination that contains the technology in question. Given the length of time and computing power required to simulate vehicle fuel economy on the test cycle for every possible combination that could be considered by the CAFE model, using a pre-defined database that represents a large ensemble of simulated technology combinations is preferable to the alternative of fully integrating a vehicle simulation model that would be required to run in real-time during the compliance simulation to evaluate the effectiveness of every combination considered (not just applied) by the model.

4. Technology Costs

In the proposal, the agencies estimated present and future costs for fuel-saving technologies, taking into consideration the type of vehicle, or type of engine if technology costs vary by application. These cost estimates are based on three main inputs. First, the agencies estimated direct manufacturing costs (DMCs), or the component and labor costs of producing and assembling

the physical parts and systems, with estimated costs assuming high volume production. DMCs generally do not include the indirect costs of tools, capital equipment, financing costs, engineering, sales, administrative support or return on investment. Second, the agencies accounted for these indirect costs via a scalar markup of direct manufacturing costs (the retail price equivalent, or RPE). Finally, costs for technologies may change over time as industry streamlines design and manufacturing processes. The agencies therefore estimated potential cost improvements with learning effects (LE). The retail cost of equipment in any future year is estimated to be equal to the product of the DMC, RPE, and LE. Considering the retail cost of equipment, instead of merely direct manufacturing costs, is important to account for the real-world price effects of a technology, as well as market realities. Absent a government mandate, motor vehicle manufacturers will not undertake expensive development and production efforts to implement technologies without realistic prospects of consumers being willing to pay enough for such technology to allow for the manufacturers to recover their investment.

a) Direct Manufacturing Costs

Direct manufacturing costs (DMCs) are the component costs of the physical parts and systems that make up a complete vehicle. The analysis used agency-sponsored tear-down studies of vehicles and parts to estimate the DMCs of individual technologies, in addition to independent tear-down studies, other publications, and confidential business information. In the simplest cases, the agency-sponsored studies produced results that confirmed third-party industry estimates, and aligned with confidential information provided by manufacturers and suppliers. In cases with a large difference between the tear-down study results and credible independent sources, study assumptions were scrutinized, and sometimes the analysis was revised or updated accordingly.

Due to the variety of technologies and their applications, and the cost and time required to conduct detailed tear-down analyses, the agencies did not sponsor teardown studies for every technology. In addition, many fuel-saving technologies were considered that are pre-production, or sold in very small pilot volumes. For those technologies, a tear-down study could not be conducted to assess costs because the product is not yet in the marketplace for evaluation. In these cases, the agencies

relied upon third-party estimates and confidential information from suppliers and manufacturers were relied upon; however, there are some common pitfalls with relying on confidential business information to estimate costs. The agencies and the source may have had incongruent or incompatible definitions of "baseline." The source may have provided DMCs at a date many years in the future, and assumed very high production volumes, important caveats to consider for agency analysis. In addition, a source, under no contractual obligation to the agencies, may provide incomplete and/or misleading information. In other cases, intellectual property considerations and strategic business partnerships may have contributed to a manufacturer's cost information and could be difficult to account for in the model as not all manufacturer's may have access to proprietary technologies at stated costs. The agencies carefully evaluated new information in light of these common pitfalls, especially regarding emerging technologies.

Specifically, the analysis used third-party, forward-looking information for advanced cylinder deactivation and variable compression ratio engines. While these cost estimates may be preliminary (as is the case with many emerging technologies prior to commercialization), the agencies consider them to be reasonable estimates of the likely costs of these technologies.

While costs for fuel-saving technologies reflect the best estimates available today, technology cost estimates will likely change in the future as technologies are deployed and as production is expanded. For emerging technologies, the best information available at the time of the analysis was utilized, and cost assumptions will continue to be updated for any future analysis. Below, discussion of each category of technologies (*e.g.*, engines, transmissions, electrification) summarizes comments on corresponding direct cost estimates, and reviews estimates the agencies have applied for today's analysis.

Indirect Costs

As discussed above, direct costs represent the cost associated with acquiring raw materials, fabricating parts, and assembling vehicles with the various technologies manufacturers are expected to use to meet future CAFE and CO₂ standards. They include materials, labor, and variable energy costs required to produce and assemble the vehicle. However, they do not

include overhead costs required to develop and produce the vehicle, costs incurred by manufacturers or dealers to sell vehicles, or the profit manufacturers

and dealers make from their investments. All of these items contribute to the price consumers ultimately pay for the vehicle. These

components of retail prices are illustrated in Table VI–23 below.

Table VI-23 – Retail Price Components

| | |
|---------------------------------|---|
| DIRECT COSTS | |
| Manufacturing Cost | Cost of materials, labor, and variable energy needed for production |
| INDIRECT COSTS | |
| Production Overhead | |
| Warranty | Cost of providing product warranty |
| Research and Development | Cost of developing and engineering the product |
| Depreciation and amortization | Depreciation and amortization of manufacturing facilities and equipment |
| Maintenance, repair, operations | Cost of maintaining and operating manufacturing facilities and equipment |
| Corporate Overhead | |
| General and Administrative | Salaries of nonmanufacturing labor, operations of corporate offices, etc. |
| Retirement | Cost of pensions for nonmanufacturing labor |
| Health Care | Cost of health care for nonmanufacturing labor |
| Selling Costs | |
| Transportation | Cost of transporting manufactured goods |
| Marketing | Manufacturer costs of advertising manufactured goods |
| Dealer Costs | |
| Dealer selling expense | Dealer selling and advertising expense |
| Dealer profit | Net Income to dealers from sales of new vehicles |
| Net income | Net income to manufacturers from production and sales of new vehicles |

In addition to direct manufacturing costs, the agencies estimated and considered indirect manufacturing costs. To estimate indirect costs, direct manufacturing costs are multiplied by a factor to represent the average price for fuel-saving technologies at retail.

In the Draft TAR and preceding CAFE and safety rulemaking analyses, NHTSA relied on a factor, referred to as the retail price equivalent (RPE), to account for indirect manufacturing costs. The RPE accounts for indirect costs like engineering, sales, and administrative support, as well as other overhead costs, business expenses, warranty costs, and return on capital considerations. In the Draft TAR (and subsequent Determination) as well as the 2012 rulemaking analysis, EPA applied an “Indirect Cost Multiplier” (ICM) approach that it first applied in the 2010 rulemaking regarding standards for MYs 2012–2016, which also accounted for indirect manufacturing costs, albeit in a different way than the RPE approach.

Some commenters recommended the agencies rely on the ICM approach for the current rulemaking, citing EPA’s prior peer review and use of this approach.⁶²⁹ Others supported the agencies’ reliance on the RPE approach, citing the National Research Council’s observations in 2015 that the ICM approach lacks an empirical basis.⁶³⁰ The agencies have carefully considered these comments, and conclude that while the ICM approach has conceptual merit, its application requires a range of

specific estimates, and data to support such estimates is scant and, in some cases, nonexistent. The agencies have, therefore, applied the RPE approach for this final rule, as in the NPRM analysis and other rulemaking analyses. The following sections discuss both approaches in detail to explain why the RPE approach was chosen for this final rule.

(1) Retail Price Equivalent

Historically, the method most commonly used to estimate indirect costs of producing a motor vehicle has been the retail price equivalent (RPE). The RPE markup factor is based on an examination of historical financial data contained in 10–K reports filed by manufacturers with the Securities and Exchange Commission (SEC). It represents the ratio between the retail price of motor vehicles and the direct costs of all activities that manufacturers engage in, including the design, development, manufacturing, assembly,

⁶²⁹ See, e.g., ICCT, NHTSA–2018–0067–11741, Attachment 3, at I–83. See also CFA, NHTSA–2018–0067–12005, Attachment B, at p.189.

⁶³⁰ See, e.g., Alliance, NHTSA–2018–0067–12073, at 143. See also National Research Council, “Cost, Effectiveness, and Deployment of Fuel Economy Technologies for Light-Duty Vehicles,” 2015, available at <https://www.nap.edu/catalog/21744/cost-effectiveness-and-deployment-of-fuel-economy-technologies-for-light-duty-vehicles> (“... the empirical basis for such multipliers is still lacking, and, since their application depends on expert judgment, it is not possible for to determine whether the Agencies’ ICMs are accurate or not”).

and sales of new vehicles, refreshed vehicle designs, and modifications to meet safety or fuel economy standards.

Figure VI-7 indicates that for more than three decades, the retail price of motor vehicles has been, on average, roughly 50 percent above the direct cost expenditures of manufacturers. This ratio has been remarkably consistent, averaging roughly 1.5 with minor variations from year to year over this period. At no point has the RPE markup exceeded 1.6 or fallen below 1.4.⁶³¹ During this time frame, the average

annual increase in real direct costs was 2.5 percent, and the average annual increase in real indirect costs was also 2.5 percent. Figure VI-7 illustrates the historical relationship between retail prices and direct manufacturing costs.⁶³²

An RPE of 1.5 does not imply that manufacturers automatically mark up each vehicle by exactly 50 percent. Rather, it means that, over time, the competitive marketplace has resulted in pricing structures that average out to this relationship across the entire

industry. Prices for any individual model may be marked up at a higher or lower rate depending on market demand. The consumer who buys a popular vehicle may, in effect, subsidize the installation of a new technology in a less marketable vehicle. But, on average, over time and across the vehicle fleet, the retail price paid by consumers has risen by about \$1.50 for each dollar of direct costs incurred by manufacturers.

Figure VI-7 – Historical Data for Retail Price Equivalent (RPE), 1972-1997 and 2007

It is also important to note that direct costs associated with any specific technology will change over time as some combination of learning and resource price changes occurs. Resource costs, such as the price of steel, can fluctuate over time and can experience real long-term trends in either direction, depending on supply and demand. However, the normal learning process generally reduces direct production costs as manufacturers refine production techniques and seek out less costly parts and materials for increasing production volumes. By contrast, this learning process does not generally influence indirect costs. The implied RPE for any given technology would thus be expected to grow over time as

direct costs decline relative to indirect costs. The RPE for any given year is based on direct costs of technologies at different stages in their learning cycles, and which may have different implied RPEs than they did in previous years. The RPE averages 1.5 across the lifetime of technologies of all ages, with a lower average in earlier years of a technology's life, and, because of learning effects on direct costs, a higher average in later years.

The RPE has been used in all NHTSA safety and most previous CAFE rulemakings to estimate costs. The National Academy of Sciences recommends RPEs of 1.5 for suppliers and 2.0 for in-house production be used to estimate total costs. The Alliance of

Automobile Manufacturers also advocates these values as appropriate markup factors for estimating costs of technology changes. An RPE of 2.0 has also been adopted by a coalition of environmental and research groups (NESCCAF, ICCT, Southwest Research Institute, and TIAX-LLC) in a report on reducing heavy truck emissions, and 2.0 is recommended by the U.S. Department of Energy for estimating the cost of hybrid-electric and automotive fuel cell costs ((see Vyas et al. (2000) in Table VI-24, below).

Table VI-24 below lists other estimates of the RPE. Note that all RPE estimates vary between 1.4 and 2.0, with most in the 1.4 to 1.7 range.

⁶³¹ Based on data from 1972–1997 and 2007. Data were not available for intervening years, but results for 2007 seem to indicate no significant change in the historical trend.

Table VI-24 – Alternate Estimates of the RPE⁶³³

| Author and Year | Value, Comments |
|---------------------------------------|--|
| Jack Faucett Associates for EPA, 1985 | 1.26 initial value, later corrected to 1.7+ by Sierra research |
| Vyas et al, 2000 | 1.5 for outsourced, 2.0 for OEM, electric, and hybrid vehicles |
| NRC, 2002 | 1.4 (corrected to > by Duleep) |
| McKinsey and Company, 2003 | 1.7 based on European study |
| CARB, 2004 | 1.4 (derived using the JFA initial 1.26 value, not the corrected 1.7+ value) |
| Sierra Research for AAA, 2007 | 2.0 or >, based on Chrysler data |
| Duleep, 2008 | 1.4, 1.56, 1.7 based on integration complexity |
| NRC, 2010 | 1.5 for Tier 1 supplier, 2.0 for OEM |

The RPE has thus enjoyed widespread use and acceptance by a variety of governmental, academic, and industry organizations. The RPE has been the most commonly used basis for indirect cost markups in regulatory analyses. However, as noted above, the RPE is an aggregate measure across all technologies applied by manufacturers and is not technology specific. A more detailed examination of these technologies is possible through an alternative measure, the indirect cost multiplier, which was developed to focus more specifically on technologies used to meet CAFE and CO₂ standards.

(2) Indirect Cost Multiplier

A second approach to accounting for indirect costs is the indirect cost multiplier (ICM). ICMs specifically evaluate the components of indirect costs likely to be affected by vehicle modifications associated with environmental regulation. EPA

developed the ICM concept to enable the application of markups more specific to each technology. For example, the indirect cost implications of using tires with better rolling resistance would not be the same as those for developing an entire new hybrid vehicle technology, which would require far more R&D, capital investment, and management oversight. With more than 80 different technologies available to incrementally achieve fuel economy improvements,⁶³⁴ a wide range of indirect cost effects might be expected. ICMs attempt to isolate only those indirect costs that would have to change to develop a specific technology. Thus, for example, if a company were to hire additional staff to sell vehicles equipped with fuel economy improving technology, or to search the technology requirements of new CO₂ or CAFE standards, the cost of these staff would be included in ICMs. However, if these functions were accomplished by existing staff, they would not be included. For example, if an executive who normally devoted 10 percent of his time to fuel economy standards compliance were to devote 50 percent of his time in response to new more stringent requirements, his salary would not be included in ICMs because he would be paid the same salary regardless of whether he devoted his time to addressing CAFE requirements, developing new performance technologies, or improving the company's market share. ICMs thus do not account for the diverted resources required for manufacturers to meet these standards, but rather for the net change in costs manufacturers might experience

because of hiring *additional* personal or acquiring *additional* assets or services.

For past rulemakings EPA developed both short-term and long-term ICMs. Long-term ICMs are lower than short-term ICMs. This decline reflects the belief that many indirect costs will decline over time. For example, research is initially required to develop a new technology and apply it throughout the vehicle fleet, but a lower level of research will be required to improve, maintain, or adapt that new technology to subsequent vehicle designs.

While the RPE was derived from data in financial statements (reflecting real-world operating and financial results), no similar data sources were available to estimate ICMs. ICMs are based on the RPE, broken into its components, as shown in Table VI-25. Adjustment factors were then developed for those components, based on the complexity and time frame of low-, medium-, and high-complexity technologies. The adjustment factors were developed from two panels of engineers with background in the automobile industry. Initially, a group of engineers met and developed an estimate of ICMs for three different technologies. This "consensus" panel examined one low complexity technology, one medium complexity technology, and one high complexity technology, with the initial intent of using these technologies to represent ICM factors for all technologies falling in those categories. At a later date, a second panel was convened to examine three more technologies (one low, one medium, and one high complexity), using a modified Delphi approach to estimate indirect cost effects. The results from the second panel identified the same pattern as those of the original report—the indirect cost multipliers increase with the

⁶³⁴ There are roughly 40 different basic unique technologies, but variations among these technologies roughly double the possible number of different technology applications.

complexity of the technology and decrease over time. The values derived in process are higher than those in the RPE/IC Report by values ranging from

0.09 (that is, the multiplier increased from 1.20 to 1.29) to 0.19 (the multiplier increased from 1.45 to 1.64). This variation may be due to differences in

the technologies used in each panel. The results are shown in Figure VI-8, together with the historical average RPE.

Figure VI-8 – Indirect Cost Estimates from EPA Consensus and Delphi Panels, Short and Long Term

In subsequent CAFE and CO₂ analyses for MYs 2011, as well as for the 2012–2016 rulemaking, a simple average of the two resulting ICMs in the low and medium technology complexity categories was applied to direct costs for all unexamined technologies in each specific category. For high complexity technologies, the lower consensus-based estimate was used for high complexity technologies currently being produced, while the higher modified Delphi-based estimate was used for more advanced technologies, such as plug-in hybrid or electric vehicles, which had little or no current market penetration. Note that ICMs originally did not include profit or “return on capital,” a fundamental difference from the RPE. However, prior to the 2012–2016 CAFE analysis, ICMs were modified to include provision for return on capital.

(3) Application of ICMs in the 2017–2025 Analysis

For the model year 2017–2025 rulemaking analysis, NHTSA and EPA

revisited technologies evaluated by EPA staff and reconsidered their method of application. The agencies were concerned that averaging consensus and modified Delphi ICMs might not be the most accurate way to develop an estimate for the larger group of unexamined technologies. Specifically, there was concern that some technologies might not be representative of the larger groups they were chosen to represent. Further, the agencies were concerned that the values developed under the consensus method were not subject to the same analytical discipline as those developed from the modified Delphi method. As a result, the agencies relied primarily on the modified Delphi-based technologies to establish their revised distributions. Thus, for the MY 2017–2025 analysis, the agencies used the following basis for estimating ICMs:

- All low complexity technologies were estimated to equal the ICM of the modified Delphi-based low technology-passive aerodynamic improvements.

- All medium complexity technologies were estimated to equal the ICM of the modified Delphi-based medium technology-engine turbo downsizing.

- Strong hybrids and non-battery plug-in hybrid electric vehicles (PHEVs) were estimated to equal the ICM of the high complexity consensus-based high technology-hybrid electric vehicle.

- PHEVs with battery packs and full electric vehicles were estimated to equal the ICM of the high complexity modified Delphi-based high technology-plug-in hybrid electric vehicle.

In addition to shifting the proxy basis for each technology group, the agencies reexamined each technology’s complexity designation in light of the examined technologies that would serve as the basis for each group. The resulting designations together with the associated proxy technologies are shown in Table VI-25.

Table VI-25 – Technology Designations by ICM Category, with Proxy Technology

| Low Technology | Medium Technology | High Tech 1 | High Tech 2 |
|----------------------------------|-------------------------------------|-------------------------|---------------------------------|
| Passive Aerodynamic Improvements | Engine Turbo Downsizing | Hybrid Electric Vehicle | Plug-in Hybrid Electric Vehicle |
| Passive Aerodynamic Improv. | 6-speed DCTs | Strong Hybrids | PHEV battery packs |
| Lubricant improvements | Mass Reduction 15-20% | PHEV and EV chargers | All Electric vehicles |
| Mass Reductions 3-10% | Turbocharging | PHEVs w/o batteries | |
| Aggressive Shift Logic | Cylinder deactivation | | |
| Engine Friction Reduction | Dual valve timing and discreet lift | | |
| Engine Downsizing | 8-speed transmissions | | |
| 6 speed transmissions | 12 volt start-stop systems | | |
| Low Drag Brakes | Active aerodynamics | | |
| Electro-hydraulic power steering | Diverting OHV/SOHC to DOHC | | |
| Electronic power steering | Gasoline direct injection | | |
| WT intake or coupled | Turbo downsizing | | |
| Improved accessories | Turbo downsizing +EGR | | |
| Early torque converter lockup | Diesel vehicles | | |
| | Variable valve lift and timing | | |
| | Lean-burn gasoline engines | | |

Many basic technologies noted in Table VI-25 have variations sharing the same complexity designation and ICM estimate. Table VI-26 lists each technology used in the CAFE model

together with their ICM category and the year through which the short-term ICM would be applied. Note that the number behind each ICM category designation refers to the source of the ICM estimate,

with 1 indicating the consensus panel and 2 indicating the modified Delphi panel.

BILLING CODE 4910-59-C

An additional adjustment was made to ICMs to account for the fact that they were derived from the RPE analysis for a specific year (2007). The agencies believed it would be more appropriate to base ICMs on the expected long-term average RPE rather than that of one specific year. To account for this, ICMs were normalized to an average RPE multiplier level of 1.5.

Table VI-27 lists values of ICMs by technology category used in the previous MY 2017–2025 rulemaking. As noted previously, the Low 1 and Medium 1 categories, which were derived using the initial consensus panel, are not used. Short-term values applied to CAFE technologies thus range from 1.24 for Low complexity technologies, 1.39 for Medium

complexity technologies, 1.56 for High1 complexity technologies, and 1.77 for High2 complexity technologies. When long-term ICMs are applied in the year following that noted in the far-right column of Table VI-27, these values will drop to 1.19 for Low, 1.29 for Medium, 1.35 for High1 and 1.50 for High2 complexity technologies.

Table VI-27 – ICMs by Technology Category Previously Used in 2017-2025 CAFE Rule

Note that ICMs for warranty costs are listed separately in Table VI-27. This was done because warranty costs are treated differently than other indirect costs. In some previous analyses (prior to MY 2017–2025), learning was applied directly to total costs. However, the agencies believe learning curves are more appropriately applied only to direct costs, with indirect costs established up front based on the ICM and held constant while direct costs are reduced by learning. Warranties are an exception to this because warranty costs

involve future replacement of defective parts, and the cost of these parts would reflect the effect of learning. Warranty costs were thus treated as being subject to learning along with direct costs.⁶³⁵

The effect of learning on direct costs, together with the eventual substitution of lower long-term ICMs, causes the effective markup from ICMs to differ from the initial ICM on a yearly basis. An example of how this occurs is provided in Table VI-28.⁶³⁶ This table, which was originally developed for the MY 2017–2025 analysis, traces the effect

of learning on direct costs and its implications for both total costs and the ICM-based markup. Direct costs are assigned a value (proportion) of 1 to facilitate analysis on the same basis as ICMs (in an ICM markup factor, the proportion of direct costs is represented by 1 while the proportion of indirect costs is represented by the fraction of 1 to the right of the decimal.) Table VI-28 examines the effects of these factors on turbocharged downsized engines, one of the more prevalent CAFE technologies.

⁶³⁵ Note that warranty costs also involve labor costs for installation. This is typically done at dealerships, and it is unlikely labor costs would be subject to learning curves that affect motor vehicle parts or assembly costs. However, the portion of

these costs that is due to labor versus that due to parts is unknown, so for this analysis, learning is applied to the full warranty cost.

⁶³⁶ Table VI-22 illustrates the learning process from the base year consistent with the direct cost

estimate obtained by the agencies. It is a mature technology well into the flat portion of the learning curve. Note that costs were actually applied in this rulemaking example beginning with MY 2017.

Table VI-28 – Derived Annual ICMs for Turbocharged Downsized Engines

| Average ICM-based markup 2017 through 2030 - | | | | | | 1.389 |

The second column of Table VI-28 lists the learning schedule applied to turbocharged downsized engines. Turbocharged downsized engines are a mature technology, so the learning schedule captures the relatively flat portion of the learning curve occurring after larger decreases have already reduced direct costs. The cost basis for turbocharged downsized engines in the analysis was effective in 2012, so this is the base year for this calculation when direct costs are set to 1. The third column shows the progressive decline in direct costs as the learning schedule in column 2 is applied to direct costs. Column 4 contains the value of all indirect costs except warranty. Turbocharged downsized engines are a medium-complexity technology, so this value is taken from the Medium2 row of Table VI-27. The initial value in 2012 is the short-term value, which is used through 2018. During this time, these indirect costs are not affected by learning, and they remain constant. Beginning in 2019, the long-term ICM from Table VI-27 is applied.

The fifth column contains warranty costs. As previously mentioned, these costs are considered to be affected by

learning like direct costs, so they decline steadily until the long-term ICM is applied in 2019, at which point they drop noticeably before continuing their gradual decline. In the sixth column, direct and indirect costs are totaled. Results indicate a decline in total costs of roughly 30 percent during this 14-year period. The last column shows the effective ICM-based markup, which is derived by dividing total costs by direct costs. Over this period, the ICM-based markup rose from the initial short-term ICM level of 1.39 to 1.45 in 2018. It then declined to 1.35 in 2019 when the long-term ICM was applied to the 2019 direct cost. Over the remaining years, it gradually rises back up to 1.41 as learning continues to degrade direct costs.

There are thus two somewhat offsetting processes affecting total costs derived from ICMs. The first is the learning curve, which reduces direct costs, which raises the effective ICM-based markup. As noted previously, learning reflects learned efficiencies in assembly methods as well as reduced parts and materials costs. The second is the application of a long-term ICM, which reduces the effective ICM-based

markup. This represents the reduced burden needed to maintain new technologies once they are fully developed. In this case, the two processes largely offset one another and produce an average real ICM over this 14-year period that roughly equals the original short-term ICM.

Figure VI-9 illustrates this process for each of the 4 technologies used to represent the universe of fuel economy and CO₂ improving technologies. As with the turbocharged engines, aerodynamic improvements and mild hybrid vehicles show a gradual increase in the effective ICM-based markup through the point where the long-term ICM is applied. At that time, the ICM-based markup makes an abrupt decline before beginning a gradual rise. The decline due to application of long-term ICMs is particularly pronounced in the case of the mild hybrid—even more so than for the advanced hybrid. The advanced hybrid ICM behaves somewhat differently because it is shown through its developing stages when more radical learning is applied, but only every few years. This produces a significant step-up in ICM levels concurrent with each learning

application, followed by a sharp decline when the long-term ICM is applied. After that, it begins a gradual rise as more moderate learning is applied to reflect its shift to a mature technology. Note that as with the turbocharged downsized engine example above, for the aerodynamic improvements and mild hybrid technologies, the offsetting

processes of learning and long-term ICMs result in an average ICM over the full time frame that is roughly equal to the initial short-term ICM. However, the advanced hybrid ICM rose to a level significantly higher than the initial ICM. This is a direct function of the rapid learning schedule applied in the early years to this developing technology.

Brand new technologies might thus be expected to have effective lifetime ICM markups exceeding their initial ICMs, while more mature technologies are more likely to experience ICMs over their remaining life span that more closely approximate their initial ICMs.

Figure VI-9 – Derived ICM-Based Markups for Advanced Hybrids, Weak Hybrids, Turbo Downsized Engines, and Passive Aerodynamic Improvements

ICMs for these 4 technologies would drive the indirect cost markup rate for the analysis. However, the effect on total costs is also a function of the relative incidence of each of the 50+ technologies shown in Table VI-26 which are assumed to have ICMs similar to one of these 4 technologies. The net

effect on costs of these ICMs is also influenced by the learning curve appropriate to each technology, creating numerous different and unique ICM paths. The average ICM applied by the model is also a function of each technology's direct cost and because ICMs are applied to direct costs, the

measured indirect cost is proportionately higher for any given ICM when direct costs are higher. The average ICM applied to the fleet for any given model year is calculated as follows:

Equation VI-1 - Average ICM Calculation

$$\sum_{n=1}^{88} \frac{D_n A_n}{\sum_{n=1}^{88} D_n A_n} * ICM_n$$

where:

D = direct cost of each technology

A = application rate for each technology

ICM = average ICM applied to each technology

and n = 1, 2 . . . 88

The CAFE model predicts technology application rates assuming manufacturers will apply technologies

to meet standards in a logical fashion based on estimated costs and benefits. The application rates will thus be different for each model year and for each alternative scenario examined. For

the MY 2017–2025 FRIA, to illustrate the effects of ICMs on total technology costs, NHTSA calculated the weighted average ICM across all technologies for the preferred alternative.⁶³⁷ This was

done separately for each vehicle type and then aggregated based on predicted sales of each vehicle type used in the model. Results are shown in Table VI–29.

Table VI-29 – Average ICM-Based Markups Applied in Preferred Alternative

Scenario MY 2017-2025 FRIA

| Model Year | Passenger Cars | Light Trucks | All Vehicles |
|------------|----------------|--------------|--------------|
| 2017 | 0.393 | 0.370 | 0.383 |
| 2018 | 0.40 | 0.377 | 0.390 |
| 2019 | 0.315 | 0.308 | 0.312 |
| 2020 | 0.322 | 0.317 | 0.320 |
| 2021 | 0.330 | 0.323 | 0.327 |
| 2022 | 0.336 | 0.329 | 0.333 |
| 2023 | 0.344 | 0.337 | 0.341 |
| 2024 | 0.357 | 0.343 | 0.351 |
| 2025 | 0.340 | 0.319 | 0.331 |
| All Years | 0.348 | 0.336 | 0.343 |

The ICM-based markups in Table VI–29 were derived in a manner consistent with the way the RPE is measured, that is, they reflect combined influences of direct cost learning and changes in indirect cost requirements weighted by both the incidence of each technology's adaptation and the relative direct cost of each technology. The results indicate generally higher ICMs for passenger cars than for light trucks. This is a function of the technologies estimated to be adopted for each respective vehicle type, especially in later years when hybrids and electric vehicles become more prevalent in the passenger car fleet. The influence of these advanced vehicles is driven primarily by their direct costs, which greatly outweigh the costs of other technologies. This results in the application of much more weight to their higher ICMs. This is most notable in MYs 2024 and 2025 for passenger cars, when electric vehicles begin to enter the fleet. The average ICM increased 0.013 in 2024 primarily because of these vehicles. It immediately dropped 0.017 in 2025 because both an additional application of steep (20 percent) learning is applied to the direct cost of these vehicles (which reduces their relative weight), and the long-term ICM becomes

effective in that year (which decreases the absolute ICM factor). Both influences occur one year after these vehicles begin to enter the fleet because of CAFE requirements.

ICMs also change over time, again, reflecting the different mix of technologies present during earlier years but that are often replaced with more expensive technologies in later years. Across all model years, the wide-ranging application of diverse technologies required to meet CAFE and CO₂ standards produced an average ICM-based markup (or RPE equivalent) of approximately 1.34, applying only 67 percent of the indirect costs found in the RPE and implying total costs 11 percent below those predicted by the RPE-based calculation.

(4) Uncertainty

As noted above, the RPE and ICM assign different markups over direct manufacturing costs, and thus imply different total cost estimates for CAFE and CO₂ technologies. While there is a level of uncertainty associated with both markups, this uncertainty stems from different issues. The RPE is derived from financial statements and is thus grounded in historical data. Although compilation of this data is subject to

some level of interpretation, the two independent researchers who derived RPE estimates from these financial reports each reached essentially identical conclusions, placing the RPE at roughly 1.5. All other estimates of the RPE fall between 1.4 and 2.0, and most are between 1.4 and 1.7. There is thus a reasonable level of consistency among researchers that RPEs are 1.4 or greater. In addition, the RPE is a measure of the cumulative effects of all operations manufacturers undertake in the course of producing their vehicles, and is thus not specific to individual technologies, nor of CAFE or CO₂ technologies in particular. Because this provides only a single aggregate measure, using the RPE multiplier results in the application of a common incremental markup to all technologies. This assures the aggregate cost effect across all technologies is consistent with empirical data, but it does not allow for indirect cost discrimination among different technologies or over time. Because it is applied across all changes, this implies the markup for some technologies is likely to be understated, and for others it is likely to be overstated.

By contrast, the ICM process derives markups specific to several CAFE and CO₂ technologies, but these markups

⁶³⁷ For each alternative, this rulemaking examined numerous scenarios based on different assumptions, and these assumptions could influence the relative frequency of selection of

different technologies, which in turn could affect the average ICM. The scenario examined here assumed a 3 percent discount rate, a 1-year payback period, real world application of expected civil

penalties, and reflects expected voluntary over-compliance by manufacturers.

have no basis in empirical data. They are based on informed judgment of a panel of engineers with auto industry experience regarding cost effects of a small sample (roughly 8 percent) of the 50+ technologies applied to achieve compliance with CAFE and CO₂ standards. Uncertainty regarding ICMs is thus based both on the accuracy of the initial assessments of the panel on the examined technologies and on the assumption that these 4 technologies are representative of the remaining technologies that were not examined. Both agencies attempted to categorize these technologies in the most representative way possible. However, while this represented the best judgment of EPA and NHTSA's engineering staffs at that time, the actual effect on indirect costs remains uncertain for most technologies. As with

RPEs, this means that even if ICMs were accurate for the specific technologies examined, indirect cost will be understated for some technologies and overstated for others.

There was considerable uncertainty demonstrated in the ICM panel's assessments, as illustrated by the range of estimates among the 14 modified Delphi panel members surrounding the central values reported by the panel. These ranges are shown in Table VI-30 and Figure VI-10, Figure VI-11, and Figure VI-12 below. For the low complexity technology, passive aerodynamic improvements, panel responses ranged from a low of basically no indirect costs (1.001 short term and 1.0 long term), to a high of roughly a 40 percent markup (1.434 and 1.421). For the medium complexity technology, turbo charged and downsized engines,

responses ranged from a low estimate implying almost no indirect cost (1.018 and 1.011), to a high estimate implying that indirect costs for this technology would roughly equal the average RPE (1.5) for all technologies (1.527 and 1.445). For the high complexity technology, plug-in hybrid electric vehicles, responses ranged from a low estimate that these vehicles would require significantly less indirect cost than the average RPE (1.367 and 1.121) to a high estimate implying they would require more indirect costs than the average RPE (2.153 and 1.691). There was considerable diversity of opinion among the panel members.⁶³⁸ This is apparent in Figure VI-10, Figure VI-11, and Figure VI-12, which show the 14 panel members' final estimates for short-term ICMs as scatter plots.

Table VI-30 – Indirect Cost Multipliers - Modified Delphi Panel

| | Short Run | | | Long Run | | |
|-----------------------|-----------|--------|-------|----------|--------|-------|
| | Low | Medium | High | Low | Medium | High |
| Average | 1.16 | 1.29 | 1.64 | 1.12 | 1.2 | 1.39 |
| Median | 1.24 | 1.264 | 1.659 | 1.062 | 1.199 | 1.396 |
| Minimum | 1.001 | 1.018 | 1.367 | 1 | 1.011 | 1.121 |
| Maximum | 1.434 | 1.527 | 2.153 | 1.421 | 1.445 | 1.691 |
| Std Deviation | 0.141 | 0.145 | 0.207 | 0.137 | 0.131 | 0.152 |
| t-distribution - Low | 1.079 | 1.206 | 1.521 | 1.041 | 1.124 | 1.302 |
| t-distribution - High | 1.241 | 1.374 | 1.759 | 1.199 | 1.276 | 1.478 |

⁶³⁸ Sample confidence intervals, which mitigate the effect of outlying opinions, indicate a less extreme but still significant range of ICMs.

Applying mean ICMs helps mitigate these potential differences, but there is clearly a significant level of uncertainty regarding indirect costs. A t-

distribution is used to estimate confidence intervals because of the small sample size (14 panel members).

Figure VI-10 – Low Complexity ICM Panel Results

Figure VI-11 – Medium Complexity ICM Panel Results

Figure VI-12 – High Complexity ICM Panel Results

Although these results were based on modified Delphi panel techniques, it is apparent the goal of the Delphi process, an eventual consensus or convergence of opinion among panel experts, was not achieved. Given this lack of consensus and the divergence of ICM-based results from the only available empirical measure (the RPE), there is considerable uncertainty that current ICM estimates provide a realistic basis of estimating indirect costs. ICMs have not been validated through a direct accounting of actual indirect costs for individual technologies, and they produce results that conflict with the only available empirical evidence of indirect cost markups. Further, they are intended to represent indirect costs specifically associated with the most comprehensive redesign effort ever undertaken by the auto industry, with virtually every make/model requiring ground-up design modifications to comply. This includes entirely new vehicle design concepts, extensive material substitution, and complete drivetrain redesigns, all of which require significant research efforts and assembly plant redesign. Under these circumstances, one might expect indirect costs to equal or possibly increase above the historical average, but not to decrease, as implied by estimated ICMs. For regulations, such as the CAFE and CO₂ emission standards under consideration, that drive changes to nearly every vehicle system, the overall average indirect costs should align with the RPE value. Applying RPE to the cost for each technology assures that alignment.

In the 2015 NAS study, the Committee stated a conceptual

agreement with the ICM method because ICM takes into account design challenges and the activities required to implement each technology. However, although endorsing ICMs as a concept, the NAS Committee stated “the empirical basis for such multipliers is still lacking, and, since their application depends on expert judgment, it is not possible to determine whether the Agencies’ ICMs are accurate or not.”⁶³⁹ NAS also stated “the specific values for the ICMs are critical because they may affect the overall estimates of costs and benefits for the overall standards and the cost effectiveness of the individual technologies.”⁶⁴⁰ The Committee encouraged continued research into ICMs given the lack of empirical data for them to evaluate ICMs used by the agencies in past analyses. On balance, and considering the relative merits of both approaches for realistically estimating indirect costs, the agencies consider the RPE method to be a more reliable basis for estimating indirect costs.

(5) Using RPE To Evaluate Indirect Costs in This Analysis

To ensure overall indirect costs in the analysis align with the historical RPE value, the primary analysis has been developed based on applying the RPE value of 1.5 to each technology. As noted previously, the RPE is the ratio of aggregate retail prices to aggregate direct

manufacturing costs. The ratio already reflects the mixture of learned costs of technologies at various stages of maturity. Therefore, the RPE is applied directly to the learned direct cost for each technology in each year. This was previously done in the MY 2017–2025 FRIA for the preferred alternative for that rulemaking, used in the above analysis of average ICMs. Results are shown in Table VI–31.

Recognizing there is uncertainty in any estimate of indirect costs, a sensitivity analyses of indirect costs has also been conducted by applying a lower RPE value as a proxy for the ICM approach. This value was derived from a direct comparison of incremental technology costs determined in the MY 2017–2025 FRIA.⁶⁴¹ This analysis is summarized in Table VI–31 below. From this table, total costs were estimated to be roughly 18 percent lower using ICMs compared to the RPE. As previously mentioned, there are two different reasons for these differences. The first is the direct effect of applying a higher retail markup. The second is an indirect effect resulting from the influence these differing markups have on the order of the selection of technologies in the CAFE model, which can change as different direct cost levels interact with altered retail markups, shifting their relative overall effectiveness.

The relative effects of ICMs may vary somewhat by scenario, but in this case, the application of ICMs produces total

technology cost estimates roughly 18 percent lower than those that would result from applying a single RPE factor to all technologies, or, conversely, the RPE produces estimates that averaged 21 percent higher than the ICM. Under

the CAFE model construct, which will apply an alternate RPE to the same base technology profile to represent ICMs, this implies an RPE equivalent of 1.24 would produce similar net impacts [$1.5/(1 + x) = 1.21$, $x = 0.24$]. This value is

applied for the ICM proxy estimate. Additional values were also examined over a range of 1.1–2.0. The results, as well as the reference case using the 1.5 RPE, are summarized in Table VI–32.

Table VI-31 – Relative Impacts of Applying ICMs vs. RPE to Determine Indirect Costs

| Model Year | Incremental Technology Total Costs (Millions\$) | | Ratios | | Difference |
|------------|---|-----------|---------|---------|------------|
| | ICM | 1.5 RPE | RPE/ICM | ICM/RPE | RPE-ICM |
| 2017 | \$3,722 | \$3,749 | 1.01 | 0.99 | 0.01 |
| 2018 | \$5,227 | \$5,522 | 1.06 | 0.95 | 0.05 |
| 2019 | \$8,256 | \$9,604 | 1.16 | 0.86 | 0.14 |
| 2020 | \$10,809 | \$12,451 | 1.15 | 0.87 | 0.13 |
| 2021 | \$14,033 | \$16,214 | 1.16 | 0.87 | 0.13 |
| 2022 | \$15,262 | \$18,079 | 1.18 | 0.84 | 0.16 |
| 2023 | \$16,883 | \$20,806 | 1.23 | 0.81 | 0.19 |
| 2024 | \$19,727 | \$24,691 | 1.25 | 0.80 | 0.20 |
| 2025 | \$20,015 | \$27,244 | 1.36 | 0.73 | 0.27 |
| Total | \$113,935 | \$138,361 | 1.21 | 0.82 | 0.18 |

Table VI-32 – Net Benefits for Technology Cost Markup Sensitivity Runs Across Scenarios

(through MY 2029) CAFE Program, 3% Discount Rate (\$B)

| Sensitivity Case | Alternative | | | | | | |
|-----------------------------|-------------|-------|-------|-------|-------|-------|-------|
| | 1 | 2 | 3 | 4 | 5 | 6 | 7 |
| Reference Case 1.50 | -16.3 | -16.0 | -13.1 | -8.7 | -1.4 | 0.8 | 0.3 |
| Technology Cost Markup 1.10 | -61.4 | -60.9 | -52.7 | -48.2 | -29.0 | -29.9 | -16.6 |

Several responders submitted comments on the issue of indirect costs. The International Council on Clean Transportation (ICCT) stated that “The agencies abandoned their previously-used indirect cost multiplier method for estimating total costs, which was vetted with peer review, and more complexly handled differing technologies with different supply chain and manufacturing aspects. The agencies have, at this point, opted to use a simplistic retail price equivalent method, which crudely assumes all technologies have a 50 percent markup from the direct manufacturing technology cost. We recommend the agencies revert back to the previously-

used and better substantiated ICM approach.”⁶⁴²

A private commenter, Thomas Stephens, noted that “In Section II. Technical Foundation for NPRM Analysis, under 1. Data Sources and Processes for Developing Individual Technology Assumptions, the agencies state that indirect costs are estimated using a Retail Price Equivalent (RPE) factor. Concerns with RPE factors and the difficulty of accounting for differences in indirect costs of different technologies when using this approach were identified by the EPA (Rogozhin et al., Using indirect cost multipliers to

estimate the total cost of adding new technology in the automobile industry, International Journal of Production Economics 124, 360–368, 2010), which suggested using indirect cost (IC) multipliers instead of RPE factors. The EPA developed and updated IC multipliers for relevant vehicle technologies with automotive industry input and review. The agencies should consider using these IC multipliers to estimate indirect manufacturing costs instead of RPE factors.”⁶⁴³

By contrast, the Alliance of Automobile Manufacturers (The Alliance) “supports the use of retail

⁶⁴² NHTSA–2018–0067–11741.

⁶⁴³ NHTSA–2018–0067–12067.

price equivalents in the compliance cost modeling to estimate the indirect costs associated with the additional added technology required to meet a given future standard. The alternative indirect cost multiplier (“ICM”) approach is not sufficiently developed for use in rulemaking. As noted by the National Research Council, the indirect cost multipliers previously developed by EPA have not been validated with empirical data.⁶⁴⁴ Furthermore, in reference to the memorandum documenting the development of ICMs previously used by EPA, Exponent Failure Analysis Associates found that,

Past Toyota Comments on Atkinson-Cycle Benefits Have Addressed Only Those Derived From Variable Valve Timing

In response to these comments the agencies continue to find the RPE approach preferable to the ICM approach, at least at this stage in the development ICM estimates, for the reasons discussed both above and previously in the NPRM. The agencies note that the concerns are not with the concept of ICMs, but rather with the judgment-based values suggested for use as ICMs, which have not been validated, and which conflict with the empirically derived RPE value. The agencies will continue to monitor any developments in ICM methodologies as part of future rulemakings.

c) Stranded Capital Costs

Past analyses accounted for costs associated with stranded capital when fuel economy standards caused a technology to be replaced before its costs were fully amortized. The idea behind stranded capital is that manufacturers amortize research, development, and tooling expenses over many years, especially for engines and transmissions. The traditional production life-cycles for transmissions and engines have been a decade or longer. If a manufacturer launches or updates a product with fuel-saving technology, and then later replaces that technology with an unrelated or different fuel-saving technology before

the equipment and research and development investments have been fully paid off, there will be unrecouped, or stranded, capital costs. Quantifying stranded capital costs accounts for such lost investments.

In the Draft TAR and NPRM analyses, only a few technologies for a few manufacturers were projected to have stranded capital costs. As more technologies are included in this analysis, and as the CAFE model has been expanded to account for platform and engine sharing and updated with redesign and refresh cycles, accounting for stranded capital has become increasingly complex. Separately, manufacturers may be shifting their investment strategies in ways that may alter how stranded capital calculations were traditionally considered. For example, some suppliers sell similar transmissions to multiple manufacturers. Such arrangements allow manufacturers to share in capital expenditures, or amortize expenses more quickly.

Manufacturers share parts on vehicles around the globe, achieving greater scale and greatly affecting tooling strategies and costs. Given these trends in the industry and their uncertain effect on capital amortization, and given the difficulty of handling this uncertainty in the CAFE model, this analysis does not account for stranded capital. The agencies’ analysis continues to rely on the CAFE model’s explicit year-by-year accounting for estimated refresh and redesign cycles, and shared vehicle platforms and engines, to moderate the cadence of technology adoption and thereby limit the implied occurrence of stranded capital and the need to account for it explicitly. The agencies will monitor these trends to assess the role of stranded capital moving forward.

d) Cost Learning

Manufacturers make improvements to production processes over time, which often result in lower costs. “Cost learning” reflects the effect of experience and volume on the cost of production, which generally results in better utilization of resources, leading to higher and more efficient production. As manufacturers gain experience through production, they refine production techniques, raw material and component sources, and assembly

methods to maximize efficiency and reduce production costs. Typically, a representation of this cost learning, or learning curves, reflect initial learning rates that are relatively high, followed by slower learning as additional improvements are made and production efficiency peaks. This eventually produces an asymptotic shape to the learning curve, as small percent decreases are applied to gradually declining cost levels. These learning curve estimates are applied to various technologies that are used to meet CAFE standards.

For the NPRM and this final rule, the agencies estimated cost learning by considering methods established by T.P. Wright⁶⁴⁵ and later expanded upon by J.R. Crawford. Wright, examining aircraft production, found that every doubling of cumulative production of airplanes resulted in decreasing labor hours at a fixed percentage. This fixed percentage is commonly referred to as the progress rate or progress ratio, where a lower rate implies faster learning as cumulative production increases. J.R. Crawford expanded upon Wright’s learning curve theory to develop a single unit cost model,⁶⁴⁶ that estimates the cost of the n^{th} unit produced given the following information is known: (1) Cost to produce the first unit; (2) cumulative production of n units; and (3) the progress ratio.

As pictured in Figure VI–13, Wright’s learning curve shows the first unit is produced at a cost of \$1,000. Initially cost per unit falls rapidly for each successive unit produced. However, as production continues, cost falls more gradually at a decreasing rate. For each doubling of cumulative production at any level, cost per unit declines 20 percent, so that 80 percent of cost is retained. The CAFE model uses the basic approach by Wright, where cost reduction is estimated by applying a fixed percentage to the projected cumulative production of a given fuel economy technology.

⁶⁴⁶ Crawford, J.R., *Learning Curve, Ship Curve, Ratios, Related Data*, Burbank, California-Lockheed Aircraft Corporation (1944).

The analysis accounts for learning effects with model year-based cost learning forecasts for each technology that reduce direct manufacturing costs over time. The agencies evaluated the historical use of technologies, and reviewed industry forecasts to estimate future volumes for the purpose of developing the model year-based technology cost learning curves.

The following section discusses the agencies' development of model year-based cost learning forecasts, including how the approach has evolved from the 2012 rulemaking for MY 2017–2025 vehicles, and how the progress ratios were developed for different technologies considered in the analysis. Finally, the agencies discuss how these learning effects are applied in the CAFE Model.

(1) Time Versus Volume-Based Learning

For the 2012 joint CAFE/CO₂ rulemaking, the agencies developed learning curves as a function of vehicle model year.⁶⁴⁷ Although the concept of this methodology is derived from Wright's cumulative production volume-based learning curve, its application for CAFE and CO₂ technologies was more of a function of time. More than a dozen learning curve schedules were developed, varying between fast and slow learning, and assigned to each technology corresponding to its level of complexity and maturity. The schedules were applied to the base year of direct manufacturing cost and incorporate a percentage of cost reduction by model year declining at a decreasing rate

through the technology's production life. Some newer technologies experience 20 percent cost reductions for introductory model years, while mature or less complex technologies experience 0–3 percent cost reductions over a few years.

In their 2015 report to Congress, the National Academy of Sciences (NAS) recommended the agencies should "continue to conduct and review empirical evidence for the cost reductions that occur in the automobile industry with volume, especially for large-volume technologies that will be relied on to meet the CAFE/GHG standards."⁶⁴⁸

In response, the agencies have incorporated statically projected cumulative volume production data of fuel economy improving technologies, representing an improvement over the previously used time-based method. Dynamic projections of cumulative production are not feasible with current CAFE model capabilities, so one set of projected cumulative production data for most vehicle technologies was developed for the purpose of determining cost impact. For many technologies produced and/or sold in the U.S., historical cumulative production data was obtained to establish a starting point for learning schedules. Groups of similar technologies or technologies of similar complexity may share identical learning schedules.

The slope of the learning curve, which determines the rate at which cost

reductions occur, has been estimated using research from an extensive literature review and automotive cost tear-down reports (see below). The slope of the learning curve is derived from the progress ratio of manufacturing automotive and other mobile source technologies.

(2) Deriving the Progress Ratio Used in This Analysis

Learning curves vary among different types of manufactured products. Progress ratios can range from 70 to 100 percent, where 100 percent indicates no learning can be achieved.⁶⁴⁹ Learning effects tend to be greatest in operations where workers often touch the product, while effects are less substantial in operations consisting of more automated processes. As automotive manufacturing plant processes become increasingly automated, a progress ratio towards the higher end would seem more suitable. The agencies incorporated findings from automotive cost-teardown studies with EPA's literature review of learning-related studies to estimate a progress ratio used to determine learning schedules of fuel economy improving technologies.

EPA's literature review examined and summarized 20 studies related to learning in manufacturing industries and mobile source manufacturing.⁶⁵⁰

⁶⁴⁸ *Cost, Effectiveness, and Deployment of Fuel Economy Technologies for Light-Duty Vehicles*, National Research Council of the National Academies (2015), available at https://www.nap.edu/resource/21744/deps_166210.pdf.

The studies focused on many industries, including motor vehicles, ships, aviation, semiconductors, and environmental energy. Based on several criteria, EPA selected five studies providing quantitative analysis from the mobile source sector (progress ratio estimates from each study are summarized in Table VI-33, below). Further, those studies expand on Wright's Learning Curve function by using cumulative output as a predictor

variable, and unit cost as the response variable. As a result, EPA determined a best estimate of 84 percent as the progress ratio in mobile source industries. However, of those five studies, EPA at the time placed less weight on the *Epple et al. (1991)* study, because of a disruption in learning due to incomplete knowledge transfer from the first shift to introduction of a second shift at a North American truck plant. While learning may have decelerated

immediately after adding a second shift, the agencies note that unit costs continued to fall as the organization gained experience operating with both shifts. The agencies now recognize that disruptions are an essential part of the learning process and should not, in and of themselves, be discredited. For this reason, the analysis uses a re-estimated average progress ratio of 85 percent from those five studies (equally-weighted).

Table VI-33 – Progress Ratios from EPA's Literature Review

| Author (Publication Date) | Industry | Progress Ratio (Cumulative Output Approach) |
|-------------------------------------|-----------------------|---|
| Argote et al. (1997) ⁶⁵¹ | Trucks | 85% |
| Benkard (2000) ⁶⁵² | Aircraft (commercial) | 82% |
| Epple et al. (1991) ⁶⁵³ | Trucks | 90% |
| Epple et al. (1996) ⁶⁵⁴ | Trucks | 85% |
| Levitt et al. (2013) ⁶⁵⁵ | Automobiles | 82% |

In addition to EPA's literature review, this progress ratio estimate was informed based on NHTSA's findings from automotive cost-teardown studies. NHTSA routinely performs evaluations of costs of previously issued Federal Motor Vehicle Safety Standards (FMVSS) for new motor vehicles and equipment. NHTSA's engages contractors to perform detailed engineering "tear-down" analyses for

representative samples of vehicles, to estimate how much specific FMVSS add to the weight and retail price of a vehicle. As part of the effort, cost and production volume are examined for automotive safety technologies. In particular, the agency estimated costs from multiple cost tear-down studies for technologies with actual production data from the *Cost and weight added by the Federal Motor Vehicle Safety*

Standards for MY 1968–2012 passenger cars and LTVs (2017).⁶⁵⁶

NHTSA chose five vehicle safety technologies with sufficient data to estimate progress ratios of each, because these technologies are large-volume technologies and are used by almost all vehicle manufacturers. Table VI-34 below includes these five technologies and yields an average progress rate of 92 percent:

Table VI-34 – Progress Ratios Researched by NHTSA

| Technology | Progress Ratio |
|---------------------------------------|----------------|
| Anti-lock Brake Systems | 87% |
| Driver Airbags | 93% |
| Manual 3-pt lap shoulder safety belts | 96% |
| Adjustable Head Restraints | 91% |
| Dual Master Cylinder | 95% |

For a final progress ratio used in the CAFE model, the five progress rates from EPA's literature review and five progress rates from NHTSA's evaluation of automotive safety technologies results were averaged. This resulted in an average progress rate of approximately 89 percent. Equal weight was placed on progress ratios from all 10 sources. More specifically, equal weight was placed on the *Eppe et al. (1991)* study, because disruptions have more recently been recognized as an essential part in the learning process, especially in an effort to increase the rate of output. Further discussion of how the progress ratios were derived for this analysis is located in FRIA Section 9.

ICCT commented that the choice to use safety technology as a model for fuel efficiency led to lower learning rates in the NPRM analysis compared to prior analyses.⁶⁵⁷ ICCT stated that safety technologies were chosen for the NPRM because they are used by almost every manufacturer, in contrast to fuel efficiency technologies, where not every manufacturer will use them, particularly when they are first introduced. ICCT stated that to show the impact of changing learning rates, the agencies should run a sensitivity analysis using the learning rates in the TAR, as well as EPA's learning rates in its Final Determination. ICCT concluded that "[w]ithout doing so and without conducting a peer review of the change in approach, it appears clear the agencies have decided to switch to a new costing method that affects all future costs, but without any significant research justification, vetting, or review."

The agencies' selection of a progress rate of 0.89 is based on an average of findings across research and literature reviews conducted by NHTSA and EPA. The EPA cited rates were derived from five studies selected from a sample of 20 transportation modal learning studies that were examined by an EPA contractor, ICF International.⁶⁵⁸ One of these 5 studies (Benkard (2000)) examines learning in the commercial aircraft industry, which the author notes has many unique features that influence marginal costs. It also has the lowest progress rate. The agencies note that EPA regulates all mobile sources, and while the inclusion of non-passenger vehicle studies in their report was

justified, it may have biased the estimate of learning attributable to the motor vehicle industry. Notably, nearly all of the other studies included in the ICF International study found progress rates higher than the 0.84 rate selected by the authors at that time. In reviewing the ICF study, NHTSA found many other studies not included in the report, including many specific to the motor vehicle and environmental technology industries. Over 90 percent of those studies indicated higher progress ratios than ICF recommended.⁶⁵⁹ The agencies' current approach includes a broader and more representative sample of these studies rather than the narrow sample selected by ICF.

The agencies do not agree that safety technologies are adopted by all manufacturers at an early stage. Most safety technologies are initially offered as options or standard equipment on only a small segment of the vehicle fleet, typically luxury vehicles. After a number of years, these technologies may be adopted on less expensive vehicles, and eventually they will become required equipment on all vehicles, but the production process is gradual, as it is with fuel efficiency technologies. FMVSS are necessarily established as performance standards—and automakers are free to develop or choose from existing technologies to achieve such performance requirements—much like automakers can develop or choose from a number of established fuel efficiency technologies to achieve fuel economy requirements. Further, the derivation of progress ratios is based on the concept of a doubling of cumulative production, not time. Therefore, even if production continues at a different pace, it should not disqualify non-fuel efficiency studies. Moreover, the derivation of the progress ratio used in the TAR and Final Determination document were not confined to fuel efficiency technologies. In fact, as noted above, they even included at least one entirely unrelated study of the aircraft industry.

Finally, the agencies note that the previous learning schedules used in the TAR and EPA's Final Determination were only developed through 2025, whereas this final rule projects learning

through 2050. The previous learning schedules are thus not directly compatible with the analysis conducted in this Final Rule, making a sensitivity analysis problematic.

(3) Obtaining Appropriate Baseline Years for Direct Manufacturing Costs To Create Learning Curves

Direct manufacturing costs for each fuel economy improving technology were obtained from various sources, as discussed above. To establish a consistent basis for direct manufacturing costs in the rulemaking analysis, each technology cost is adjusted to MY 2018 dollars. For each technology, the DMC is associated with a specific model year, and sometimes a specific production volume, or cumulative production volume. The base model year is established as the MY in which direct manufacturing costs were assessed (with learning factor of 1.00). With the aforementioned data on cumulative production volume for each technology and the assumption of a 0.89 progress ratio for all automotive technologies, the agencies can solve for an implied cost for the first unit produced. For some technologies, the agencies used modestly different progress ratios to match detailed cost projections if available from another source (for instance, batteries for plug-in hybrids and battery electric vehicles).

This approach produced reasonable estimates for technologies already in production, and some additional steps were required to set appropriate learning rates for technologies not yet in production. Specifically, for technologies not yet in production in MY 2017 (the baseline analysis fleet), the cumulative production volume in MY 2017 is zero, because manufacturers have not yet produced the technologies. For pre-production cost estimates in the NPRM, the agencies often relied on confidential business information sources to predict future costs. Many sources for pre-production cost estimates include significant learning effects, often providing cost estimates assuming high volume production, and often for a timeframe late in the first production generation or early in the second generation of the technology. Rapid doubling and re-doubling of a low cumulative volume base with Wright's learning curves can provide unrealistic cost estimates. In addition, direct manufacturing cost projections can vary depending on the initial production volume assumed. Accordingly, the agencies carefully examined direct costs with learning, and made adjustments to the starting point for those technologies on the learning curve to better align

⁶⁵⁷ NHTSA–2018–0067–11741.

⁶⁵⁹ See, for example, progress ratios of multiple technologies referenced in *The Carbon Productivity Challenge: Curbing Climate Change and Sustaining Economic Growth*, McKinsey Climate Change Special Initiative, McKinsey Global Institute, June 2008 (quoting from UC Berkeley Energy Resource Group, Navigant Consulting) and *Technology Innovation for Climate Mitigation and its Relation to Government Policies*, Edward S. Rubin, Carnegie Mellon University, Presentation to the UNFCCC Workshop on Climate Change Mitigation, Bonn, Germany, June 19, 2004.

with the assumptions used for the initial direct cost estimate.

(4) Cost Learning as Applied in the CAFE Model

For the NPRM analysis, the agencies updated the manner in which learning effects apply to costs. In the Draft TAR analysis, the agencies had applied learning curves only to the incremental direct manufacturing costs or costs over the previous technology on the technology tree. In practice, two things were observed: (1) If the incremental direct manufacturing costs were positive, technologies could not become less expensive than their predecessors on the technology tree, and (2) absolute costs over baseline technology depended on the learning curves of root technologies on the technology tree. For the NPRM and final rule analysis, the agencies applied learning effects to the incremental cost over the null technology state on the applicable technology tree. After this step, the agencies calculated year-by-year incremental costs over preceding technologies on the tech tree to create the CAFE model inputs. As discussed below, for the final rule, the agencies revised the CAFE model to replace incremental cost estimates with absolute estimates, each specified relative to the null technology state on the applicable technology tree. This change facilitated quality assurance and is expected to make cost inputs more transparently relatable to detailed model output. Likewise, this change made it easier to apply learning curves in the course of developing inputs to the CAFE model.

The agencies grouped certain technologies, such as advanced engines, advanced transmissions, and non-battery electric components and assigned them to the same learning schedule. While these grouped technologies differ in operating characteristics and design, the agencies chose to group them based on their complexity, technology integration, and economies of scale across manufacturers. The low volume of certain advanced technologies, such as hybrid and electric technologies, poses a significant issue for suppliers and prevents them from producing components needed for advanced transmissions and other technologies at more efficient high scale production. The technology groupings were carried over from the NPRM analysis for the final rule analysis.⁶⁶⁰ Like the NPRM, this final rule analysis uses the same groupings that considers market availability, complexity of technology integration, and production volume of the technologies that can be implemented by manufacturers and suppliers. For example, technologies like ADEAC and VCR are grouped together; these technologies were not in production or were only in limited introduction in MY 2017, and are planned to be introduced in limited production by a few manufacturers. The details of these technologies are discussed in Section VI.C.

In addition, for the final rule, as discussed in Section VI.A.4 Compliance Simulation, the agencies expanded

model inputs to extend the explicit simulation of technology application through MY 2050, in response to comments on the NPRM. Accordingly, the agencies updated the learning curves for each technology group to cover MYs through 2050. For MYs 2017–2032, the agencies expect incremental improvements in all technologies, particularly in electrification technologies because of increased production volumes, labor efficiency, improved manufacturing methods, specialization, network building, and other factors. While these and other factors contribute to continual cost learning, the agencies believe that many fuel economy improving technologies considered in this rule will approach a flat learning level by the early 2030s. Specifically, older and less complex internal combustion engine technologies and transmissions will reach a flat learning curve sooner when compared to electrification technologies, which have more opportunity for improvement. For batteries and non-battery electrification components, the agencies estimated a steeper learning curve that will gradually flatten after MY 2040. For a more detailed discussion of the electrification learning curves used for the final rule analysis, see Section VI.C.3.e) Electrification Costs. The following Table VI–35 and Table VI–36 show the learning curve schedules for CAFE model technologies for MYs 2017–2033 and MYs 2034–2050.

following chart shows learning rates for several technologies applicable to midsize sedans, demonstrating that while the agencies estimate that such learning effects have already been almost entirely realized for engine turbocharging (a technology that has been in production for many years), the agencies estimate that significant opportunities to reduce the cost of the greatest levels of mass reduction (*e.g.*,

MR5) remain, and even greater opportunities remain to reduce the cost of batteries for HEVs, PHEVs, BEVs. In fact, for certain advanced technologies, the agencies determined that the results predicted by the standard learning curves progress ratio was not realistic, based on unusual market price and production relationships. For these technologies, the agencies developed specific learning estimates that may

diverge from the 0.89 progress rate. As shown in Figure VI-14, these technologies include: Turbocharging and downsizing level 1 (TURBO1), variable turbo geometry electric (VTGE), aerodynamic drag reduction by 15 percent (AERO15), mass reduction level 5 (MR5), 20 percent improvement in low-rolling resistance tire technology over the baseline, and battery integrated starter/generator (BISG).

Figure VI-14 – Examples of Year-by-Year Cost Learning Effects (Midsize Sedan)

(5) Potential Future Approaches to Considering Cost Learning in the CAFE Model

As discussed above, cost inputs to the CAFE model incorporate estimates of volume-based learning. As an alternative approach, the agencies have considered modifications to the CAFE model that would calculate degrees of volume-based learning dynamically, responding to the model's application of affected technologies. While it is intuitive that the degree of cost

reduction achieved through experience producing a given technology should depend on the actual accumulated experience (*i.e.*, volume) producing that technology, such dynamic implementation in the CAFE model is thus far infeasible. Insufficient data have been available regarding manufacturers' historical application of specific technology. Further, insofar as the agencies' estimates of underlying direct manufacturing costs already make some assumptions about volume and

scale, insufficient information is currently available to determine how to dynamically adjust these underlying costs. It should be noted that if learning responds dynamically to volume, and volume responds dynamically to learning, an internally consistent model solution would likely require iteration of the CAFE model to seek a stable solution within the model's representation of multiyear planning. As discussed below, the CAFE model now supports iteration to balance vehicle

cost and fuel economy changes with corresponding changes in sales volumes, but, this iteration is not yet implemented in a manner that would necessarily support the balance of learning effects on a multiyear basis. The agencies invited comment on the issue, seeking data and methods that would provide the basis for a practicable approach to doing so. Having reviewed comments on cost learning effects, the agencies conclude it remains infeasible to calculate degrees of volume-based learning in a manner that responds dynamically to modeled technology application. The agencies will continue to examine this issue for future development.

e) Cost Accounting

The CAFE model applied for the NPRM analysis used an incremental approach to specifying technology cost estimates, such that the cost for any given technology was specified as an incremental value, relative to the technology immediately preceding on the relevant technology pathway. For example, the cost of a 7-speed transmission was specified as an amount beyond the cost of a 6-speed transmission. This approach necessitated careful dynamic accounting for the progressive application of the technology as the model worked on a step-by-step basis to “build” a technology solution. As discussed in the corresponding model documentation, the model included complex logic to “back out” some of these costs carefully when, for example, replacing a conventional powertrain with a hybrid-electric system.⁶⁶¹

To facilitate specification of detailed model inputs and review of detailed model outputs, today’s CAFE model replaces incremental cost inputs with absolute cost inputs, such that the estimated cost of each technology is specified relative to a common reference point for the relevant technology pathway. For example, the cost of the above-mentioned 7-speed transmission is specified relative to a 4-speed transmission, as is the cost of every other transmission technology. This change in the structure of cost inputs does not, by itself, change model results, but it does make the connection between these inputs and corresponding outputs more transparent. Model documentation accompanying today’s analysis presents details of the updated structure for model cost inputs.

5. Other Inputs to the Agencies’ Analysis

CAFE Model input files described above defining the analysis fleet and the fuel-saving technologies to be included in the analysis span more than a million records, but deal with a relatively discrete range of subjects (*e.g.*, what vehicles are in the fleet, what are the key characteristics of those vehicles, what fuel-saving technologies are expected to be available, and how might adding those technologies impact vehicles’ fuel economy levels and costs). The CAFE Model makes use of a considerably wider range of other types of inputs, and most of these are contained in other model input files. The nature and function of many of these inputs remains unchanged relative to the model and input files applied for the analysis documented in the proposal that preceded today’s notice. The CAFE Model documentation accompanying today’s notice lists and describes all model inputs, and explains how inputs are used by the model. Many commenters addressed not only the model’s function and design, but also specific inputs. Most input values are discussed either above (*e.g.*, the preceding subsection addresses specific inputs regarding technology costs) or below, in subsections discussing specific economic, energy, safety, and environmental factors. The remainder of this subsection provides an overview of the scope of different model input files. The overview is organized based on CAFE Model file types, as in the model documentation.

a) Market Data File

The “Market Data” file contains the detailed description—discussed above—of the vehicle models and model configurations each manufacturer produces for sale in the U.S. The file also contains a range of other inputs that, though not specific to individual vehicle models, may be specific to individual manufacturers. The file contains a set of specific worksheets, as follows:

“Manufacturers” worksheet: Lists specific manufacturers, indicates whether manufacturers are expected to prefer paying CAFE fines to applying technologies that would not be cost-effective, indicates what “payback period” defines buyers’ willingness to pay for fuel economy improvements, enumerates CAFE and CO₂ credits banked from model years prior to those represented explicitly, and indicates how sales “multipliers” are to be applied when simulating compliance with CO₂ standards.

“Credits and Adjustments”

worksheet: Enumerates estimates—specific to each manufacturer and fleet—of expected CO₂ and CAFE adjustments reflecting improved AC efficiency, reduced AC refrigerant leakage, improvements to “off cycle” efficiency, and production of flexible fuel vehicles (FFVs). The model applies AC refrigerant leakage adjustments only to CO₂ levels, and applies FFV adjustments only to CAFE levels.

“Vehicles” worksheet: Lists vehicle models and model configurations each manufacturer produces for sale in the U.S.; identifies shared vehicle platforms; indicates which engine and transmission is present in each vehicle model configuration; specifies each vehicle model configuration’s fuel economy level, production volume, and average price; specifies several engineering characteristics (*e.g.*, curb weight, footprint, and fuel tank volume); assigns each vehicle model configuration to a regulatory class, technology class, engine class, and safety class; specifies schedules on which specific vehicle models are expected to be redesigned and freshened; specifies how much U.S. labor is involved in producing each vehicle model/configuration; and indicates whether specific technologies are already present on specific vehicle model configurations, or, due to engineering or product planning considerations, should be skipped.

“Engines” worksheet: Identifies specific engines used by each manufacturer and for each engine, lists a unique code (referenced by the engine code specified for each vehicle model configuration and identifies the fuel(s) with which the engine is compatible, the valvetrain design (*e.g.*, DOHC), the engine’s displacement, cylinder configuration and count, and the engine’s aspiration type (*e.g.*, naturally aspirated, turbocharged). The worksheet also indicates whether specific technologies are already present on specific engines, or, due to engineering or product planning considerations, should be skipped.

“Transmissions” worksheet: Similar to the Engines worksheet, identifies specific transmissions used by each manufacturer and for each transmission, lists a unique code (referenced by the transmission code specified for each vehicle model configuration and identifies the type (*e.g.*, automatic or CVT) and number of forward gears. Also indicates whether specific technologies are already present or, due to engineering or product planning considerations, should be skipped.

⁶⁶¹ The CAFE Model is available at <https://www.nhtsa.gov/corporate-average-fuel-economy/compliance-and-effects-modeling-system> with documentation and all inputs and outputs supporting today’s notice.

b) Technologies File

The Technologies file identifies about six dozen technologies to be included in the analysis, indicates when and how widely each technology can be applied to specific types of vehicles, provides most of the inputs involved in estimating what costs will be incurred, and provides some of the inputs involved in estimating impacts on vehicle fuel consumption and weight. The file contains the following types of worksheets:

“Parameters” worksheet: Not to be confused with the “Parameters” file discussed below, this worksheet in the Technologies file indicates, for each technology class, the share of the vehicle’s curb weight represented by the “glider” (the vehicle without the powertrain).

“Technologies” worksheet: For each named technology, specifies the share of the entire fleet to which the technology may be additionally applied in each model year.

Technology Class worksheets: In a separate worksheet for each of the 10 technology classes discussed above (and an additional 2—not used for this analysis—for heavy-duty pickup trucks and vans), identifies whether and how soon the technology is expected to be available for wide commercialization, specifies the percentage of miles a vehicle is expected to travel on a secondary fuel (if applicable, as for plug-in hybrid electric vehicles), indicates a vehicle’s expected electric power and all-electric range (if applicable), specifies expected impacts on vehicle weight, specifies estimates of costs in each model year (and factors by which electric battery costs are expected to be reduced in each model year), specifies any estimates of maintenance and repair cost impacts, and specifies any estimates of consumers’ willingness to pay for the technology.

Engine Type worksheets: In a separate worksheet for each of 28 initial engine types identified by cylinder count, number of cylinder banks, and configuration (DOHC, unless identified as OHV or SOHC), specifies estimates of costs in each model year, as well as any estimates of impacts on maintenance and repair costs.

c) Parameters File

The “Parameters” file contains inputs spanning a range of considerations, such as economic and labor utilization impacts, vehicle fleet characteristics, fuel prices, scrappage and safety model coefficients, fuel properties, and emission rates. The file contains a set of specific worksheets, as follows:

Economic Values worksheet: Specifies a variety of inputs, including social and consumer discount rates to be applied, the “base year” to which to discount social benefits and costs (*i.e.*, the reference years for present value analysis), discount rates to be applied to the social cost of CO₂ emissions, the elasticity of highway travel with respect to per-mile fuel costs (also referred to as the rebound effect), the gap between test (for certification) and on-road (aka real world) fuel economy, the fixed amount of time involved in each refuel event, the share of the tank refueled during an average refueling event, the value of travel time (in dollars per hour per vehicle), the estimated average number of miles between mid-trip EV recharging events (separately for 200 and 300-mile EVs), the rate (in miles of capacity per hour of charging) at which EV batteries are recharged during such events, the values (in dollars per vehicle-mile) of congestion and noise costs, costs of vehicle ownership and operation (*e.g.*, sales tax), economic costs of oil imports, estimates of future macroeconomic measures (*e.g.*, GDP), and rates of growth in overall highway travel (separately for low, reference, and high oil prices).

Vehicle Age Data worksheet: Specifies nominal average survival rates and annual mileage accumulation for cars, vans and SUVs, and pickup trucks. These inputs are used only for displaying estimates of avoided fuel savings and CO₂ emissions while the model is operating. Calculations reported in model output files reflect, among other things, application of the scrappage model.

Fuel Prices worksheet: Separately for gasoline, E85, diesel, electricity, hydrogen, and CNG, specifies historical and estimated future fuel prices (and average rates of taxation). Includes values reflecting low, reference, and high estimates of oil prices.

Scrappage Model Values worksheet: Specifies coefficients applied by the scrappage model, which the CAFE Model uses to estimate rates at which vehicles will be scrapped (removed from service) during the period covered by the analysis.

Historic Fleet Data worksheet: For model years not simulated explicitly (here, model years through 2016), and separately for cars, vans and SUVs, and pickup trucks, specifies the initial size (*i.e.*, number new vehicles produced for sale in the U.S.) of the fleet, the number still in service in the indicated calendar year (here, 2016), the relative shares of different fuel types, and the average fuel economy achieved by vehicles with different fuel types, and the averages of

horsepower, curb weight, fuel capacity, and price (when new).

Safety Values worksheet: Specifies coefficients used to estimate the extent to which changes in vehicle mass impact highway safety. Also specifies statistical value of highway fatalities, the share of incremental risk (of any additional driving) internalized by drivers, rates relating the cost of damages from non-fatal losses to the cost of fatalities, and rates relating the occurrence of non-fatal injuries to the occurrence of fatalities.

Fatality Rates worksheet: Separately for each model year from 1975–2050, and separately for each vehicle age (through 39 years) specifies the estimated nominal number of fatalities incurred per billion miles of travel by which to offset fatalities.

Credit Trading Values worksheet: Specifies whether various provisions related to compliance credits are to be simulated (currently limited to credit carry-forward and transfers), and specifies the maximum number of years credits may be carried forward to future model years. Also specifies statutory (for CAFE only) limits on the quantity of credit that may be transferred between fleets, and specifies amounts of lifetime mileage accumulation to be assumed when adjusting the value of transferred credits. Also accommodates a setting indicating the maximum number of model years to consider when using expiring credits.

Employment Values worksheet: Specifies the estimated average revenue OEMs and suppliers earn per employee, the retail price equivalent factor applied in developing technology costs, the average quantity of annual labor (in hours) per employee, a multiplier to apply to U.S. final assembly labor utilization in order to obtain estimated direct automotive manufacturing labor, and a multiplier to be applied to all labor hours.

Fuel Properties worksheet: Separately for gasoline, E85, diesel, electricity, hydrogen, and CNG, specifies energy density, mass density, carbon content, and tailpipe SO₂ emissions (grams per unit of energy).

Fuel Import Assumptions worksheet: Separately for gasoline, E85, diesel, electricity, hydrogen, and CNG, specifies the extent to which (a) changes in fuel consumption lead to changes in net imports of finished fuel, (b) changes in fuel consumption lead to changes in domestic refining output, (c) changes in domestic refining output lead to changes in domestic crude oil production, and (d) changes in domestic refining output lead to changes in net imports of crude oil.

Emissions Health Impacts worksheet: Separately for NO_x, SO₂ and PM_{2.5} emissions, separately for upstream and vehicular emissions, and for each of calendar years 2016, 2020, 2025, and 2030, specifies estimates of various health impacts, such as premature deaths, acute bronchitis, and respiratory hospital admissions.

Carbon Dioxide Emission Costs worksheet: For each calendar year through 2080, specifies low, average, and high estimates of the social cost of CO₂ emissions, in dollars per metric ton. Accommodates analogous estimates for CH₄ and N₂O.

Criteria Pollutant Emission Costs worksheet: Separately for NO_x, SO₂ and PM_{2.5} emissions, separately for upstream and vehicular emissions, and for each of calendar years 2016, 2020, 2025, and 2030, specifies social costs on a per-ton basis.

Upstream Emissions (UE) worksheets: Separately for gasoline, E85, diesel, electricity, hydrogen, and CNG, and separately for calendar years 2017, 2020, 2025, 2030, 2035, 2040, 2045, and 2050, and separately for various upstream processes (e.g., petroleum refining), specifies emission factors (in grams per million BTU) for each included criteria pollutant (e.g., NO_x) and toxic air contaminant (e.g., benzene).

Tailpipe Emissions (TE) worksheets: Separately for gasoline and diesel, for each of model years 1975–2050, for each vehicle vintage through age 39, specifies vehicle tailpipe emission factors (in grams per mile) for CO, VOC, NO_x, PM_{2.5}, CH₄, N₂O, acetaldehyde, acrolein, benzene, butadiene, formaldehyde, and diesel PM₁₀.

d) Scenarios File

The CAFE Model represents each regulatory alternative as a discrete scenario, identifying the first-listed scenario as the baseline relative to which impacts are to be calculated. Each scenario is described in a worksheet in the Scenarios input file, with standards and related provisions specified separately for each regulatory class (passenger car or light truck) and each model year. Inputs specify the standards' functional forms and defining coefficients in each model year. Multiplicative factors and additive offsets are used to convert fuel economy targets to CO₂ targets, the two being directly mathematically related by a linear transformation. Additional inputs specify minimum CAFE standards for domestic passenger car fleets, determine whether upstream emissions from electricity and hydrogen are to be included in CO₂ compliance calculations, specify the governing rates

for CAFE civil penalties, specify estimates of the value of CAFE and CO₂ credits (for CAFE Model operating modes applying these values), specify how flexible fuel vehicles (FFVs) and PHEVs are to be accounted for in CAFE compliance calculations, specific caps on adjustments reflecting improvements to off-cycle and AC efficiency and emissions, specify any estimated amounts of average Federal tax credits earned by HEVs, PHEVs, BEVs, and FCVs. The worksheets also accommodate some other inputs, such as those as involved in analyzing standards for heavy-duty pickups and vans, not used in today's analysis.

e) "Run Time" Settings

In addition to inputs contained in the above-mentioned files, the CAFE Model makes use of some settings selected when operating the model. These include which standards (CAFE or CO₂) are to be evaluated; what model years the analysis is to span; when technology application is to begin; what "effective cost" mode is to be used when selecting among technologies; whether use of compliance credits is to be simulated and, if so, until what model year; whether dynamic economic models are to be exercised and, if so, how many sales model iterations are to be undertaken and using what price elasticity; whether low, average, or high estimates are to be applied for fuel prices, the social cost of carbon, and fatality rates; by how much to scale benefits to consumers; and whether to report an implicit opportunity cost.

f) Simulation Inputs

As mentioned above, the CAFE Model makes use of databases of estimates of fuel consumption impacts and, as applicable, battery costs for different combinations of fuel saving technologies. For today's analysis, the agencies developed these databases using a large set of full vehicle and accompanying battery cost model simulations developed by Argonne National Laboratory. To be used as files provided separately from the model and loaded every time the model is executed, these databases are prohibitively large, spanning more than a million records and more than half a gigabyte. To conserve space and speed model operation, the agencies have integrated the databases into the CAFE Model executable file. When the model is run, however, the databases are extracted and placed in an accessible location on the user's disk drive. The databases, each of which is in the form of a simple (if large) text file, are as follows:

"FE1_Adjustments.csv:" This is the main database of fuel consumption estimates. Each record contains such estimates for a specific indexed (using a multidimensional "key") combination of technologies for each of the technology classes in the Market Data and Technologies files. Each estimate is specified as a percentage of the "base" technology combination for the indicated technology class.

"FE2_Adjustments.csv:" Specific to PHEVs, this is a database of fuel consumption estimates applicable to operation on electricity, specified in the same manner as those in the main database.

"Battery_Costs.csv:" Specific to technology combinations involving vehicle electrification (including 12V stop-start systems), this is a database of estimates of corresponding base costs (before learning effects) for batteries in these systems.

g) On Road Fuel Economy and CO₂ Emissions Gap

Rather than rely on the compliance values of fuel economy for either historical vehicles or vehicles that go through the full compliance simulation, the model applies an "on-road gap" to represent the expected difference between fuel economy on the laboratory test cycle and fuel economy under real-world operation. In other words, all of the reported physical impacts analysis (including emissions impacts) are based on actual real world fuel consumption and emissions, not on values based on 2-cycle fuel economy ratings and CO₂ emission rates, nor on regulatory incentives such as sales multipliers that treat a single vehicle as two vehicles, or that set aside emissions resulting from generation of electricity to power electric vehicles. This was a topic of interest in the recent peer review of the CAFE model. While the model currently allows the user to specify an on-road gap that varies by fuel type (gasoline, E85, diesel, electricity, hydrogen, and CNG), it does not vary over time, by vehicle age, or by technology combination. It is possible that the "gap" between laboratory fuel economy and real-world fuel economy has changed over time, that fuel economy changes as a vehicle ages, or that specific combinations of fuel-saving technologies have a larger discrepancy between laboratory and real-world fuel economy than others. For today's analysis, and considering data EPA collects from manufacturers regarding vehicles' fuel economy and CO₂ as tested for both fuel economy and emissions compliance and for vehicle fuel economy and emissions labeling

(labeling making use of procedures spanning a wider range of real-world vehicle operating conditions), the agencies have determined that the future gap is, at this time, best estimated using the same values applied for the analysis documented in the NPRM. The agencies will continue to assess such test data and any other available data regarding real-world fuel economy and emissions and, as warranted, will revise methods and inputs representing the gap between laboratory and real-world fuel economy and CO₂ emissions in future rulemakings. The sensitivity analysis summarized in the FRIA accompanying the final rule includes cases representing narrower and wider gaps.

C. The Model Applies Technologies Based on a Least-Cost Technology Pathway to Compliance, Given the Framework Above

The CAFE model, discussed in detail above, is designed to simulate compliance with a given set of CAFE or tailpipe CO₂ emissions standards for each manufacturer that sells vehicles in the United States. For the final rule analysis, the model began with a representation of the MY 2017 vehicle model offerings for each manufacturer that included the specific engines and transmissions on each model variant, observed sales volumes, and all fuel economy improving technology that is already present on those vehicles. From there the model added technology, in response to the standards being considered, in a way that minimized the cost of compliance and reflected many real-world constraints faced by automobile manufacturers. The model addressed fleet year-by-year compliance, taking into consideration vehicle refresh and redesign schedules and shared platforms, engines, and transmissions among vehicles.

The agencies evaluated a wide array of technologies manufacturers could use to improve the fuel economy of new vehicles, in both the immediate future and during the timeframe of this rulemaking, to meet the fuel economy and CO₂ standards. The agencies evaluated costs for these technologies, and looked at how costs may change over time. The agencies also considered how fuel-saving technologies may be used on many types of vehicles (ranging from small cars to trucks) and how the technologies may perform in improving fuel economy and CO₂ emissions in combination with other technologies. With cost and effectiveness estimates for technologies, the agencies forecast how manufacturers may respond to potential standards and can estimate the

associated costs and benefits related to technology and equipment changes. This assists the assessment of technological feasibility and is a building block for the consideration of economic practicability of the standards.

The agencies described in the NPRM that the characterization of current and anticipated fuel-saving technologies relied on portions of the analysis presented in the Draft TAR, in addition to new information that had been gathered and developed since conducting that analysis, and the significant, substantive input that was received during the Draft TAR comment period.⁶⁶² The Draft TAR considered many technologies previously assessed in the 2012 final rule;⁶⁶³ in some cases, manufacturers have nearly universally adopted a technology in today's new vehicle fleet (for example, electric power steering), but in other cases, manufacturers only occasionally use a technology in today's new vehicle fleet (like turbocharged engines). For a few technologies considered in the 2012 rulemaking, manufacturers began implementing the technologies but have since largely pivoted to other technologies due to consumer acceptance issues (for instance, drivability and performance feel issues associated with some dual clutch transmissions without a torque converter) or limited commercial success.

In some cases, EPA and NHTSA presented different analytical approaches in the Draft TAR. However, for the NPRM and final rule analysis, the agencies harmonized their analytical approach to use one set of effectiveness values (developed with one tool), one set of cost assumptions, and one set of assumptions about the limitations of some technologies. To develop these assumptions, the agencies evaluated many sources of data, in addition to many stakeholder comments received on the Draft TAR. The preferred approach was to harmonize on sources and methodologies that were data-driven and reproducible for independent verification, produced using tools utilized by OEMs, suppliers, and academic institutions, and using tools that could support both CAFE and CO₂ analysis. As the agencies noted in the NPRM, a single set of assumptions also facilitated and focused public comment by reducing burden on stakeholders who sought to review all of the supporting documentation surrounding the analysis.

The agencies also identified a preference to use values developed from careful review of commercialized technologies; however, in some cases for technologies that are new, and are not yet for sale in any vehicle, the analysis relied on information from other sources, including CBI and third-party research reports and publications. The agencies strived to keep the technology analysis as current as possible in light of the ongoing technology development and implementation in the automotive industry. Additional emerging technologies added for the final rule analysis are described in further detail, below.

The agencies' process to develop effectiveness assumptions is described in detail in Section VI.B.3 Technology Effectiveness, and summarized here. The NPRM and final rule analysis modeled combinations of more than 50 fuel economy-improving technologies across 10 vehicle types (an increase from five vehicle types in NHTSA's Draft TAR analysis). Only 10 vehicle technology classes were used because large portions of the production volume in the analysis fleet have similar specifications, especially in highly competitive segments. For instance, many mid-sized sedans, small SUVs, and large SUVs coalesce around similar specifications, respectively. Baseline simulations have been aligned around these modal specifications. Parametrically combining these technologies generated more than 100,000 unique combinations per vehicle class. Multiplying the unique technology combinations by the 10 technology classes resulted in the simulation of more than one million individual full-vehicle system models. Modeling was also conducted to determine appropriate levels of engine downsizing required to maintain baseline vehicle performance when advanced mass reduction technology or advanced engine technology were applied. Performance neutrality is discussed in detail in VI.B.3.

Some baseline vehicle assumptions used in the simulation modeling were updated since the Draft TAR based on public comments, and further assessment of the NPRM and final rule analysis fleets. The agencies updated assumptions about curb weight, as well as technology properties like baseline rolling resistance, aerodynamic drag coefficients, and frontal areas. Many of the assumptions are aligned with published research from the Department of Energy and other independent

⁶⁶² 83 FR 43021–22 (Aug. 24, 2018).

⁶⁶³ 77 FR 62624 (Oct. 15, 2012).

sources.⁶⁶⁴ Additional transmission technologies and more levels of aerodynamic technologies than NHTSA presented in the Draft TAR analysis were also added for the analysis. Having additional technologies in the model allowed the agencies to assign baselines and estimate fuel-savings opportunities with more precision.

To develop technology cost assumptions, the agencies estimated present and future costs for fuel-saving technologies, taking into consideration the type of vehicle, or type of engine if technology costs vary by application. Since the 2012 final rule, many cost assessments, including tear down studies, were funded and completed, and presented as part of the Draft TAR analysis. These studies evaluated transmissions, engines, hybrid technologies, and mass reduction.⁶⁶⁵ The NPRM and final rule analyses use the 2016 Draft TAR's cost estimates for many technologies. In addition to those studies, the analysis also leveraged research reports from other organizations to assess costs.⁶⁶⁶ Consistent with past analyses, this analysis used BatPaC to provide estimates for future battery costs for hybrids, plug-in hybrids, and electric vehicles, taking into account the different battery design characteristics and taking into account the size of the battery for different applications.⁶⁶⁷ The

agencies also updated technology costs for the NPRM to 2016 dollars, because, as in many cases, technology costs were estimated several years ago, and since then have further updated technology costs to 2018 dollars for the final rule.

Cost and effectiveness values were estimated for each technology included in the analysis. As mentioned above, more than 50 technologies were considered in the NPRM and final rule analyses, and the agencies evaluated many combinations of these technologies in many applications. In the NPRM, the agencies identified overarching potential issues in assessing technology effectiveness and cost, including:

- *Baseline vehicle technology level assessed as too low, or too high.* Compliance information was extensively reviewed and supplemented with available literature on the vehicle models considered in the analysis fleet. Manufacturers could also review the baseline technology assignments for their vehicles, and the analysis incorporates feedback received from manufacturers.

- *Technology costs too low or too high.* Tear down cost studies, CBI, literature, and the 2015 NAS study information were referenced to estimate technology costs. In cases where one technology appeared to exceed all other technologies on cost and effectiveness, information was acquired from additional sources to confirm or reject assumptions. Cost assumptions for emerging technologies were reassessed in cases where new information became available.

- *Technology effectiveness too high or too low in combination with other vehicle technologies.* Technology effectiveness was evaluated using the Autonomie full-vehicle simulation modeling, taking into account the impact of other technologies on the vehicle and the vehicle type. Inputs and modeling for the analysis took into account laboratory test data for production and some pre-production technologies, technical publications, manufacturer and supplier CBI, and simulation modeling of specific technologies. Evaluating recently introduced production products to inform the technology effectiveness models of emerging technologies was preferred; however, some technologies that are not yet in production were considered using CBI. Simulation modeling used carefully chosen baseline configurations to provide a consistent, reasonable reference point for the incremental effectiveness estimates.

- *Vehicle performance not considered or applied in an infeasible manner.*

Performance criteria, including low speed acceleration (0–60 mph time), high speed acceleration (50–80 mph time), towing, and gradeability (six percent grade at 65 mph) were also considered. In the simulation modeling, resizing was applied to achieve the same performance level as the baseline for the least capable performance criteria but only with significant design changes. The analysis struck a balance by employing a frequency of engine downsizing that took product complexity and economies of scale into account.

- *Availability of technologies for production application too soon or too late.* A number of technologies were evaluated that are not yet in production. CBI was gathered on the maturity and timing of these technologies and the cadence at which manufacturers could adopt these technologies.

- *Product complexity and design cadence constraints too low or too high.* Product platforms, refresh and redesign cycles, shared engines, and shared transmissions were also considered in the analysis. Product complexity and the cadence of product launches were matched to historical values for each manufacturer.

- *Customer acceptance under estimated or over estimated.* Resale prices for hybrid vehicles, electric vehicles, and internal combustion engine vehicles were evaluated to assess consumer willingness to pay for those technologies. The analysis accounts for the differential in the cost for those technologies and the amount consumers have actually paid for those technologies. Separately, new dual-clutch transmissions and manual transmissions were applied to vehicles already equipped with these transmission architectures.

The agencies sought comments on all assumptions for fuel economy technology costs, effectiveness, availability, and applicability to vehicles in the fleet.

Several commenters compared the technology effectiveness and cost estimates from prior rulemaking actions to the NPRM, some commenting that the NPRM analysis represented a better balance of input from all stakeholders regarding the potential costs and benefits of future fuel economy improving technologies,⁶⁶⁸ and some commenting that the NPRM analysis represented a step back from the Draft TAR and EPA's Proposed Determination in terms of both the analysis itself and the resulting conclusions about the level of technology required to meet the

⁶⁶⁴ See, e.g., Islam, E., A. Moawad, N. Kim, and A. Rousseau, 2018a, An Extensive Study on Vehicle Sizing, Energy Consumption and Cost of Advance Vehicle Technologies, Report No. ANL/ESD-17/17, Argonne National Laboratory, Lemont, Ill., Oct 2018. https://www.autonomie.net/pdfs/ANL_BaSc_FY17_Report_10042018.pdf. Last accessed March 18, 2020; Pannone, G. "Technical Analysis of Vehicle Load Reduction Potential for Advanced Clean Cars," April 29, 2015. Available at <https://www.arb.ca.gov/research/apr/past/13-313.pdf>. Last accessed December 28, 2019.

⁶⁶⁵ FEV prepared several cost analysis studies for EPA on subjects ranging from advanced 8-speed transmissions to belt alternator starter, or Start/Stop systems. NHTSA also contracted with Electricore and EDAG on teardown studies evaluating mass reduction. The 2015 NAS report on fuel economy technologies for light-duty vehicles also evaluated the agencies' technology costs developed based on these teardown studies, and the technology costs used in this proposal were updated accordingly.

⁶⁶⁶ For example, the agencies relied on reports from the Department of Energy's Office of Energy Efficiency & Renewable Energy's Vehicle Technologies Office. More information on that office is available at <https://www.energy.gov/eere/vehicles/vehicle-technologies-office>. Other agency reports that were relied on for technology or other information are referenced throughout the NPRM and accompanying PRIA, and this final rule and the accompanying PRIA.

⁶⁶⁷ For instance, battery electric vehicles with high levels of mass reduction may use a smaller battery than a comparable vehicle with less mass reduction technology and still deliver the same range on a charge. See, e.g., Ward, J. & Gohlke, D. & Nealer, Rachael. (2017). The Importance of Powertrain Downsizing in a Benefit-Cost Analysis of Vehicle Lightweighting. JOM. 69.

⁶⁶⁸ See, e.g., NHTSA-2018-0067-11928.

augural standards.⁶⁶⁹ Specifically, while some commenters stated that the Draft TAR and subsequent EPA midterm review documents had recently concluded that augural standards were achievable with very low levels of electrification based on currently available information on technology effectiveness and cost,⁶⁷⁰ other commenters reiterated that conventional gasoline powertrains alone were insufficient to achieve post-2021 model year targets.⁶⁷¹

Generally, the automotive industry supported the agencies' NPRM analysis over previous analyses. In addition to the automotive industry's support of the agencies' use of one modeling tool for analysis, discussed in Section IV, above, the industry also commented in support of specific technology effectiveness, cost, and adoption assumptions used in the updated analysis.

The Alliance commented in support of the NPRM modeling approach, and referenced important technology-specific features of the modeling process, including "The acknowledgement and application of real-world limitations on technology application including a limit on the number of engine displacements available to any one manufacturer, application of shared platforms, engines, and transmissions, and the reality that improvements and redesigns of components are not only extended across vehicles but sometimes constrained in implementation opportunity to common vehicle redesign cycles; recognition of the need for manufacturers to follow "technology" pathways that retain capital and implementation expertise, such as specializing in one type of engine or transmission instead of following an unconstrained optimization that would cause manufacturers to leap to unrelated technologies and show overly optimistic costs and benefits; the application of specific instead of generic technology descriptions that allow for the above-mentioned real-world constraints; [and] the need to accommodate for intellectual property rights in that not all technologies will be available to all manufacturers."⁶⁷²

More specifically, the Alliance commented that the analysis appropriately restricted the application of some technologies, like the application of low rolling resistance tires on performance vehicles, and

limited aerodynamic improvements for trucks and minivans.⁶⁷³ Similarly, the Alliance commented in support of the decision to exclude HCR2 technology from the analysis, citing previous comments stating that "the inexplicably high benefits ascribed to this theoretical combination of technologies has not been validated by physical testing."

Ford commented more broadly that "[t]he previous analyses performed by the Agencies too often selected technology benefits from the high-end of the forecasted range, and cost from the lower-end, in part because deference was given to supplier or other third-party claims over manufacturers' estimates."⁶⁷⁴ Ford noted that, "[m]anufacturer estimates, while viewed as conservative by some, are informed by years of experience integrating new technologies into vehicle systems in a manner that avoids compromising other important attributes (NVH, utility, safety, etc.)," continuing that "[t]he need to preserve these attributes often limits the actualized benefit of a new technology, an effect insufficiently considered in projections from most non-OEM sources." Ford concluded, as mentioned above, that the NPRM analysis better balanced these considerations.

Toyota commented that the discrepancy between the automotive industry and prior regulatory assessments stemmed from "agency modeling relying on overly optimistic assumptions about technology cost effectiveness and deployment rates."⁶⁷⁵ Toyota pointed to a prior analysis that projected compliance for Toyota's MY 2025 lineup using the ALPHA model as an example of how "the agency's analysis failed to account for customer requirements (cost, power, weight-adding options, etc.) that erode optimal fuel economy, and normal business considerations that govern the pace of technology deployment." In contrast, Toyota stated that the "[m]odeled technology cost, effectiveness, and compliance pathways in the proposed rulemaking rely on more recent data as well as more realistic assumptions about the level of technology already on the road today, the pace of technology deployment, and trade-offs between vehicle efficiency and customer requirements."

Honda, in its feedback on the models used in the standard setting process, commented that "the current version of the CAFE model is reasonably accurate in terms of technology efficiency, cost,

and overall compliance considerations, and reflects a notable improvement over previous agency modeling efforts conducted over the past few years."⁶⁷⁶

FCA commented in recognition of the CAFE model improvements over the Draft TAR version, but noted they "continue to believe that the cost and benefits used as inputs to the model are overly optimistic."⁶⁷⁷ FCA used its updated Jeep Wrangler Unlimited and Ram 1500 pickup models as examples of vehicles that "provide real life examples of the costs and benefits that can be achieved with fuel and weight saving technology;" however, "after all of the real world concerns such as emissions, drivability, OBD, and fuels are considered, the benefits observed remain less than those derived by the Autonomie model and used as inputs to the Volpe model."

Conversely, environmental groups, consumer groups, and some States and localities commented that the Draft TAR and subsequent EPA analyses were more representative of the current state of vehicle technologies. These groups all generally commented, in different terms, that the NPRM analysis technology effectiveness was understated and technology costs were overstated, and additional constraints the agencies placed on the analysis, like excluding technologies already in production or constraining technology pathways, also helped lead to that result.⁶⁷⁸

ICCT commented that the agencies "ignored their own rigorous 2015–2017 technological assessment, and have adopted a series of invalid and unsupportable decisions which artificially constrain the availability and dramatically under-estimate levels of effectiveness of many different fuel economy improvement and GHG-reduction technologies and unreasonably increase modeled compliance costs."⁶⁷⁹ ICCT also commented that the agencies ignored, suppressed, dismissed, or restricted the use of work done to update technologies and technology cost and effectiveness assessments since the 2012 final rule for MYs 2017–2025. ICCT stated that the "invalid high cost result [of the modeled augural standards in 2025] was created by the agencies by making many dozens of unsupported changes in the technology effectiveness and availability inputs, the technology cost inputs, and the technology package constraints."

ICCT stated that “the agencies failed to capture the latest available information and, as a result, their assessment incorrectly and artificially overstates technology costs.”

CARB commented that the agencies did not present sufficient new evidence to change previous technical findings, specifically in regards to conventional vehicle technologies.⁶⁸⁰ CARB stated that instead of relying on new information, as had been asserted as justification for the proposal, the analysis was based on older data that did not reflect current technology. Accordingly, CARB pointed out that previous analysis by the agencies projected far less need for electrification than what was required in the proposal, stating that the underlying cause is a reduction in the assumed cumulative improvements for what advanced gasoline technology is able to achieve.

A coalition of States and Cities similarly commented that “[t]he Agencies’ conclusions regarding the technology necessary to meet the 2025 standards and the cost of that technology run counter to the evidence before the agency, diverge from prior factual findings without explanation and without transparency as to the source of data relied on, and are unsupported by any reasoned analysis. Such analysis bears many hallmarks of an arbitrary and capricious action.”⁶⁸¹

Roush Industries, commenting on behalf of CARB, commented that “the 2018 PRIA projected average costs for technology implementation to achieve the existing standards to be significantly overstated and in conflict with the 2016 Draft TAR cost estimates generated by the Agencies only two years earlier.”⁶⁸² Roush commented that the Draft TAR analyses of cost and incremental fuel economy improvement necessary to achieve the augural standards was consistent with Roush’s own estimates and other published data.

Similarly, H-D Systems (HDS), commenting on behalf of the California DOJ, commented that “the estimates in the 2016 TAR on technology cost and effectiveness still represent the correct estimates based on the latest available data.”⁶⁸³ HDS, in its analysis of the costs of technologies to meet different potential standards between the Draft TAR and the NPRM, noted that “costs for most conventional (*i.e.*, non-electric) drivetrain technologies were similar in

both reports in that costs were within +5% of the average of the costs from the two reports. The only exception was the cost estimate for the High CR second generation Atkinson cycle or HCR2 engine which was estimated to be much more expensive. Due to differences in nomenclature, transmission technology costs could not be directly compared but were similar at the highest efficiency level. In contrast, cost of hybrid technology was estimated to be much higher in the PRIA and were 200 to 250% higher for strong hybrids. Costs of drag reduction, rolling resistance reduction and auxiliary system technologies were also quite similar but the cost of mass reduction was substantially higher in the PRIA by a factor of 2 to 3. Costs of engine friction reduction appear not to be included in the cost computation for the PRIA although the technology appears to be integrated into some of the engine technology packages analyzed in the PRIA to estimate effectiveness.”

CFA commented that “[t]he overarching discussion of technology developments that introduces the NHTSA analysis is fundamentally flawed and infects the entire proposal,” taking issue with the NPRM statement that “some options considered in the original order for the National Program ha[d] not worked out as EPA/NHTSA anticipated.”⁶⁸⁴ CFA commented that the agencies failed to note that some technology options have performed better than anticipated, and “the fact that some technologies have done better than expected is a basis for increasing the standards, not in the context of a mid-term review that was supposed to tweak the long-term program.”

NCAT commented that the “inflation of projected technology costs does not appear to be attributable primarily to the projected cost of any given technology, but rather to modeling constraints on the application of such technologies to vehicles. Many of these constraints appear to be arbitrary and NHTSA’s departure from prior analyses in these respects is not adequately supported.”⁶⁸⁵

Environmental groups and States also commented that the agencies either should reincorporate all the Draft TAR or the EPA Proposed and Final Determination analyses’ technologies, technology effectiveness values, and technology costs into the analysis, and/or compare the final rule analysis with those prior analyses to show how the updated assumptions changed the results from those prior analyses.

For example, ICCT commented that “[f]or the agencies to conduct a credible regulatory assessment they must remove all the technology availability constraints, re-incorporate and make available the full portfolio of technology options as was available in EPA’s analysis for the original 2017 Final Determination, and include at least 15 g/mile CO₂ for off-cycle credits by 2025, to credibly reflect the real-world technology developments in the auto industry.”⁶⁸⁶ ICCT also stated that “[t]he agencies need to identify each and every technology cost input used in their modeling, and provide a clear engineering and evidence based justification for why that cost differs from the costs employed in the extremely well documented and well justified Draft TAR and in EPA’s 2016 TSD and 2017 Final Determination, taking into account the above discussion of significant new evidence developed since those prior estimates were made. Absent such disclosure and justification, the default assumption needs to be that the prior costs estimated based on the most recent data are more appropriate than the estimates used for the proposal.”

In addition, groups of commenters were equally split on the ability of technologies to meet different compliance targets. For example, the Alliance commented that “the only technologies that have demonstrated the improvements necessary to meet the MY 2025 standards are strong hybrids, plug-in electric vehicles, and fuel cell electric vehicles. The Agencies’ analysis for this Proposed Rule predict the need for significant growth in sales of electrified vehicles, a finding consistent with third-party analyses.”⁶⁸⁷ In contrast, UCS commented that electrified powertrains “are not especially relevant for the MY 2022–2025 regulations.”⁶⁸⁸

The agencies are aware that the prior analyses concluded that compliance with the augural standards could largely be met through advances in gasoline vehicle technologies, and with only very low levels of strong hybrids and electric vehicles. As the agencies stated in the NPRM, consistent with both agencies’ statutes, the proposal was entirely *de novo*, based on an entirely new analysis reflecting the best and most up-to-date information available to the agencies at the time of this rulemaking.⁶⁸⁹ As discussed in Section IV, Section VI.B, and further below, the NPRM and final rule analyses reflect updates to

technology effectiveness estimates, technology costs, and the methodology for applying technologies to vehicles that the agencies believed better represent the state of technology and the associated costs compared to prior analyses, that result in pathways to compliance that look both similar and different to those in prior analyses.

That said, several of the effectiveness and cost values used in the NPRM and final rule analysis were directly carried over from the 2012 rule for MYs 2017–2025, Draft TAR, and EPA Midterm Evaluation analyses.⁶⁹⁰ Several others were carried over from the 2015 NAS report,⁶⁹¹ which the agencies heavily relied upon in past analyses even if specific cost or effectiveness values were not used. Different technology effectiveness estimates, cost estimates, or adoption constraints were employed where the agencies had information, from technical reports, manufacturers, or other stakeholders, indicating that a technology could or could not be feasibly adopted in the rulemaking timeframe, or a technology could or could not be adopted in the way that the agencies had previously modeled it. Notably, most differences in pathways to compliance are attributable to only a few significant differences between this rulemaking analysis and prior rulemaking analyses.

For example, as discussed in Section VI.B.3 Technology Effectiveness and Modeling and Section VI.C.1 Engine Paths, in the EPA Draft TAR and Proposed Determination analyses, effectiveness of HCR engine technologies and downsized turbocharged engine technologies were estimated using Tier 2 certification fuel. Tier 2 certified fuel has a higher octane rating compared to regular octane fuel.^{692 693 694} As summarized by EPA in the PD TSD, “EPA’s estimate of effectiveness for gasoline-fueled engines and engine technologies was based on Tier 2 Indolene fuel although protection for operation in-use on Tier 3 gasoline (87 AKI E10) was included in the analysis of engine technologies considered both within the Draft TAR and Proposed Determination. Additionally, in the technology assessment for this Proposed Determination, EPA has considered the required engine sizing and associated effectiveness adjustments when

performance neutrality is maintained on 87AKI gasoline typical of real-world use.”⁶⁹⁵

NHTSA’s effectiveness analysis for the Draft TAR used some engine maps also developed using premium octane gasoline. However, at the time NHTSA stated the agency would ensure all future engine model development will be performed with regular grade octane gasoline.⁶⁹⁶ Commenters like Ford stated the effectiveness estimates for turbo downsized engine packages were too high, in part because of the use of high octane fuel. However they also commented in appreciation of NHTSA’s acknowledgement that any subsequent analysis would be based on fuel at an appropriate octane level, as they stated the impact of the change needed to be reflected in future analyses.⁶⁹⁷

Engine specifications used to create the engine maps for the NPRM and the final rule analysis were developed using Tier 3 fuel to assure the engines were capable of operating on real world regular octane (87 pump octane = (R+M/2)). The process was similar to what manufacturers must do to ensure engines have acceptable noise, vibration, harshness, drivability, performance, and will not fail prematurely when operated on regular octane fuel. This eliminated the need for any adjustments that were applied in the 2016 Draft TAR and PD TSD to account for Tier 2 to Tier 3 fuel properties. This accounts for some of the effectiveness and cost differences for engine technologies between the Draft TAR/Proposed Determination and the NPRM/final rule. For more details, see Section VI.C.1 Engine Paths.

The agencies believe ICCT’s and other commenters’ assertions that the engine maps should reflect Tier 2 fuel and not be updated for Tier 3 fuel would ignore these important considerations, and would provide engine maps that could not achieve the fuel economy improvements unless operated on high octane fuel. Therefore, the agencies determined that engine maps developed for the Draft TAR and EPA Proposed Determination that were based on Tier 2 fuel should not be used for the NPRM and final rule analyses for these technical reasons.

As another related example, the agencies described that prior analyses had relied heavily on the availability of the HCR2 (or ATK2) “future” Atkinson Cycle engine as a cost-effective pathway

to compliance for stringent alternatives, but many engine experts questioned its technical feasibility and near-term commercial practicability.⁶⁹⁸ The agencies explained that EPA staff began theoretical development of this conceptual engine with a best-in-class 2.0L Atkinson cycle engine and then increased the efficiency of the engine map further, through the theoretical application of additional technologies in combination, including cylinder deactivation, engine friction reduction, and cooled exhaust gas recirculation. While the potential of such an engine is interesting, nevertheless the engine remains entirely speculative. No production HCR2/ATK2 engine, as outlined in the EPA SAE paper,⁶⁹⁹ has ever been commercially produced. Furthermore, the engine map has not been validated with hardware, bench data, or even on a prototype level (as no such engine exists to test to validate the engine map).

Vehicle manufacturers also commented on EPA’s effectiveness assumptions and estimates of HCR2/ATK2 model’s future penetration levels in the Draft TAR, stating “[t]he effectiveness values for the ‘futures’ ATK2 package—projected at 40% penetration in 2025MY and includes cooled exhaust gas recirculation (CEGR) and cylinder deactivation (DEAC)—are too high, primarily due to overly-optimistic efficiencies in the base engine map, insufficient accounting of CEGR and DEAC integration losses, and no accounting of the impact of 91RON Tier 3 test fuel,” and that “44% fleet-wide penetration of ATK2 in 2025MY is unrealistic given the limited number of powertrain refresh cycles available before 2025MY. In addition, it is unreasonable to assume that OEMs already heavily invested in different high-efficiency powertrain pathways (e.g., turbo-downsizing) would be able to commit the immense resources needed to reach these high ATK2 penetration levels in such a short time.”⁷⁰⁰

Accordingly, the agencies decided to not include HCR2 technology in the NPRM and final rule analysis. The engine model was not used because no observable physical demonstration of the speculative technology combination model has yet been created. Further,

many questions remain about the model's practicability as specified, especially in high load, low engine speed operating conditions. The HCR2 model combines multiple technologies to provide cumulative estimate of benefits without consideration the practical interaction of technologies. This approach runs contrary to the modeling approach attempted in the NPRM and final rule analysis. The approach the agencies tried to follow restricted models to adding discrete advanced technologies. This approach allowed an accounting of synergetic effects, identified incremental benefits, and increased the precision of cost estimates.

As another example, further discussed in Section VI.B.1 Analysis Fleet, the agencies had traditionally taken different approaches to assigning baseline road load reduction technology assignments. For analyzing baseline levels of mass reduction in an analysis fleet, NHTSA had developed for the Draft TAR a regression model to summarize a vehicle's weight savings using a relative performance approach and accounting for vehicle content, using cost curves developed from teardown studies of a MY 2011 Honda Accord and MY 2014 Chevrolet Silverado pickup truck. EPA developed its own methodology that classified vehicles based on weight reductions from a MY 2008 vehicle, compared to the MY 2014 version of the same vehicle, using a cost curve from a teardown study of a MY 2010 Toyota Venza. In the EPA's mass reduction technology costing approach, a cost reduction was applied when mass reduction 1 technology was applied to a system at mass reduction 0 technology level. NHTSA's approach, used in the NPRM and final rule analysis, set baseline mass reduction assignments so costs of implementing mass reduction technologies are fully applied as vehicle platforms move along the mass reduction technology path.

The agencies also included additional advanced powertrain technologies and other vehicle-level technologies in the technology pathways between the Draft TAR and NPRM, and between the NPRM and final rule. However, manufacturers and suppliers have repeatedly told the agencies that there are diminishing returns to increasing the complexity of advanced gasoline engines, including in the amount of fuel efficiency benefit that they can provide. For example, Toyota commented, in response to the EPA SAE paper benchmarking the 2018 Camry with the 2.5L Atkinson-cycle engine and "futuring" midsize exemplar vehicles

based on the generated engine map,⁷⁰¹ that although EPA's addition of cylinder deactivation to the hypothetical 2025 exemplar vehicle is technically possible and would provide some fuel economy and CO₂ benefit, the primary function of cylinder deactivation is to reduce engine pumping losses which the Atkinson cycle and EGR already accomplish on the 2018 Camry.⁷⁰² Toyota concluded, "The overlapping and redundant measures to reduce engine pumping losses would add costs with diminishing efficiency returns." Similarly, BorgWarner commented that they "do not expect that variable compression ratio (VCR) or homogeneous charge compression ignition (HCCI) will see broad application in the short term, if ever. While each of these technologies can offer marginal efficiency gains at some engine speed-load conditions, the use of down-sized boosted engines with 8–10 speed transmissions makes it possible to run engines at near optimum conditions and effectively minimizes gains from VCR or HCCI. VCR mechanisms result in additional mass, cost and complexity, and true HCCI has yet to be demonstrated in a production vehicle. The agencies do not believe that OEMs will judge these technologies to be cost effective."⁷⁰³

So, while previous analyses may have shown pathways to compliance with increasingly complex advanced gasoline engines, the NPRM and final rule analyses more appropriately reflect that the most complex gasoline engine technologies will account for a smaller share of manufacturers' products during the rulemaking timeframe. However, despite this fact, the NPRM and final rule analysis include *more* advanced powertrain technologies than previous analyses, in part to account for important considerations like intellectual property and the fact that some manufacturers have already started down the path of incorporating a certain advanced engine technology in their product portfolio, and that abrupt switching to another advanced engine technology would result in unrealistic stranding of capital costs. In addition, greater precision in how cumulative technologies applied to engines, as estimated through the Autonomie effectiveness modeling, appropriately reflects the diminishing returns to efficiency benefits that those advanced

engines can provide. Moreover, as identified by a wide range of commenters, battery costs are projected to fall in the rulemaking timeframe to a point where, in the compliance modeling, it becomes more cost effective to add electrification technologies to vehicles than to apply other advanced gasoline engine technologies.

Finally, the agencies declined to incorporate some information and data for the NPRM or final rule central analysis for reasons discussed in the following sections. In general, the data produced by agencies or submitted by commenters failed to isolate effectiveness impacts of individual technologies (or in some cases a combination of two or several technologies). The data included effects from additional unaccounted and undocumented technologies. Because the effectiveness improvement measured or claimed resulted from more than just the reported sources, the actual effectiveness of the technology or technologies is obfuscated and easily under or over predicted. Using effectiveness values generated in this manner carries a high risk of double counting effectiveness and undercounting costs.

In many cases, this problem exists where data or information is based on laboratory testing or on-road testing of production vehicles or components including engines and transmissions. Production vehicles and components usually include multiple technology improvements from one redesign to the next, and rarely incorporate just a single technology change. Furthermore, technology improvements on production vehicles in some cases cannot be readily observed, such as the level of mechanical friction in an engine, and isolation and identification of the improvement attributable to each technology would be impractical given the costs and time required to do so. That said, in some cases, where possible to do so, the agencies used the data or information from production vehicles to corroborate information from the Autonomie simulations. However, the agencies declined to apply that data or information directly in the analysis if the effectiveness improvement attributable to a particular technology could not be isolated.

The agencies made these updates from prior analyses not, as some commenters have suggested, to "artificially overstate technology costs,"⁷⁰⁴ or to "ignore the knowledge and expertise of the EPA engineering

and compliance staff,”⁷⁰⁵ “so that the model in many instances selects more expensive, less fuel efficient technology while excluding less expensive and more efficient alternatives,”⁷⁰⁶ but because the updates reflected the agencies’ reasonable assessment of the current state of vehicle technologies and their costs, and the state of future vehicle technologies and costs in the rulemaking timeframe.

Separate from the decision to update assumptions used for the NPRM analysis from prior analyses, the agencies did refine some technology effectiveness and cost assumptions from the NPRM to this final rule analysis. In addition to being appropriate for technical reasons, this should address some commenters’ overarching concerns about understated technology effectiveness and overstated technology costs. For example, several commenters noted that the costs of BISG/CISG systems were higher for small Cars/SUVs and medium cars than for medium SUVs and pickup trucks, which the Alliance and FCA described as “implausible” and “misaligned with industry understanding,” and which ICCT described as “contrary to basic engineering logic, which holds that a system which would be smaller and have lower energy and power requirements would be less expensive, not more.”⁷⁰⁷ The agencies agree, and have made changes to address this issue, as described in Section VI.C.3.a) Electrification.

After considering comments, the agencies also added several engine technologies and technology combinations for the final rule analysis. These included a basic high compression ratio Atkinson cycle engine, a variable compression ratio engine, a variable turbo geometry engine, and a variable turbo geometry with electric assist engine (VTGe). The NPRM discussed and provided engine maps for each of these technologies. The agencies also added new technology combinations including diesel engines with cylinder deactivation, turbocharged engines with advanced cylinder deactivation, diesel engines paired with manual transmissions, and diesel engines paired with 12-volt start-stop technology. Transmission revisions included updating the effectiveness of 6-speed automatic transmissions, applying updated shift logic for 10-speed automatic transmissions, and increasing the gear span for efficient 10-speed automatic transmissions. Mass

reduction technology was expanded to include up to 20 percent curb weight reduction, compared with up to 10 percent for the NPRM. These changes, and the comments upon which they were based, are described in further detail in the following sections.

1. Engine Paths

The internal combustion (IC) engine is a heat engine that converts chemical energy in a fuel into mechanical energy. Chemical energy of the fuel is first converted to thermal energy by means of combustion or oxidation with air inside the engine. This thermal energy raises the temperature and pressure of the gases within the engine, and the high-pressure gas then expands against the internal mechanisms of the engine. This expansion is converted by the mechanical linkages of the engine to a rotating crankshaft, which is the output of the engine. The crankshaft, in turn, is connected to a transmission to transmit the rotating mechanical energy to the desired final use, particularly the propulsion of vehicles.

IC engines can be categorized in a number of different ways depending upon which technologies are designed into the engine: By type of ignition (*e.g.*, spark ignition or compression ignition), by engine cycle (*e.g.*, Otto cycle or Atkinson cycle), by valve actuation (*e.g.*, overhead valve (OHV), single overhead camshaft (SOHC), or dual overhead camshaft (DOHC)), by basic design (*e.g.*, reciprocating or rotary), by configuration and number of cylinders (*e.g.*, inline four-cylinder (I4) or V-shaped six-cylinder (V6)), by air intake (*e.g.*, forced induction (turbo or super charging) or naturally aspirated), by method of fuel delivery (*e.g.*, port injection or direction injection), by fuel type (*e.g.*, gasoline or diesel), by application (*e.g.*, passenger car or light truck), or by type of cooling (*e.g.*, air-cooled or water-cooled). For each combination of technologies among the various categories, there is a theoretical maximum efficiency for all engines within that set. There are various metrics that can be used to compare engine efficiency, and the four metrics the agencies use or discuss in this preamble are:

- Brake specific fuel consumption (BSFC), which is the mass of fuel consumed per unit of work output (amount of fuel used to produce power);
- Brake thermal efficiency (BTE), which is the total fuel energy released per unit of work output (percentage of fuel used to produce power);
- Fuel consumption (gallons per mile), which looks at the gallons of fuel

consumed per unit of work output (mile travelled); and

- Fuel economy (in MPG), which is the amount of work output (miles travelled) per unit (gallon) of fuel consumed.

When comparing the efficiency of IC engines, it is important to identify the metric(s) used and the test cycle for the measurement because results vary widely when engines operate over different test cycles. Two-cycle fuel economy tests used to certify vehicles’ compliance with the CAFE standards tend to overestimate the average fuel economy motorists will typically achieve during on-road operation.⁷⁰⁸ In the NPRM and for this final rule analysis, the agencies considered technology effectiveness for the 2-cycle test procedures and AC and off-cycle test procedures to evaluate how technologies could be applied for manufacturers to comply with standards. The agencies also considered real world operation beyond these test procedures when considering IC engine technologies in order to assure the technologies were configured and specified in a manner that could be used in real world vehicle applications.

a) Fuel Octane

As mentioned in other sections of the Preamble, the agencies go to great lengths to ensure engine technologies considered for potential compliance pathways are feasible for real-world implementation and effectiveness. An important facet of this evaluation are both the fuels that are used for efficiency testing and also the fuels that consumers may purchase in the marketplace.

In the NPRM, the agencies included a general overview of fuel octane (stability) level, including levels currently available, and the potential impact of fuel octane on engines developed for the U.S. market.⁷⁰⁹ The agencies described that a typical, overarching goal of optimal spark-ignited engine design and operation is to maximize the greatest amount of energy from the fuel available, without manifesting detrimental impacts to the engine over expected operating conditions. Design factors, such as compression ratio, intake and exhaust valve control specifications, and combustion chamber and piston characteristics, among others, are all impacted by the octane of the fuel consumers are anticipated to use.⁷¹⁰

⁷⁰⁸ 77 FR 62988.

⁷⁰⁹ PRIA at 253.

⁷¹⁰ In addition, PRIA Chapter 6 contains a brief discussion of fuel properties, octane levels used for

⁷⁰⁵ NHTSA–2018–0067–11741 at I–23.

⁷⁰⁶ NHTSA–2018–0067–12123.

⁷⁰⁷ NHTSA–2018–0067–11741.

The agencies also discussed potential challenges associated with octane levels available currently, and how those octane levels may play a role in potential vehicle fuel efficiency improvements. Vehicle manufacturers typically develop their engines and engine control system calibrations based on the fuel available to consumers. In many cases, manufacturers may recommend a fuel grade for best performance and to prevent potential damage. In some cases, manufacturers may *require* a specific fuel grade for both best performance, to achieve advertised power ratings, and/or to prevent potential engine damage.

Consumers, though, may or may not choose to follow the manufacturer's recommendation or requirement for a specific fuel grade for their vehicle. As such, vehicle manufacturers often choose to employ engine control strategies for scenarios where the consumer uses a lower than recommended, or required, fuel octane level, as a way to mitigate potential engine damage over the life of a vehicle. These strategies limit the extent to which some efficiency improving engine technologies can be implemented, such as increased compression ratio and intake system and combustion chamber designs that increase burn rates and rate of in-cylinder pressure rise. If the minimum octane level available in the market were higher (especially the current sub-octane regular grade in the mountain states), vehicle manufacturers might not feel compelled to design vehicles sub-optimally to accommodate such blends.

When knock (also referred to as detonation) is encountered during engine operation, at the most basic level, non-turbocharged engines can adjust the timing of the spark that ignites the fuel, as well as the amounts of fuel injected at each intake stroke ("fueling"). In turbocharged applications, knocking is typically controlled by adjusting boost levels along with spark timing and/or the amount of fuel injected. Past rulemakings discussed other techniques that may be employed to allow higher compression ratios, including optimizing spark timing, and adding of cooled exhaust gas recirculation (EGR). Regardless of the type of spark-ignition engine or technology employed, efforts to reduce or prevent knock with the lower-octane fuels that are available in the market result in the loss of potential power output, creating a "knock-

limited" constraint on performance and efficiency.

The agencies noted that despite limits imposed by available fuel grades, manufacturers continue to make progress in extracting more power and efficiency from spark-ignited engines. Production engines are safely operating with regular 87 AKI fuel with compression ratios and boost levels once viewed as only possible with premium fuel. According to the Department of Energy, the average gasoline octane level has remained fundamentally flat starting in the early 1980's and decreased slightly starting in the early 2000s. During this time, however, the average compression ratio for the U.S. fleet has increased from 8.4 to 10.52, a more than 20 percent increase. As explained by the Department of Energy, "[t]here is some concern that in the future, auto manufacturers will reach the limit of technological increases in compression ratios without further increases in the octane of the fuel."⁷¹¹ As such, manufacturers are still limited by the fuel grades available to consumers and the need to safeguard the durability of their products for all of the available fuels; thus, the potential improvement in the design of spark-ignition engines continues to be overshadowed by the fuel grades available to consumers.

EPA and NHTSA also described ongoing research and positions from automakers and advocacy groups on fuel octane levels, including comments received during past agency rulemakings and on the 2016 Draft TAR regarding the potential for increasing octane levels in the U.S. market. The agencies described arguments for adjusting to octane levels, including making today's premium grade the base grade of fuel available, which could enable low cost design changes to improve fuel economy and reduce tailpipe CO₂ emissions. Challenges associated with this approach include the increased cost to consumers who drive vehicles designed for current regular octane grade fuel, who would not benefit from the use of the higher cost higher-octane fuel. The costs of such a transition to higher-octane fuel would be high and persist well into the future, since unless current regular octane fuel were unavailable in the North American market, manufacturers would be effectively unable to redesign

their engines to operate on higher-octane fuel. In addition, the full benefits of such a transition would not be realized until vehicles with such redesigned engines were produced for a sufficient number of model years largely to replace the current on-road vehicle fleet. The transition to net positive benefits would take many years.

The agencies also described input received from renewable fuel industry stakeholders and from the automotive industry supporting high-octane gasoline fuel blends to enable fuel economy and CO₂ improving technologies such as higher compression ratio engines. Stakeholders suggested that mid-level (e.g., E30) high-octane ethanol blends should be considered and that EPA should consider requiring that mid-level blends be made available at service stations. Stakeholders supporting higher-octane blends suggested that higher-octane gasoline could provide auto manufacturers with more flexibility to meet more stringent standards by enabling opportunities for use of lower tailpipe CO₂ emitting technologies (e.g., higher compression ratio engines, improved turbocharging, optimized engine combustion).

The agencies sought additional comment in the NPRM on various aspects of current fuel octane levels and how fuel octane could play a role in the future. More specifically, the agencies sought comment on how increasing fuel octane levels could have an impact on product offerings and engine technologies, as well as what improvements to fuel economy and tailpipe CO₂ emissions could result from higher-octane fuels. The agencies sought comment on an ideal octane level for mass-market consumption, and whether there were downsides with increasing the available octane levels and, potentially, eliminating lower-octane fuel blends. EPA also requested comment on whether and how EPA could require the production and use of higher-octane gasoline consistent with Title II of the Clean Air Act.

The agencies received numerous, wide-ranging comments in response to the NPRM discussion, and some direct responses to the agencies' requests for comments. The commenters included fuel producers, individual vehicle manufacturers, environmental groups, vehicle suppliers, fuel advocacy groups, and agricultural organizations, among others. Commenters provided a broad range of comments ranging from explication of the many challenges to increasing available octane levels, to claims of the substantial efficiency

engine simulation and in real-world testing, and how octane levels can impact performance under these test conditions.

⁷¹¹ Fact of the Week, *Fact #940: August 29, 2016 Diverging Trends of Engine Compression Ratio and Gasoline Octane Rating*, U.S. Department of Energy, <https://www.energy.gov/eere/vehicles/fact-940-august-29-2016-diverging-trends-engine-compression-ratio-and-gasoline-octane> (last visited Mar. 21, 2018).

increases that could be easily obtained by requiring higher-octane levels.

Several ethanol industry stakeholders commented in support of requiring higher-octane fuels using mid-level ethanol blends. The High-Octane, Low Carbon (HOLC) Alliance commented that it believes “NHTSA and EPA have a critical opportunity to cost-effectively ensure progress in fuel efficiency and CO₂ emissions standards. Scientific experts agree that high-octane, low-carbon fuel can yield greater fuel economy and emissions benefits when paired with internal combustion engines (ICEs). But, to realize such benefits, automobile manufacturers require approval sooner rather than later to such fuels. Alternatively, automobile manufacturers will be limited in their ability to maximize the environmental performance of their vehicles until non-liquid fuel engines become more readily available. In finalizing the Proposed Rule, the HOLC Alliance strongly urges EPA and NHTSA to establish a pathway forward toward incentivizing the production and adoption of higher-octane, lower carbon fuels. By doing so, EPA and NHTSA can continue to incrementally increase CO₂ and fuel economy standards, respectively.”⁷¹²

Renewable Fuels Associations (RFA) commented that “it strongly believes vehicles and fuels must be considered together as integrated systems. As EPA has recognized in the past, a ‘systems approach enables emission reductions that are both technologically feasible and cost effective beyond what would be possible looking at vehicle and fuel standards in isolation.’ Because ethanol-based high-octane low-carbon fuel blends would enable cost-effective gains in fuel economy and carbon dioxide reductions, the agencies should take steps to support [high-octane low-carbon] fuels in the final SAFE rule.”⁷¹³

RFA cited several studies indicating benefits are available from raising the floor of fuel octane levels currently available, and, particularly, “[t]he results from the studies reviewed generally support a main conclusion that splash blending ethanol is a highly effective means of raising the octane rating of gasoline and enabling low-cost efficiencies and reduced emissions in modern spark-ignition engines.”⁷¹⁴ In addition, National Corn Growers Association stated that, “[w]ithout a change in fuel, automakers are reaching the limits on the efficiency gains that

can be achieved with technology changes.”⁷¹⁵

The National Corn Growers Association, in conjunction with associated corn growing and agricultural groups, pointedly stated the EPA should, “[s]et a minimum fuel octane level of 98 RON and phase out low octane fuels as new optimized vehicles enter the market in MY 2023,” and concluded that approving a “midlevel ethanol blend vehicle certification fuel would enable automakers to expedite design and testing of optimized vehicles for use with this new fuel.”⁷¹⁶

The 25x25 Alliance commented that “to meet the dual goals of greater fuel efficiency and reduced GHG emissions, the utilization of higher compression spark ignition internal combustion engines will be essential. Increasing engine compression improves thermal efficiency. However, as compression increases, higher-octane fuels will be needed to prevent engine knock. Automakers and advocacy groups have expressed support for increases to fuel octane levels for the US market. Ethanol with its octane rating of 113 offers engine knock resistance at a lower cost than any other octane booster in gasoline. In addition, ethanol’s lower direct and life-cycle GHG emissions as compared to gasoline are well documented. For this reason, a fuel produced from a mixture of ethanol and gasoline and used in conjunction with advanced high compression engines presents itself as a technology pathway capable of complying with new CAFE/GHG standards.” They continue, “HOLC supporters recognize numerous barriers and other associated regulatory hurdles must be resolved before HOLC ethanol fuels are adopted at large scale. . . . 25x25 believes it is imperative that the vehicle and fuel be treated as a comprehensive system. To date CAFE/GHG standards have largely focused on vehicle engine technology. Advanced engine vehicles perform best in concert with fuels of suitable properties and composition to optimally enable and power them.”⁷¹⁷

The American Coalition for Ethanol (ACE) commented that “high-octane blends comprised of 25 to 30 percent ethanol would help bring down the cost for consumers compared to the

premium-priced octane level advocated by oil refiners. Ethanol has a blending octane rating of nearly 113 and trades at a steep discount to gasoline. In many wholesale markets today, ethanol costs at least 60 cents per gallon less than gasoline. Ethanol delivers the highest octane at the lowest cost, allowing automakers to benefit by continuing to develop high-compression engine technologies and other product offerings to achieve efficiency improvements and reduced emissions. The ideal way to transition from today’s legacy fleet to new vehicles with advanced engine technologies designed to run optimally on a high-octane fuel is to utilize FFVs as bridge vehicles that can provide immediate demand for mid-level ethanol blends.”⁷¹⁸

Growth Energy commented that with a mid-level ethanol blend, automakers not only get higher-octane that they can use to optimize engines and gain further fuel efficiency, they will also see a fuel that has demonstrably lower carbon dioxide emissions.⁷¹⁹ The Illinois Corn Growers’ Association et al., commented that “NHTSA and EPA must adapt the existing regulatory structure to reflect the specific characteristics of mid-level blend fuels. Working together, the ethanol industry, automakers, EPA and NHTSA can bring about, during the period covered by the SAFE program, a new generation of high efficiency internal combustion engines optimized to take advantage of this new fuel’s unique properties.”⁷²⁰

Ethanol industry commenters provided comment on several EPA actions they believe would be necessary to support higher-octane mid-level fuel blends:

- Set a minimum fuel octane level and phase out low-octane fuels as new optimized vehicles enter the market;
- Approve a high-octane, mid-level ethanol blend vehicle certification fuel;
- Correct the fuel economy formula by updating the R-Factor to be at or nearly “1” to reflect documented operation of modern engine technology;
- Extend a RVP waiver of 1 psi to all gasoline containing at least 10 percent ethanol;
- Adopt the Argonne National Laboratory GREET model to determine updated lifecycle carbon emissions for ethanol;

- Establish meaningful credits to automakers to incentivize transition to higher-octane fuel vehicles and continue to support flex-fuel vehicles; and

- Provide equal treatment to vehicle technologies that reduce carbon emissions.

The Clean Fuels Development Coalition, et al. suggested that, “the ‘ideal octane level’ to optimize LDV performance, fuel efficiency, and reduce harmful emissions and consumer costs is 98–100 RON produced with E30+ ‘clean octane.’”⁷²¹ Concurrently, the HOLC Alliance and ACE, among others, also supported that 98 to 100 RON would be ideal octane levels for the nation.⁷²²

BorgWarner, a supplier to major automobile manufacturers, commented that “[f]uel octane is a limiting factor in the selection of compression ratio for all spark-ignition engines and the amount of boost for turbocharged engines. Higher-octane is particularly effective for using higher compression ratios with boosted engines,” and stated that “[t]here is substantial merit to raising the minimum octane required because current fuel pricing penalizes consumers for using higher-octane fuel. A base octane of 95 RON would be consistent with Europe. This would allow consistent development of engines for the broader US–EU market. Prior to the introduction of ethanol into gasoline, the base blend for regular fuel was typically 92 RON. Addition of 10% ethanol to this base blend gave 95 RON regular, so the base blend would be reformulated to retain the 92 RON at a lower cost. Returning to the previous base blend would be cost effective to the consumer.”⁷²³

Auto manufacturers also provided comment on the topic of higher-octane fuels. The Alliance of Automobile Manufacturers (the Auto Alliance) commented that it “has long advocated for the availability of cost-effective, higher-octane fuel. The Alliance also believes the Agencies should require a transition to a higher minimum-octane gasoline (minimum 95–98 RON). There are several ways to produce higher-octane grade gasoline, such as expanding the ethanol availability, but the Alliance does not promote any sole or particular pathway.”⁷²⁴ The Alliance

reiterated its position regarding fuel octane levels where, “[t]he Alliance has long supported two goals regarding the octane (anti-knock) properties of gasoline: (1) The availability of cost effective higher-octane fuels, greater than 95 Research Octane Number (RON) and (2) the immediate elimination of subgrade fuel less than 87 anti-knock index (AKI).” The Alliance also noted that “[t]he higher-octane fuel that is available today is sold as a premium grade. To support future engine technologies, the approach taken with today’s premium fuel option would not be expected to provide an attractive value proposition to the customer; therefore, a new higher minimum-octane gasoline, 95–98 RON, is needed to achieve anticipated performance.”

Ford Motor Company agreed with the Auto Alliance’s collective comments on fuel octane level and added specific support to raising minimum octane levels, stating that “Ford concurs with those comments and supports increasing the marketplace octane rating in the U.S. to a minimum of 95 Research Octane Number (RON).” Ford also generally supported the agencies’ fuel octane discussion in terms of impacts to vehicle performance, where “[h]igher octane gasoline enables opportunities for the use of key energy-efficient technologies, including: Higher compression ratio engines, lighter and smaller engines, improved turbocharging, optimized engine combustion phasing/timing, and low temperature combustion strategies. All of these technologies paired with higher-octane gasoline permit smaller engines to meet the demands of the consumer while at the same time providing higher overall efficiencies.”⁷²⁵

Volkswagen commented “[t]here may be several potential ways to achieve a high-octane fuel that may be more costly to the vehicle than others. Achieving an E10 high-octane fuel may mean a different hardware set than on E20 or E30 high-octane fuel. Elimination of sub-grades of market fuel (less than 87AKI) quickly is very important. If current 87 AKI and 85 AKI fuels remain in the market for backward compatibility (such as if an E30 were chosen as the high-octane fuel of the future), a robust method at the fuel dispensing station and incorporated into the fueling station equipment to prevent mis-fueling is necessary. However, an E10 high-octane pathway might have far fewer compatibility problems and might

bring extra fuel economy to the drivers of those current vehicles.”⁷²⁶

The agencies also received comments from the petroleum industry regarding higher-octane fuels. API commented that “[g]iven the multiple engine technology pathways available to the automakers for achieving future fuel economy and CO₂ emissions targets, the challenge of determining future market fuel gasoline octane number needs is complex and not yet settled. API believes that the octane number issue should be part of a comprehensive transport policy that addresses both vehicles and fuels as a system. API and its members are engaged in collaborations with the automakers and other stakeholders to better understand future fuel requirements for emerging powertrain technologies.” API also commented “the future for gasoline octane number will be driven by the stringency of regulations that set future fuel economy and CO₂ requirements, the collective responses of the automakers to those regulations, consumer preferences regarding vehicles and fuels, and fuel supply economics. EPA’s authority to regulate gasoline octane number is doubtful. Therefore, EPA should not attempt to regulate gasoline octane number at this time.”⁷²⁷

In terms of challenges associated with potential high-octane fuel deployment, the American Fuel & Petrochemical Manufacturers (AFPM) commented that, “[a]side from a lack of legal authority, EPA faces numerous technical, logistical, and legal challenges and uncertainties in requiring the use of higher-octane fuels. Any such requirement would need a separate rulemaking dedicated to such a purpose with an extensive technical record in support, including test data on vehicles designed for the higher-octane fuel and on the existing fleet with and without higher-octane.”⁷²⁸

AFPM also commented that it does not support the potential regulatory requirement for the production or use of higher octane gasoline as a compliance option. AFPM commented that EPA lacks the authority to require the use of higher octane fuels under CAA § 211(c)(1)(A). AFPM further commented “[t]he only vehicles legally permitted to use more than 15 percent ethanol blends are flex-fuel vehicles, which are currently certified to utilize both E10 and E85. Without an alternative certification for an auto

manufacturer to build an E30 certified vehicle, which would require extensive testing and certification procedures as well as sufficient market availability of the certification fuel, it would be inappropriate for the Administration to consider such vehicles as a viable option in the 2022–2026 compliance period.”

Gasoline retailers also commented regarding higher-octane fuels. NACS and SIGMA commented that they support examining the use of such fuels as a potential path towards future emissions reductions and that it will be important that the agencies appropriately consider and address a variety of related issues, including:

1. How to allow and handle the expanded sales of higher-octane fuels, which may include fuels that currently face barriers to sale, such as E15;

2. Streamlining the registration and regulation of higher-level blends of ethanol;

3. Addressing misfueling liability concerns of retailers;

4. Streamlining federal labeling requirements and ensuring federal preemption of state requirements; and

5. Addressing any other regulatory and legislative challenges associated with the use of higher-octane fuels.⁷²⁹

NATSO commented that “the Agencies should under no circumstances consider ‘requiring that mid-level [ethanol] blends be made available at service stations’” and went on to say that “retailers would need to be assured that they will not be held responsible for customers that misfuel . . . Federal dispenser labeling requirements would have to be streamlined and state requirements would have to be preempted. . . . Auto manufacturers would have to warrant all new higher-octane vehicles up to at least E15 depending upon vehicles’ capabilities, and would have to affirmatively state which cars in the existing fleet can run on E15 and ensure that the cars are warrantied or retroactively warrantied as such.”⁷³⁰

UCS commented that “[a]n orderly transition to high-octane fuel would take several years to complete. It will take time for the necessary regulations to be finalized, for vehicles optimized for high-octane gasoline to come to market and to build out the fuel distribution infrastructure to make this fuel broadly available. And even once high-octane gasoline is in use, it will

take more time for automakers to phase-in new models optimized for high-octane fuel and to fully replace the legacy E10 fleet. Another factor to consider is that the rising share of high-octane gasoline will be buffered by falling sales of gasoline, given increasing fuel efficiency, such that the overall demand for ethanol will change more slowly. The agencies’ expectation is that high-octane gasoline will not significantly enter commerce before 2026, and subsequently will only gradually gain market share through 2040. There is no realistic prospect of completing this process before 2025 or 2026, the timeframe of this rulemaking. The appropriate context for this discussion within vehicle rules is the next round of fuel economy and emission standards. Even then, an expeditious rulemaking process will be required to achieve adequate regulatory clarity to facilitate rapid adoption post-2026.” UCS also commented “[we] strongly oppose granting fuel economy credits based on the technical potential of vehicles to operate on high-octane fuel before there is clear evidence that high-octane fuel is in use and the potential fuel economy benefits are being realized on the road.”⁷³¹

The agencies have reviewed the submissions received in response to their solicitation of comments concerning fuel octane levels and recognize the potential that higher-octane fuels, coupled with advanced engine technologies, can provide for improvements to fuel economy and tailpipe CO₂ emissions. The agencies agree with commenters that establishing a higher minimum octane for gasoline is a complex undertaking that would require consideration of a wide array of difficult issues. In light of the complexity of the constellation of issues, the fact that EPA did not propose new octane requirements, and that EPA’s authority to set fuel requirements resides in CAA section 211(c)(1), the agencies recognize that the present rulemaking is not the appropriate vehicle to set octane levels. If EPA pursues future rulemaking action on this topic, it would consider these comments in that context and in consideration of the appropriate statutory provisions. The agencies note that the current vehicle certification process provides a path to certify a vehicle requiring the use of high-octane fuel, which allows the impact of such fuels to be captured over the required certification test cycles for CO₂ emissions and fuel economy.

EPA also is declining to adopt new incentives for flex-fueled vehicles (FFVs) (vehicles designed to operate on gasoline or E85 or a mixture), as some commenters suggested. FFV incentives were not identified by EPA in its request for comments in the proposed rule and are outside the scope of this rulemaking.

The analyses conducted for this rulemaking assumed the use of Tier 3 fuels, where applicable, which are considered directly representative, or a reasonable proxy for, fuels available for consumers to purchase. As explained in the previous paragraph, agency actions related to test fuels, consumer available fuels, or flexible-fuel incentives are out of scope of this rulemaking. However, to the extent that the agencies consider any additional rulemaking actions related to fuel octane requirements and/or availability, the agencies note that further analysis to set CAFE and CO₂ standards would also reflect any potential, related impacts of those potential changes.

b) Engine Maps

Engine paths include numerous engine technologies that manufacturers can use to improve fuel economy and reduce CO₂ emissions. Some engine technologies can be incorporated into existing engine design architectures with minor or moderate changes to the engine, but many engine technologies require an entirely new engine architecture or a major refresh. For this final rule analysis, twenty-three unique engine technologies are available for adoption, and are evaluated uniquely across the ten separate vehicle types (technology classes).

For the NPRM and final rule analysis, the impact of engine technologies on fuel consumption, torque, and other metrics was characterized using GT-POWER® modeling conducted by IAV Automotive Engineering, Inc. (IAV). IAV is one of the world’s leading automotive industry engineering service partners and has extensive experience in testing and modeling engines and combustion. GT-POWER is a commercially available engine modeling tool with detailed cylinder and combustion modeling capabilities.⁷³² GT-POWER is used to simulate engine behavior and provides data on engine metrics, including power, torque, airflow, volumetric efficiency, fuel consumption, turbocharger performance, and other parameters. The primary outputs of IAV’s use of GT-POWER for this

analysis are the development of engine maps that provide operating characteristics of engines equipped with specific technologies.

When an engine is running, at any given point in time, the operation can be characterized by the engine's crankshaft rotational speed (typically in revolutions per minute, or RPM) and engine output (torque) level. Engines can operate at a range of engine speed and torque levels. Engine maps provide a visual representation of various engine performance characteristics at each engine speed and torque combination across the operating range of the engine. A common example of a performance characteristic is BSFC.⁷³³ Other characteristics include engine emissions, engine efficiency, and engine power.

Engine maps have the appearance of topographical maps, typically with engine speed on the horizontal axis and engine torque on the vertical axis. A third engine characteristic, BSFC, is displayed as contours, defining the operating regions for that BSFC with each contour showing all operating points at a specified BSFC value. Once created, the data they contain is referenced for engine fuel consumption at a given engine speed and torque operating point.

For the NPRM and final rule analysis, the agencies relied on IAV to develop engine maps representing each of the engine technologies. IAV used benchmark production engine test data, component test data, and manufacturers and suppliers' technical publications to develop a one-dimensional GT-POWER engine model for the baseline engine technology configuration. Technologies were incrementally added to the baseline model to assess their impact on fuel consumption. The following is a representative example of how IAV created the engine maps used in this analysis.

First, IAV defined the characteristics of Eng01 (a base VVT engine) and optimized it for all the combustion parameters while minimizing fuel consumption and maintaining performance. The result of this was a fuel map as a function of BMEP and engine RPM. IAV then took the same Eng01 and adopted characteristics of SGDI technology to the base engine. The new engine (Eng18, VVT and SGDI) was then optimized for all combustion parameters while minimizing fuel consumption and maintaining performance. The result was an engine

fuel map for Eng18, as a function of BMEP and engine speed. The engine map is directly comparable to the engine map for Eng01 and the difference in those engine maps specifically identifies the effectiveness impact of VVT and SGDI technologies. This process was repeated for all of the IAV engine maps that used Eng01 (VVT) as the baseline engine. This methodology ensured the engine maps represent the maximum improvement in BSFC for each engine configuration change, while considering real world design constraints.

IAV used its global engine database that includes benchmarking data, engine test data, single cylinder test data, prior modeling studies, and technical publications and information presented at conferences to populate the assumptions and inputs used for engine map modeling, and to validate the ultimate results.⁷³⁴ Argonne used the engine maps resulting from this analysis as inputs for the Autonomie full vehicle modeling and simulation.

As described in the NPRM and PRIA, the agencies developed engine maps for technologies that are in production today or that are expected to be available in the rulemaking timeframe. The agencies recognize that engines with the same combination of technologies produced by different manufacturers will have differences in BSFC and other performance measures, due to differences in the design of engine hardware (e.g., intake runners and head ports, valves, combustion chambers, piston profile, compression ratios, exhaust runners and ports, turbochargers, etc.), control software, and emission calibration. Therefore, the engine maps are intended to represent the levels of performance that can be achieved on average across the industry in the rulemaking timeframe.

Accordingly, the agencies noted that it was expected that the engine maps developed for this analysis will differ from engine maps for manufacturers' specific engines. For a given engine configuration, some production engines

may be less efficient and some may be more efficient than the engine maps presented in the analysis. However, the agencies intended and expected that the incremental changes in performance modeled for this analysis, due to changes in technologies or technology combinations, will be similar to the incremental changes in performance observed in manufacturers' engines for the same changes in technologies or technology combinations. Most importantly, using a single engine model as a reference provides a common base for comparison of all incremental changes resulting from technology changes, and anchors incremental technology effectiveness values to a common reference. The effectiveness values from the internal simulation results were validated against detailed engine maps produced from engine benchmarking programs, as well as published information from industry and academia, ensuring reasonable representation of simulated engine technologies.⁷³⁵

As discussed in the NPRM, the agencies updated the list of engine technologies, before and after the Draft TAR, based on stakeholder comments and consultations with CARB, Argonne, and IAV. The technology list was built on the technologies that were considered in the 2012 final rule, and included technologies that are being implemented or that are under development and feasible for production in the rulemaking timeframe. The agencies noted that some advanced engines were included in the simulation that were, and often still are, not yet in production, and the engine maps for those engines were either based on CBI or theoretical data. The agencies also stated in the NPRM that the final rule analysis may include updated engine maps for existing modeled engines, or entirely new maps added to the analysis if either action could improve the quality of the fleet-wide analysis.

While there are a large number of possible combinations of engine technologies, the agencies categorized the IAV engine maps used in the NPRM full vehicle simulations into six categories. The categories were based on engine architecture and include: Dual overhead camshaft (DOHC) engines, single overhead camshaft (SOHC) engines, turbocharged engines, hybrid Atkinson cycle engines,⁷³⁶ non-hybrid

⁷³⁵ Bottcher, L., Grigoriadis, P. "ANL—BSFC map prediction Engines 22–26." IAV (April 30, 2019). 20190430_ANL_Eng 22–26 Updated_Docket.pdf.

⁷³⁶ These types of Atkinson cycle engines are mainly for hybrid applications like Toyota Prius or Ford C-Max.

⁷³³ The amount of fuel needed to achieve a specific power, or how efficiently an engine uses fuel to produce work.

Atkinson mode engines, and diesel engines. Another unique technology that was available for adoption for the NPRM analysis was the advanced cylinder deactivation (ADEAC) for the SOHC and DOHC engines, however this technology was modeled using a fixed effectiveness value rather than an

engine map, because the agencies did not have sufficient data to be used as input to the engine map or full vehicle simulation modeling. In addition, the agencies provided potential engine maps and additional specifications for several other technologies that could be considered for the final rule analysis.

These included a basic high compression ratio Atkinson mode engine, a Miller cycle engine, and an engine with an electric assist.

The full list of engine maps used in the NPRM is presented in Table VI-39 below.

BILLING CODE 4910-59-P

Table VI-39 – Engine Maps Used for NPRM Analysis

| Engines | Technologies | Notes | Engine Reference Peak Power (kW) |
|---------|--|--|----------------------------------|
| Eng01 | DOHC VVT | Parent NA engine, Gasoline, 2.0L, 4 cyl, NA, PFI, DOHC, dual cam VVT, CR10.2 | 108 |
| Eng02 | DOHC VVT+VVL | VVL added to Eng01 | 108 |

BILLING CODE 4910–59–C

Comments on engine maps varied, with industry commenters generally supporting the maps used in the NPRM analysis and CARB and environmental advocate commenters generally objecting to the maps. The Alliance argued that previously-modeled fuel efficiency improvements for downsized, turbocharged engine technologies were “highly optimistic,” and stated that the updated engine maps used for the NPRM analysis were an improvement.

ICCT argued that the IAV engine maps used for the NPRM analysis were out of date, and better engine maps benchmarked by EPA staff were available and should have been used instead.⁷³⁷ UCS similarly stated that Argonne work used for previous CAFE technical documents had relied on outdated engine maps, and that the new IAV engine maps used in this rulemaking were developed for a different purpose and had not been benchmarked against the latest engines either on the road or in development.⁷³⁸ ICCT questioned whether the agencies had validated engines 13 and 14 with physical testing and/or simulation modeling to the level of quality of EPA’s simulation modeling.⁷³⁹ ICCT further asserted that EPA’s benchmarked engine maps had been “knowingly disregarded” for the NPRM analysis, and stated that the NPRM analysis was therefore arbitrary.⁷⁴⁰ ICCT commented that the agencies must conduct and

disclose a systematic investigation and comparison of engine benchmarking, engine modeling, and transmission modeling completed by EPA, Ricardo, and Argonne for model year 2014–2018 vehicles. ICCT recommended that the agencies rely on engine maps used for past EPA ALPHA modeling while the agencies conduct such an investigation.

The agencies believe it is most important for engine map data to provide accurate BSFC information for known technologies and technology levels. The agencies disagree with statements that IAV engine maps are outdated. The majority of the engine maps were developed specifically to support the midterm review and encompass engine technologies that are present in the analysis fleet and technologies that could be applied in the rulemaking timeframe. In many cases those engine technologies are mainstream today and will continue to be during the rulemaking timeframe. For example, the engines on some MY 2017 vehicles in the analysis fleet have technologies that were initially introduced ten, or more, years ago. Having engine maps representative of those technologies is important for the analysis. The most basic engine technology levels also provide a useful baseline for the incremental improvements for other engine technologies. The timeframe for the testing or modeling is unimportant, because time by itself doesn’t impact engine map data. A given engine or model will produce the same BSFC map regardless of when testing or modeling is conducted. Simplistic discounting of engine maps based on temporal considerations alone could result in discarding useful technical information. Also, narrow use of temporal considerations would also result in the discarding of several engine maps from

Ricardo that were used for the EPA Draft TAR and Proposed Determination analyses.⁷⁴¹ Therefore, with the engine maps used representing current technologies regardless of development date, the agencies do not agree with commenter assertions.

The same commenters also appear to misunderstand how the agencies’ effectiveness data, including engine maps, were used in the NPRM analysis (and in past rulemakings). The analysis never applies *absolute* BSFC levels from the engine maps to any vehicle model or configuration for the rulemaking analysis. The *absolute* fuel economy values from the full vehicle Autonomie simulations are used only to determine *incremental* effectiveness for switching from one technology to another technology. The *incremental* effectiveness is applied to the absolute fuel economy of vehicles in the analysis fleet, which are based on CAFE compliance data. For subsequent technology changes, incremental effectiveness is applied to the absolute fuel economy level of the previous technology configuration. Therefore, for a technically sound analysis, it is most important that the *differences in BSFC among the engine maps* be accurate, and not the absolute values of the individual engine maps. However, achieving this can be challenging.

A technically sound approach is to use a single or very small number of baseline engine configurations with well-defined BSFC maps, and then, in a very systematic and controlled process, add specific well-defined technologies and create a BSFC map for each unique

technology combination. This could theoretically be done through engine or vehicle testing, but testing would need to be conducted on a single engine, and each configuration would require physical parts and associated engine calibrations to assess the impact of each technology configuration, which is impractical for the rulemaking analysis because of the extensive design, prototype part fabrication, development, and laboratory resources that are required to evaluate each unique configuration. Modeling is an approach used by industry to assess an array of technologies with more limited testing. Modeling offers the opportunity to isolate the effects of individual technologies by using a single or small number of baseline engine configurations and incrementally adding technologies to those baseline configurations. This provides a consistent reference point for the BSFC maps for each technology and for combinations of technologies which enables the differences in effectiveness among technologies to be carefully identified and quantified. The agencies selected this approach for the NPRM and final rule. Engine maps were created by IAV using this technically sound and rigorous methodology. Both absolute engine maps and the incremental differences in engine maps were presented in the PRIA.

Using a mix of engine maps from engine modeling and from benchmarking data provides no common reference for measuring impacts of adding specific technological improvements. In addition, as discussed in further detail in Section VI.C.1.e), manufacturers often implement multiple fuel-saving technologies simultaneously when redesigning a vehicle and it is not possible to isolate the effect of individual technologies by using laboratory measurements of a single production engine or vehicle with a combination of technologies. Because so many vehicle and engine changes are involved, it is not possible to attribute effectiveness improvements accurately for benchmarked engines to specific technology changes. This leads to overcounting or undercounting technology effectiveness.

Further, while two or more different manufacturers may produce engines with the same high level technologies (such as a DOHC engine with VVT and SGDI), each manufacturer's engine will have unique component designs that cause its version of the engine to have a unique engine map. For example, engines with the same high level technologies have unique intake manifold and exhaust manifold runners,

cylinder head ports and combustion chamber geometry that impact charge motion, combustion and efficiency, as well as unique valve control, compression ratios, engine friction, cooling systems, and fuel injector spray characteristics, among other factors. The agencies developed and used a single engine map to represent each technology and each combination of engine technologies.

Therefore, it should not be expected that any of the agencies' engine maps would necessarily align with a specific manufacturer's engine, unless of course the engine map was developed from that specific engine. The agencies do not agree that comparing an engine map used for the rulemaking analysis to a single specific benchmarked engine has technical relevance, beyond serving as a general corroboration for the engine map. When a vehicle is benchmarked, the resulting data is dictated by the unique combination of technologies and design constraints for the whole vehicle system. For these reasons, the agencies do not agree with ICCT that Eng13 and Eng14 should be validated by conducting full vehicle modeling and comparing the results with a single benchmarked vehicle. The engine maps used in this analysis are precisely controlled for specific incremental technology adoption and not for comparisons of absolute performance of a specific vehicle's engine.

Differences are also explained by the NPRM and final rule analyses using large-scale full vehicle Autonomie simulations to estimate effectiveness instead of rough LPM approximations based on limited ALPHA simulation work.⁷⁴² These issues are discussed in more detail in Section VI.B.3.

Accordingly, the agencies declined directly to use the Ricardo and other EPA engine maps created from engine benchmarking as inputs for this rulemaking because, among other reasons discussed below, they did not afford the opportunity to evaluate the effectiveness improvements for specific, individual technologies. For example, the 2018 Toyota Camry 2.5L engine that EPA benchmarked had a broad array of observable technologies, and several more that were not observable.⁷⁴³ However, there was no baseline from which to isolate or compare any of the individual technology improvements.

⁷⁴² 2016 EPA Proposed Determination TSD at p.2–276 to 2–279

⁷⁴³ EPA Test Data. 2018 Toyota Camry 2.5L A25A-FKS Engine Tier 3 Fuel. Available at <https://www.epa.gov/sites/production/files/2019-04/2018-toyota-2.5l-a25a-fks-engine-tier3-fuel-test-data-package-dated-04-08-19.zip>. Last accessed Nov. 20, 2019.

For example, Toyota commented on this benchmarking, stating:

Past Toyota comments on Atkinson-cycle benefits have addressed only those derived from variable valve timing (VVT) with late intake valve closing (LIVC) that enables a 13:1 compression ratio. The total 18.6 percent improvement of the 2018 Camry 2.5L over the previous generation also includes benefits from cEGR and internal engine design changes such as to the block, cylinder head, pistons, valvetrain, as well as drivetrain and body/chassis enhancements.⁷⁴⁴

Toyota's comments emphasize that the efficiency improvements in this engine were driven by several additional technological improvements, and not merely the cEGR, Atkinson cycle engine and higher compression ratio design that was assumed for the EPA Draft TAR and Proposed Determination analyses.⁷⁴⁵

The agencies do agree component, engine, and vehicle test data are very important for validating systems models, such as Autonomie, and for validating model inputs, such as engine maps. Accordingly, the agencies *did* fully consider engine maps used in prior rulemakings, along with a broad array of other data as part of the process for evaluating the IAV engine maps used for the NPRM and the final rule analysis simulation work. Engine maps from Ricardo, EPA benchmarking, NHTSA-sponsored benchmarking,⁷⁴⁶ information from technical papers and conferences,⁷⁴⁷ extensive data and

expertise from the Argonne AMTL vehicle testing group and Energy modeling group,⁷⁴⁸ and the 2015 NAS report,⁷⁴⁹ were all sources used to confirm that incremental technology effectiveness estimates were appropriate. The engine maps developed by IAV provided reliable and reasonable estimates for the incremental impacts of engine technologies. The use of this approach explains some of the effectiveness differences between the NPRM and final rule analyses, and the

EPA Draft TAR and Proposed Determination analyses.

In considering ICCT's comment about using IAV engine maps or EPA's engine maps, as an exercise, the agencies compared two IAV engine maps to the EPA's benchmarked Toyota 2.5L naturally aspirated engine and Honda's 1.5L turbocharged downsized engine.^{750 751} The IAV engines were modeled and simulated in a midsize non-performance vehicle with an automatic transmission and the same road load technologies, MR0, ROLL0 and AERO0, to isolate for the benefits associated with the specific engine maps.⁷⁵² Eng 12, a 1.6L, 4 cylinder, turbocharged, SGDI, DOHC, dual cam VVT, VVL engine was selected as the closest engine configuration to the Honda 1.5L. Eng 22b, a 2.5L, 4 cylinder, VVT Atkinson cycle engine, was selected as the closest engine configuration to the Toyota 2.5L. As discussed before, both the Toyota 2.5L naturally aspirated engine and Honda's 1.5L engine have incorporated a number of fuel saving technologies including improved accessories and engine friction reduction. In order to assure an "apples-to-apples" comparison, both IACC and EFR technologies were applied to the IAV engine maps. IACC technology provides an additional 3.6% incremental improvement and EFR

provides an additional 1.4% incremental improvement beyond the IAV engine maps for midsize non-performance vehicles.⁷⁵³

The comparison shows effectiveness of the IAV engine maps and effectiveness values for the final rule analysis are in line with the Honda 1.5L and the Toyota 2.5L benchmarked engines. Figure VI-15 below shows the effectiveness improvements for the EPA benchmarked engines and the corresponding IAV engine maps incremental to a baseline vehicle. Accordingly, the agencies believe that the methodology used in this analysis, and the engine maps and incremental effectiveness values used, are in line with benchmarking data and are reasonable for the rulemaking analysis. The agencies believe the approach used in this rulemaking analysis appropriately allows the agencies to account for a wide array of engine technologies that could be adopted during the rulemaking timeframe. Declining to use manufacturer-specific engines allows the agencies to ensure that all effectiveness and cost improvements due to the incremental addition of fuel economy improving technologies are appropriately accounted for.

Next, Roush Industries (“Roush”), writing on behalf of the California Air Resources Board, commented that the NPRM-modeled engines vary in cylinder size, which would significantly alter combustion, heat transfer, knock tolerance, and other important operating parameters.⁷⁵⁴ Roush stated that a more accurate simulation, which would improve incremental fuel economy improvement, should maintain a consistent cylinder displacement (500cc) and vary the number of cylinders or expected fuel consumption maps.⁷⁵⁵

The agencies believe that holding cylinder volume constant is the appropriate approach to research seeking to identify the impacts of technological changes on BSFC, torque, power, and other characteristics, when holding cylinder volume constant. However, as explained in Section VI.B.3.a)(2) Maintaining Vehicle

Attributes and Section VI.B.3.a)(6) Performance Neutrality, CAFE and CO₂ rulemaking analyses attempt to maintain vehicle attributes, including performance, and hold all of the attributes constant when showing pathways that improve fuel economy. Therefore, the agencies’ analyses require engine maps that attempt to hold *performance* constant—not necessarily cylinder size. Since certain fuel economy improving technologies would *increase* performance if cylinder size is held constant, such as when adding turbocharging technology, the agencies appropriately include changes in displacement and cylinder volume for technologies that have a significant impact on engine torque and power, such as turbocharging. For a number of fuel economy improving technologies that had smaller impacts on engine torque and power, the engine maps were created with cylinder volume held constant. Table VI–39 identifies the engine displacement information for each of the engine maps. For example, the same engine displacement (2.0 L) and cylinder displacement (500 cc) was used for creating engine maps for naturally aspirated engines Eng01, Eng02, Eng03, Eng04, Eng05a, Eng5b, Eng06a, Eng07a, and Eng08a, whereas engine displacement (1.6 L) and cylinder displacement (400 cc) is used

for creating the engine map for turbocharged engine Eng12 in order to maintain performance. The agencies have concluded that the approach used for the NPRM and the final rule analysis is the most technically sound approach given the data needs and assessments required for CAFE and CO₂ rulemaking.

Roush also commented as follows:

[S]everal of the base engine maps used in the 2018 PRIA analysis exhibit maximum thermal efficiency (lowest fuel consumption) at 2000–3000 rpm and at maximum load, which is unrealistic for normal passenger vehicle engines. Such maps will over predict fuel economy for extremely down-sized applications (very small engine in a heavy vehicle). This is because there is no fuel economy penalty for running the engine at a high loads point where, in reality, BSFC is high due to retarding spark timing to prevent knocking and fuel enrichment to reduce exhaust temperatures to protect exhaust valves and turbocharger components.⁷⁵⁶

For example, Roush stated that Eng12 is predicted to have its highest efficiency at very high load and high engine speeds with no degradation in brake specific fuel consumption (BSFC) at engine speeds between 2,000 rpm and 4,500 rpm all the way up to peak load, which is unrealistic because

⁷⁵² See ANL—All Assumptions_Summary_FRM_06172019_FINAL and ANL—Summary of Main Component Performance Assumptions_FRM_06172019_FINAL for midsize class characteristics.

⁷⁵³ The NPRM and this final rule analysis allowed the adoption of IACC technologies in the CAFE model that provided an additional 3.6% incremental improvement for the midsize car vehicle class. As discussed in [Section VI.C Other Technologies], these benefits are not shown in the IAV engine simulated results, so they were added manually for this comparison.

⁷⁵⁶ Roush Industries on behalf of California Air Resources Board, Rogers_Final_Final_NPRM_10.26.2018, Docket No. NHTSA–2018–0067–11984, at 11.

turbocharged engines at high loads require retarded spark timing to prevent knock and fuel enrichment to prevent overheating of the turbocharger and related components.⁷⁵⁷ Roush stated that these factors would increase fuel consumption and reduce efficiency under real-world conditions.⁷⁵⁸ Roush also stated that another effect of the Eng12 fuel consumption curve would be to predict unreasonably good fuel consumption at very high power levels for downsized turbocharged engines. Roush stated this could bias technology pathways in over-predicting fuel economy benefits for small engines installed in heavier vehicles, causing an overly optimistic predicted performance of the vehicle with regard to drivability, acceleration, and fuel consumption, which would create unrealistic real-world pathways to compliance.⁷⁵⁹

As discussed in the Argonne model documentation for the final rule analysis, the simulations used to determine incremental effectiveness for the NPRM and final rule analyses were conducted using 2-cycle test procedures, because they are the test procedures used for CAFE and CO₂ compliance.⁷⁶⁰ Therefore, the engines maps are intended to represent BSFC accurately under those test conditions and do not need to capture BSFC under every operating condition. During 2-cycle test conditions, engines do not operate for extended periods at the speed and high load conditions noted by Roush. A few vehicle and engine combinations may operate at those speed and load points only briefly during the 2-cycle CAFE and CO₂ tests. Engines are capable of operating for short periods of time under higher exhaust temperature conditions and manufacturers commonly delay fuel enrichment until it is needed to protect engine components (in particular exhaust valves and exhaust manifolds) from excessive temperatures that can impact engine durability. Fuel enrichment can be delayed because it takes a period of time at higher temperature for components to heat up and reach a temperature that would

impact durability. Because these high speed and load conditions occur for a relatively short time during the CAFE and CO₂ test cycles, and then return to lower speed and/or load conditions with lower exhaust temperature, engines operate for the entire CAFE and CO₂ test cycles without triggering fuel enrichment. The fuel enrichment delay also enables vehicles to comply with criteria emission regulations and improves real world fuel economy. Therefore, the engine maps used for the NPRM and final rule analysis fully represent how engines operate during CAFE and CO₂ test cycles, and properly do not include fuel enrichment at all 2-cycle operating conditions. Also, a trained knock model was used to develop the engine maps, and the spark timing reflects appropriate levels for engine operation during the delay in fuel enrichment.

Next, regarding developing the NPRM engine maps to account for Tier 3 test fuel, the Alliance and Ford stated that the engine maps using Tier 3 test fuel represented an improvement over prior analyses. The Alliance stated that previous EPA modeling had incorrectly used Tier 2 premium octane fuel to predict the benefits of engine technologies, which overstated fuel economy gains that would be achievable when using regular-grade octane Tier 3 fuel. Ford provided similar comments, and also noted that regular grade octane fuel will be required for compliance after the 2020 model year.⁷⁶¹

In contrast, ICCT and UCS both commented that the agencies had incorrectly updated the IAV engine maps developed with Tier 2 test fuel to account for Tier 3 fuel.⁷⁶² ICCT stated that the update reduced the effectiveness of the turbo technologies and suggested that the fuel update adjustment should not have been done at all, stating manufacturers that label vehicles as “premium fuel recommended” are required to show no emissions changes over all test cycles when using premium octane fuel and therefore reducing effectiveness for fuel differences, as the agencies did with the IAV engine maps, is unrealistic and inappropriate.

UCS also commented more specifically on the impact of the adjustment from Tier 2 to Tier 3 fuel related to the knock threshold for advanced engines, noting that

manufacturers consider different approaches to different fuels, and not all of those approaches necessitate reductions in efficiency, as the agencies’ assumption suggests. UCS stated that charge cooling can reduce knock in direct injection engines, resulting in an “effective octane” difference of a six point increase for E10, thus potentially compensating for the difference in octane between Tier 2 (E0 93 AKI) and Tier 3 (E10 87 AKI) fuels. UCS argued that excluding this consideration led the agencies to restrict advanced engines like HCR2 and reduce the effectiveness of turbocharged engines with CEGR. UCS suggested that there would be a reduction in the costs between the baseline and proposed standards if the analysis allowed the application of HCR2 engines and corrected the effectiveness of turbocharged CEGR engines.

Both ICCT and UCS also stated that the adjustment ignored a 2018 EPA study showing that, while fuel consumption increases with the switch from Tier 2 to Tier 3 test fuel, emissions are reduced, meaning that the agencies’ adjustment is wrong “for some technologies because [CO₂]-per-mile emissions can be lower with the switch to higher octane ethanol blends.” UCS also stated that the adjustment factor applied is wrong for two reasons, first because converting solely with energy density would assume a 3.7 percent increase in fuel consumption compared to the observed 2.7 percent increase, and second because the adjustment goes in the wrong direction when applied to CO₂ emissions, which show a reduction of 1.4 percent on the test cycle. UCS stated that the Autonomie model accordingly overstates CO₂ emissions on Tier 3 fuel by 4.2 percent. UCS argued that the adjustment to account for Tier 3 test fuel therefore double counts any penalty in fuel economy and ignores CO₂ tailpipe reductions, which would result in an improvement on the test cycle. Because the CAFE test procedure already has an adjustment in place to correct for fuel properties relative to 1975 test fuel, but carbon-related exhaust emissions do not, UCS stated that the fuel adjustment could lead to drastically conservative fuel economy and CO₂ curves.

ICCT stated that the agencies could fix this issue by relying on EPA’s engine maps, where EPA had accounted for cost and effectiveness of technology used to protect operation on regular octane fuel by increasing costs and reducing effectiveness.

Some of these comments can be addressed with a simple clarification: The NPRM contained text that was

⁷⁶⁰ A Detailed Vehicle Simulation Process To Support CAFE and CO₂ Standards for the MY 2021–2026 Final Rule Analysis.

⁷⁶¹ Ford Motors, Attachment, Docket No. EPA-HQ-OAR-2018-0283-5691, at 7.

⁷⁶² International Council on Clean Transportation, Attachment 3, Docket No. NHTSA-2018-0067-11741, at I-82; Union of Concerned Scientists, Technical Appendix, Docket No. NHTSA-2018-0067-12039, at p. 15.

inconsistent regarding how the analysis accounted for the engine maps (which were based on Tier 3 fuel). The separate model documentation correctly described that, for the NPRM analysis, the agencies developed fuel maps for Tier 3 fuel and did not adjust the final Autonomie outputs.⁷⁶³ The NPRM text, however, incorrectly stated that “(a)n adjustment factor was applied to the Autonomie simulation results to adjust them to reflect Tier 2 certification fuel. Argonne adjusted the vehicle fuel economy results to present certification fuel by using the ratio of the lower heating values to the rest and certification fuels.” In fact, no adjustments were made to the NPRM Autonomie simulation outputs, as the modeled engine maps were appropriately modeled using Tier 3 fuel.

As discussed in detail in VI.C.1.a) Fuel Octane, engine specifications used to create the engine maps for the NPRM and the final rule were developed using Tier 3 fuel. Tier 3 fuel was used to ensure the engines were capable of operating on real world regular octane (87 pump octane = $(R+M/2)$). This capability is in line with what manufacturers must do to ensure engines have acceptable noise, vibration, harshness, drivability and performance levels, and will not fail prematurely when operated on regular octane fuel. If the agencies developed engine maps based on Tier 2 fuel alone, the engine maps would reflect the engines’ ability to have higher compression ratios and to operate with greater levels of spark advance than could be implemented by manufacturers, who must take into account operation on regular octane fuels used by a majority of U.S. consumers.⁷⁶⁴ Not considering regular octane fuel operation by manufacturers would lead to engine durability, and engine noise, vibration, harshness, and drivability issues. Manufacturers have told the agencies that even for vehicles designed to operate on high octane fuel, the engines and controls must be designed to operate on every fuel octane level available in the U.S. to avoid these issues.⁷⁶⁵ Thus, developing engine maps based on Tier 2 fuel alone would incorrectly overstate the BSFC

improvements achievable in the real world.

Based on these comments and considerations, the agencies determined the engine maps developed for the NPRM appropriately account for fuel octane, and better approximate BSFC achieved by the majority of engines used in the U.S. vehicle fleet. The agencies believe ICCT’s and other commenters’ assertions that the engine maps should reflect Tier 2 fuel and not be updated for Tier 3 fuel would ignore these important considerations, and would provide engine maps that could not be achieved by engines in the real world. The agencies determined that engine maps developed for the Draft TAR and EPA Proposed Determination that were based on Tier 2 fuel should not be used for the NPRM and final rule analyses for these reasons.

EPA is addressing the impact of Tier 3 fuel on fuel economy and CO₂ emissions compliance test results as part of a separate rulemaking. The separate rulemaking may establish an adjustment to account for the impacts of the change in test fuel. Those impacts are beyond the scope of this rulemaking. The analysis for this rule uses fuel economy and CO₂ emissions of the vehicles in the MY 2017 analysis fleet as the reference for absolute fuel economy and CO₂ emissions. The analysis starts with absolute compliance data from MY 2017 and adopts technologies incrementally to determine future compliance. Because MY 2017 absolute compliance values are based on Tier 2 fuel, and standards are based on the use of Tier 2 fuel, there is no need to make any adjustments for the differences in energy content and carbon content of Tier 2 and Tier 3 fuel.⁷⁶⁶

The agencies considered ICCT’s statement that manufacturers that label vehicles as “premium fuel recommended” are required to show no emissions changes over all test cycles when using regular octane fuel, and therefore reducing effectiveness for fuel differences as the agencies did with the IAV engine maps is unrealistic and inappropriate. The agencies believe these conclusions are technically incorrect. The existence of an EPA

compliance regulation does not impact the laws of nature, which govern issues associated with the impact of fuel octane on the ability to improve engine BSFC and on engine durability, noise, vibration, harshness, and drivability. It is widely recognized and accepted that higher octane fuels allow engines to be designed with higher compression ratios, faster combustion rates, and more optimal spark advance, which improve BSFC. Section VI.C.1.a) discusses comments advocating for increasing the minimum fuel octane specification to enable these improvements. The engine maps developed by IAV and used for the Draft TAR and NPRM were consistent with these trends and showed that BSFC is better with Tier 2 (higher octane) fuel than Tier 3 (lower octane) fuel.⁷⁶⁷ ICCT did not provide any data supporting the concept that there is no shift in BSFC, fuel economy, or CO₂ emissions when engines are optimized with different octane fuels, or between Tier 2 and Tier 3 fuel. It is appropriate to note that the EPA regulation does provide a tolerance which in practice allows a small level of shift in emissions.⁷⁶⁸

Regarding comments that certain combinations of technologies can enable BSFC improvements while controlling spark knock, the agencies in fact considered a very broad array of engine technology combinations for the analysis, including several added technologies as discussed further below. The agencies believe the rigorous methodology used to develop the engine maps resulted in engine maps representing the maximum improvement in BSFC for each engine configuration, while also addressing real world constraints. Engine maps for the new technologies were presented in PRIA Chapter 6.3.2.2.16.4. The PRIA also discussed that IAV maps were developed considering a very comprehensive list of combustion operating parameters as part of the IAV GT-Power engine modeling. IAV’s GT-Power engine modeling included sub-models to account for heat release through a predictive combustion model, knock characteristic through a kinetic fit knock model, physics-based heat flow model physics based friction model, and IAV’s proprietary Optimization Tool Box.⁷⁶⁹ These independent models were

⁷⁶⁶ During the 1980s, the U.S. Environmental Protection Agency (EPA) incorporated the R factor into fuel economy calculations in order to address concerns about the impacts of test fuel property variations on corporate average fuel economy (CAFE) compliance, which is determined using the Federal Test Procedure (FTP) and Highway Fuel Economy Test (HFET) cycles. The R factor is defined as the ratio of the percent change in fuel economy to the percent change in volumetric heating value for tests conducted using two differing fuels.

⁷⁶⁸ 40 CFR 1066.210 (b) Accuracy and Precision.

⁷⁶⁹ IAV’s Optimization Tool Box is a module of IAV Engine. IAV Engine, as the basic platform for designing engine mechanics, provides a large number of tools that have proven their worth across the globe in several decades of automotive

run concurrently to make sure engine design requirements were met for each engine configuration that was modeled.

Finally, in response to the agencies' request for comment on including the additional engine maps presented in the NPRM as potential technological pathways, several commenters stated that the agencies should include those technologies, in addition to other emerging engine technologies.⁷⁷⁰ After considering these comments, the agencies added several engine technologies and technology combinations to the final rule analysis. The additions included a basic high compression ratio Atkinson mode engine (HCR0), a variable compression ratio engine (VCR), a variable turbo geometry engine (VTG), and a variable turbo geometry with electric assist engine (VTGe). The agencies also added advanced cylinder deactivation technology (TURBOAD) to Eng12 (TURBOD) in the Autonomie modeling for the final rule analysis. Like with ADEAC, the agencies did not have IAV engine maps for TURBOAD, so the agencies took the effectiveness values as predicted by full vehicle simulations of a TURBOD and added 1.5 percent or 3 percent respectively for I-4 engines and V-6 or V-8 engines, as explained in more detail further below. The agencies also included more iterations of existing technologies, like diesel engines with cylinder deactivation, diesel engines paired with manual transmissions, and diesel engines paired with 12-volt start stop technology, in addition to more combinations of hybrid technologies that are discussed further in Section VI.C.3, below.

The following sections list and describe the comprehensive set of engine technologies and combinations of engine technologies that have been included in the analysis. The agencies also discuss the additional engine technologies added for the final rule, and reasons for excluding a small number of technologies proffered by commenters. The agencies believe the wide array of engine technologies included in the final rule analysis and the methodology used to develop the engine maps to measure the effectiveness of those technologies reasonably represents the scope of technologies that should be considered during the rulemaking timeframe.

development work at IAV. The modules help designers, computation engineers and simulation specialists in designing mechanical engine components—for example, in laying out valvetrains and timing gears as well as crankshafts.

⁷⁷⁰ ICCT Docket # NHTSA-2018-0067-11741 at I-19—I-22; CARB Docket # NHTSA-2018-0067-11873 at 107–108.

c) Engine Modeling in the CAFE Model (1) Basic Engines

The NPRM described that there are a number of engine technologies that manufacturers can use to improve fuel economy and CO₂ emissions. Some engine technologies can be incorporated into existing engines with minor or moderate changes to the engines, but many engine technologies require an entirely new engine architecture. The terms “basic engine technologies” and “advanced engine technologies” are used only to define how the CAFE model applies a specific engine technology and handles incremental costs and effectiveness improvements. “Basic engine technologies” refer to technologies that, in many cases, can be adapted to an existing engine with minor or moderate changes to the engine, compared to “advanced engine technologies” that generally require significant changes or an entirely new engine architecture.

In the CAFE model, basic engine technologies may be applied in combination with other basic engine technologies; advanced engine technologies (defined by an engine map) stand alone as an exclusive engine technology. The words “basic” and “advanced” are not meant to confer any information about the level of sophistication of the technology. Also, many advanced engine technology definitions include some basic engine technologies, but these basic technologies are already accounted for in the costs and effectiveness values of the advanced engine. The “basic engine technologies” need not be (and are not) applied in addition to the “advanced engine technologies” in the CAFE model.

(a) DOHC

In the NPRM analysis, the agencies characterized dual overhead cam (DOHC) engine technology as “basic.” DOHC engine configurations have two camshafts per cylinder head, one operating the intake valves and one operating the exhaust valves. Four basic engine technologies—variable valve timing (VVT), variable valve lift (VVL), stoichiometric gasoline direct injection (SGDI), and basic cylinder deactivation (DEAC)—were considered for DOHC engines. Implementing these technologies involves changes to the cylinder head of the engine, but the engine block, crankshaft, pistons, and connecting rods require few, if any, changes.

Variable valve timing (VVT) is a family of valve-train designs that dynamically adjusts the timing of the

intake valves, exhaust valves, or both, in relation to piston position. VVT can reduce pumping losses, provide increased engine torque and horsepower over a broad engine operating range, and allow unique operating modes, such as Atkinson cycle operation, to further enhance efficiency. VVT is nearly universally used in the MY 2017 fleet.⁷⁷¹ In the NPRM analysis, the VVT technology modeled by IAV was based on dual (independent) cam phasing. This was a more advanced VVT technology that allowed controlling of valve overlap, which can be used to control internal EGR to minimize fuel consumption at low engine loads.⁷⁷² VVT enables control of many aspects of air flow, exhaust scavenging, and combustion relative to fixed valve timing engines. Engine parameters such as volumetric efficiency, effective compression ratio, and internal exhaust gas recirculation (iEGR) can all be enabled and accurately controlled by a VVT system.

Variable valve lift (VVL) dynamically adjusts the distance a valve travels from the valve seat optimizing airflow over a broad range of engine operating conditions. The technology can increase effectiveness by reducing pumping losses and may improve efficiency by affecting in-cylinder charge (fuel and air mixture), motion, and combustion. VVL is less common in the 2017 fleet than VVT. Some manufacturers have implemented a limited, discrete approach to VVL where just two valve lift profiles are available versus a full-range, continuously variable implementation.

Stoichiometric gasoline direct injection (SGDI) sprays fuel at high pressure directly into the combustion chamber, which provides cooling of the in-cylinder charge via in-cylinder fuel vaporization to improve spark knock tolerance and enable an increase in compression ratio and/or more optimal spark timing for improved efficiency. SGDI appears in about half of basic engines produced in MY 2017, and the technology is used in many advanced engines as well.⁷⁷³

Basic cylinder deactivation (DEAC) disables intake and exhaust valves and

⁷⁷¹ 98.1 percent of MY2017 vehicles are equipped with VVT. EPA Report. *The 2018 EPA Automotive Trends Report*. <https://nepis.epa.gov/Exe/ZyPDF.cgi/P100W5C2.PDF?Dockey=P100W5C2.PDF> at Table 4.1 Production Share by Engine technology.

⁷⁷² 2015 NAS at p. 32.

⁷⁷³ 49.7 percent of MY2017 vehicles are equipped with SGDI. EPA Report. *The 2018 EPA Automotive Trends Report*. <https://nepis.epa.gov/Exe/ZyPDF.cgi/P100W5C2.PDF?Dockey=P100W5C2.PDF> at Table 4.1 Production Share by Engine technology.

turns off fuel injection for the deactivated cylinders during light-load operation. The engine runs temporarily as though it were a smaller engine, which reduces pumping losses and improves efficiency. In the MY 2017 fleet, manufacturers used DEAC on V6, V8, V10, and V12 engines in OHV, SOHC, and DOHC engine configurations. With some engine configurations in some operating conditions, DEAC creates noise-vibration-and-harshness (NVH) challenges. NVH challenges are significant for V6 and I4 DEAC configurations, and limit the operating range where DEAC can operate. For I4 engine configurations with smaller displacements, there are fewer operating conditions where engine load is low enough to use DEAC, which limits effectiveness. No manufacturers produced I4 DEAC engines in MY 2017. Typically, the smaller the engine displacement, the less opportunity DEAC provides to improve fuel consumption.

The agencies provided engine fuel maps for each of the eight DOHC engines (Eng01, Eng02, Eng03, Eng04,

Eng18, Eng19, Eng20, and Eng21) used for the NPRM analysis. Each of these engines incrementally added technology to Eng01, a basic VVT engine, while holding all other factors constant like ambient temperature, ambient pressure, and fuel type.

For the NPRM analysis, the agencies estimated the effectiveness of DEAC using full vehicle modeling and simulation. In the NPRM PRIA 6.2.1.2, the agencies discussed how Autonomie uses a specific control logic for cylinder deactivation for naturally aspirated engines that takes into consideration for noise, vibration, and harshness.⁷⁷⁴ For the final rule analysis, the agencies took steps to use full vehicle modeling and simulation to apply DEAC to both naturally aspirated and turbocharged engines. The same control logic was applied to the turbocharged engine cylinder deactivation (TURBOD) for the final rule analysis.

The agencies used the same assumptions for advanced cylinder deactivation (ADEAC) in the final rule analysis. In the NPRM the agencies stated engine maps were not available at the time of the analysis, and said that

ADEAC was estimated to improve a basic engine with VVL, VVT, SGDO, and DEAC by three percent (for 4 cylinder engines) and six percent (for engines with more than 4 cylinders).⁷⁷⁵ The new technology combination for turbocharged advanced cylinder deactivation (TURBOAD) uses a similar approach for determining effectiveness. The agencies have applied a one-and-a-half percent effectiveness improvement estimate for 4-cylinder or smaller engines and a three percent effectiveness estimate for 6-cylinder or larger engines relative to TURBOD.

For the final rule analysis the basic engine path for DOHCs are shown in Figure VI-16 and the high-level engine specifications are shown in Table VI-41. The baseline basic DOHC engine, Eng01, was the starting point and other engine technologies were incrementally adopted to determine effectiveness. Adoption of DEAC technology for turbocharged engines is discussed in Section VI.C.1.e)(2). Similarly, ADEAC technology is discussed in Section VI.C.1.e)(4).

BILLING CODE 4910-59-C

(b) SOHC

Similar to DOHC engines, SOHC engines were characterized as “Basic” engine technologies in the NPRM analysis. They are characterized by having a single camshaft in the cylinder head operating both the intake and exhaust valves. Four basic engine technologies, VVT, VVL, SGDI, and DEAC were considered for SOHC engines. Implementing these technologies involves changes to the cylinder head of the engine, but the engine block, crankshaft, pistons, and connecting rods require few, if any, changes.

The agencies provided engine fuel maps for each of these types of SOHC engines and requested comments. Engine maps 5b, 6a, 7a, and 8a were modeled SOHC engines. The SOHC engine models used engine 5a, which was based on Eng01 as a reference, by removing one camshaft. Eng5a was included for the Draft TAR, but not included for the NPRM analysis due to high BSFC from higher friction that was inherited from the DOHC engine design. A level 0.1 bar of friction reduction over the entire operating range for engine maps 5b, 6a, 7a, and 8a was applied to represent improvements over existing

engine designs. The addition of friction reduction to these engines was a result of consideration of deliberative interagency comments received during the Draft TAR review process noting higher fuel consumption on the baseline SOHC engine 5a relative to other modern SOHC engines.

Meszlér on behalf of NRDC commented that “[a]lthough variable valve timing (VVT) technology is identified as an available refresh technology, the NPRM CAFE model (unlike the version used for the 2016 TAR analysis) actually assumes that all baseline vehicles include VVT technology. As a result, the approximately 9 percent of model year 2016 sales that do not actually include VVT are not credited with any efficiency benefit for adoption of the technology”⁷⁷⁶

We agree with this comment, and for the final rule analysis updated the CAFE model to add a non-VVT level engine in the 2017 analysis fleet and to allow those vehicles to adopt VVT technologies at a refresh or redesign. However, the agencies did not have engine maps for the non-VVT engines, so the agencies applied a fixed-value effectiveness estimate from similar VVT

⁷⁷⁶ Meszlér, at 32.

engine maps to represent the effectiveness for non-VVT engines. The agencies used the effectiveness of a similar configuration technology package of another engine to represent non-VVT engines. Non-VVT SOHC engines may add any combination of VVL with SGDI and DEAC. The agencies believe that the estimated effectiveness used for VVT engines was appropriate because the effectiveness offset is in line with 2015 NAS estimates for VVT engines with respect to VVL engines.^{777 778}

The basic engine path for SOHC engines used in this final rule is shown in Figure VI-17 and the specifications are shown in Table VI-42. Note, that Eng5a is only a reference used to build the rest of the SOHC engines.

BILLING CODE 4910-59-C

(2) Turbocharged Downsized Engines

Engine maps 12, 13, and 14 modeled turbocharged downsized engines. Turbocharged downsized engines are characterized by technology that can create greater-than-atmospheric pressure in the engine intake manifold when higher output is needed. The raised pressure results in an increased volume of airflow into the cylinder supporting combustion, increasing the specific power of the engine. An increased specific power means the engine can generate more power per unit of volume, which allows engine volume to be reduced while maintaining performance, thereby increasing fuel

efficiency. IAV Eng12 was the base engine for all simulated turbocharged engines and was validated using engine dynamometer test data.⁷⁷⁹

One notable change that the agencies made for the NPRM analysis based on stakeholder comments to the Draft TAR was to update the turbo family engine maps to assume operation on regular octane fuel (Tier 3, or 87 AKI), instead of premium fuel (Tier 2, or 93 AKI), to assure the maps accounted for real world constraints that impact durability and drivability, and noise, vibration, and harshness. Using regular octane fuel

⁷⁷⁹ Bottcher, L. Grigoriadis, P. "ANL—BSFC map prediction Engines 22–26" April, 30, 2019. IAV_20190430_Eng 22–26 Updated_Docket.pdf.

is consistent with the fuel octane that manufacturers specify be used in the majority of vehicles (manufacturers generally only specify premium fuel is required for higher performance models, although that is not always the case), and enables the modeling to account for important design and calibration issues associated with regular octane fuel. The agencies noted in the NPRM that using the updated engine maps addressed over-estimation of potential fuel economy improvements and ensured that the analysis reflected real-world constraints faced by manufacturers to assure engine durability and acceptable drivability. Importantly, assuming no change in fuel octane required to

operate a vehicle ensures that the agencies are modeling technology pathways that can improve fuel economy while maintaining vehicle performance, capability, and other attributes.

Compared with the NHTSA analysis in the Draft TAR, the turbocharged and downsized engine maps adjusted at high torque and low speed operation, and at high speed operation to account for knock limitations when using regular octane fuel. The knock model used to develop the turbocharged engines was trained on production and development engines tested at IAV to quantify the effects of different octane fuels.⁷⁸⁰ Below the knock threshold, there is no change to the fuel consumption maps. The agencies noted that with the fuel octane change there are generally two major effects in the regions where the engine is knock-limited: First, spark timing is retarded causing a reduction in combustion efficiency and hence an increase in BSFC, and second, an increase in combustion and exhaust temperatures requiring fuel enrichment to cool those temperatures for engine component protection and resulting in increased BSFC.^{781 782}

The agencies also noted that for Eng14, the turbocharged downsized engine with cooled exhaust gas recirculation (cEGR), cEGR was added at the higher speeds where further reduction in combustion temperature was required. The higher specific heat capacity of cEGR reduced the need for fuel enrichment by lowering combustion temperatures and limiting the amount of spark retardation necessary to manage spark knock. With increasing load, cEGR is also used to lower combustion temperatures to reduce NO_x emissions. The agencies explained that because IAV's models are not trained for emissions, cEGR was only considered for areas that are knock-limited and/or to reduce combustion temperatures. Because cEGR has the impact of slowing down burn rates, the amount of cEGR that could be utilized was balanced to maintain efficient

combustion. Combustion stability was also evaluated to assure cEGR rates did not cause excessive cycle-to-cycle combustion variations, which adversely impact drivability.⁷⁸³

Some commenters criticized these downsized turbocharged IAV maps, referencing deliberative EPA comments docketed pursuant to the Clean Air Act procedural requirements at 42 U.S.C. 7607, which stated that the assumptions for Eng12's fuel octane, heating value, and carbon content were not representative of certification fuel and did not appear to be consistently used for the various engine maps, concluding that the resultant engine maps were not representative of CO₂ performance of turbocharged engines over the certification cycle. ICCT stated it appeared these concerns had not been addressed for the NPRM, and that "this problem essentially affect[ed] all engines on the turbocharged engine pathway."⁷⁸⁴

The agencies disagree with ICCT's comments relating both to whether fuel specifications were used consistently and whether the fuel specifications for fuel octane, heating value and carbon content were representative of the same fuel. First, the EPA deliberative comments were resolved in the deliberative process through the clarification that a single fuel specification was used to develop all of the engines and engine maps. Therefore, the engine maps are internally consistent. The fuel specification was presented in the NPRM section PRIA Chapter 6.3.2.2.17. Second, the agencies considered future fuel and emissions standards by using regular octane fuel for this analysis. The assumptions for the fuel used in this analysis align with the EPA's Tier 3 standards that went into effect January 1, 2017.⁷⁸⁵ For the reasons discussed further above, the agencies believe it is important to use Tier 3 fuel for engine maps used for rulemaking analysis.

Roush claimed that the turbocharged engine maps used in the analysis were responsible for an overly-conservative estimate of underlying combustion engine efficiencies, arguing that many production engines available today use the same technology packages identified

in the PRIA but with significantly higher efficiencies.⁷⁸⁶ Roush noted that the base turbocharged engine map used in the PRIA, Eng12, is assumed to have variable valve lift (VVL), but with a turbocharged engine the benefit of VVL over dual variable valve timing (VVT) is limited.⁷⁸⁷ Roush argued that almost all vehicle manufacturers use lower-cost dual VVT systems in their turbocharged engines, and that the agencies' base turbocharged engine assumption is unrealistic with a correspondingly high cost.⁷⁸⁸

Roush contrasted its critique of Eng12 with an EPA ALPHA run of a 2016 Honda Civic 1.5L turbocharged engine (L15B7) with continuously variable intake and exhaust camshaft phasing (CVVT), which is less expensive than the CVVL, arguing that it showed greater efficiency over more of the engine map at a lower cost than Eng12. Roush further argued that since the L15B7 engine is the first generation of the new Honda turbocharged engine, "even further fuel consumption improvement is highly likely in the period through MY2025."⁷⁸⁹

As the agencies explained further above, from a technical perspective there is no reason why the 2016 Honda Civic 1.5 L Turbo should have an engine map that is the same as Eng12, Eng13, or Eng14. The turbocharged engine technologies represented by Eng12, Eng13 and Eng14 are not representative of any specific engine from any one manufacturer. Honda's 1.5L turbocharged engine incorporates a unique combination of technologies including electric wastegate, sodium-filled exhaust valves, light weight internal components, friction reduction technologies, 2-stage oil pump, low viscosity oil (0W–20), and a unique exhaust system.⁷⁹⁰

While there are an enormous number of different technology combinations that manufacturers could apply on their

⁷⁸⁰ Knock models are based on Gamma Technology's kinetic fit model per the technical paper titled, "A combustion model for IC engine combustion simulations with multi-component fuels," by YoungChul Ra, Rolf D. Reitz—Engine Research Center, University of Wisconsin-Madison.

⁷⁸¹ Fuel enrichment is extra fuel is injected at the intake manifold port or directly into the cylinder. Fuel vaporization and the fuel's thermal mass reduces combustion and exhaust temperatures. Changes to the air/fuel ratio also impact combustion speed which impacts the knock limit.

engines, the agencies' analysis must select a reasonable number of configurations—in fact, the agencies analyze thousands of unique make/model/powertrain combinations and apply them to over one hundred thousand unique technology combinations for each of ten classes for this rulemaking. See Section VI.B.3.a)(6) and Section VI.B.3 for more details. For turbocharged engines, the agencies selected eight combinations which represent a wide range of technologies, combinations of technologies, and effectiveness improvements for the rulemaking analysis, as listed in Table VI–40. Three of the combinations were added based on commenter's recommendations. While it is possible to identify other combinations, such as the unique technologies Honda chose for its 1.5L Turbo engine, agencies do not believe it would be appropriate to select all of the technologies on one specific manufacturer's engine for the rulemaking analysis. Doing so would, appropriately, raise questions about the availability of proprietary designs and controls to other manufacturers, among other considerations.

The agencies also believe that the engine maps for Eng12, Eng13 and Eng14 show reasonable differences in BSFC maps that characterize the impact of each of these technology combinations, and differences relative to naturally aspirated engines. As discussed further above, incremental differences in BSFC are used for the rulemaking analysis. Roush's comments center on the comparison of absolute effectiveness values for a specific production vehicle, and do not address incremental effectiveness among a range of technologies, nor the appropriate baseline reference for the Honda 1.5L Turbo for technology content and for effectiveness. The ALPHA simulation for the 2016 Honda Civic 1.5L turbocharged engine provides absolute test data and has no baseline for assessing incremental effectiveness. Because there is no baseline, there is no basis for identifying which specific technologies have changed, nor any basis for determining the incremental effectiveness of each individual technology.

Regarding Roush's comment that that further fuel consumption improvement for the Honda L15B7 is highly likely in the period through MY 2025, Roush provided no information or data on what specific technologies would further improve the fuel consumption of that engine. With no defined new technology to consider, there is no basis for estimating the costs, nor for estimating the effectiveness of Roush's

assertion. Without further information, the agencies can only point to the additional engine technologies considered for this final rule, discussed further below.

ICCT also stated that IAV's handling of cooled EGR (cEGR) in the engine maps was inappropriate, as IAV analyzed cEGR as a knock-abatement technology instead of a fuel efficiency technology. ICCT stated that this is reason that the NPRM analysis showed no benefit to cEGR, and if the agencies had used EPA's properly modeled cEGR effectiveness based on validated data, the effectiveness of cEGR would have been more realistic.

Similarly, Roush commented that cEGR application in the modeled turbocharged engines is excluded in engine operating modes that highly influence vehicle fuel economy. Roush contrasted Eng13, a turbocharged engine with VVT, direct injection, and cEGR, with the Mazda 2.5L SkyActiv Turbo engine available in the 2016 Mazda CX–9, which also employs cEGR.

The agencies believe Eng14 was created and modeled using a sound technical methodology, using constraints that the industry uses to ensure the engines would meet durability and customer acceptability criteria. IAV turbocharged engines adopted VVT and VVL to maximize volumetric efficiency and improve the combustion process. Engines with VVT control intake and exhaust valve timing to recycle burned exhaust gas into the combustion chamber. The recycling of exhaust gases using VVT is commonly called internal EGR. Cooled EGR (cEGR) is a *second* method for diluting the incoming air that takes exhaust gases, passes them through a cooler to reduce their temperature, and then mixes them with incoming air in the intake manifold. Diluting the incoming air with inert exhaust gas reduces pumping losses, thereby improving BSFC. The dilution also reduces combustion rates, temperatures, and pressures, which mitigates spark knock and reduces the need for fuel enrichment at higher loads to control exhaust temperature for component durability (typically, exhaust valves and exhaust manifold). Not only does this exhaust gas displace some incoming air, but it also heats the incoming air and lowers its density. Both interactions lower the volumetric efficiency of the engine.⁷⁹¹ Cooled EGR

⁷⁹¹ Volumetric efficiency (VE) in internal combustion engine engineering is defined as the ratio of the mass density of the air-fuel mixture drawn into the cylinder at atmospheric pressure (during the intake stroke) to the mass density of the same volume of air in the intake manifold. Ideally, you want this to be high as possible to maximize

is a more effective way of reducing combustion temperature in higher load and higher speed engines like turbocharged engines.

As mentioned above, IAV developed engine specifications, including the rate of internal EGR and cEGR, using variation in combustion criteria used by industry to ensure the engines would meet durability and customer acceptability criteria. In addition to reducing pumping losses, EGR slows the combustion rate and causes combustion to be less consistent cycle-to-cycle as the concentration increases. Industry and researchers use a measurement known as coefficient of variation of indicated mean effective pressure (COV of IMEP) to evaluate combustion stability. Industry commonly recognizes values greater than 3.0 percent as unacceptable because above those levels, the combustion instability creates a noticeable and objectionable drivability problem for vehicle occupants, referred to as “surge.” Surge is perceived as the vehicle accelerating and decelerating erratically, instead of running smoothly. IAV set EGR rates at each of the engine operating conditions at the highest level that did not exceed 3.0 percent COV of IMEP. Therefore, the IAV engine maps *did* maximize efficiency within real-world constraints, similar to how manufacturers develop their engines. At the lower speed and load conditions of the 2-cycle tests, the COV of IMEP threshold was reached using internal EGR alone, so additional cEGR was not applied. At higher load conditions, such as the US06 cycle, cEGR was applied.

ICCT's statement that the engine maps were only developed considering knock-abatement is inaccurate. In the PRIA Chapter 6.3.2.2.11, the agencies discussed the application of internal EGR in combination with cEGR for Eng14. VVT technology, with which Eng14 is equipped, maximizes EGR usage first in areas where the engine primarily operates, such as low load and low speed area like city cycle and highway cycle tests used in CAFE compliance testing. Cooled EGR is applied at higher speed and higher load conditions, such as the US06 test cycle.

Using EPA's modeled cEGR would have resulted in infeasible engine maps because they were developed assuming the exclusive use of high octane Tier 2 fuel, and using a COV of IMEP threshold of 5 percent, which is beyond the level that is deemed acceptable to consumers in the real world.⁷⁹² The use of these

thermal efficiency during the power stroke (combustion phase).

⁷⁹² EPA Proposed Determination TSD at 2–295.

criteria results in engine maps with BSFC levels that cannot be achieved by manufacturers that must ensure their engines are durable and are acceptable to customers with fuels that are used and available. The reference engine for EPA's cEGR concept was a 2010 Ricardo prototype V6 engine that used 98 RON fuel (93AKI or premium fuel) to determine effectiveness.⁷⁹³ The problems associated with using high octane Tier 2 to develop engine maps are discussed in detail in Section VI.C.1.a). The issues associated with excessive cEGR rates and COV of IMEP, are discussed immediately above. In addition, the cEGR engine maps that EPA used were never evaluated with regular octane Tier 3 fuel to assess the further degradation in BSFC and COV of IMEP that would occur where spark advance would need to be decreased to address spark knock, as decreasing spark advance directionally makes both BSFC and COV of IMEP worse.⁷⁹⁴ Also, because some models are still under development, ALPHA effectiveness estimates in the Draft TAR and derived for the Proposed Determination do not provide the best available basis for assessing effectiveness impacts.⁷⁹⁵ Therefore, the assumptions used for the EPA Draft TAR and Proposed Determination engine maps overstate feasible improvements and therefore do not provide meaningful comparisons to the engine maps used for the NPRM and final rule analyses.

Finally, with regards to Roush's comparison of Eng13 to the 2016 Mazda SkyActiv-G 2.5L Turbo, the agencies believe these engines use technologies that are sufficiently different so as to render a comparison not useful, even for a very rough validation of Eng13. Most fundamentally, as discussed in PRIA Chapter 6.3.2.2.11 and 6.3.2.2.13, the Mazda 2.5L Turbo is a Miller cycle engine, whereas Eng13 is an Otto cycle engine. Also, the Mazda 2.5L Turbo has cEGR, whereas Eng13 does not.⁷⁹⁶ On a

more detailed level, as described in PRIA Chapter 6.3.2.2.20.10, Eng13 has a BSFC of 238 g/kwh, whereas Roush refers to an engine having a BSFC of 250 g/kwh.⁷⁹⁷ The agencies therefore believe comparing the 2016 Mazda SkyActiv-G 2.5L Turbo to Eng13 is not a useful or relevant comparison. In the PRIA, the agencies included an engine map for a Miller cycle engine and requested comments on whether it should be included in the final rule analysis. Based on the comments, as discussed further below, the agencies added a Miller cycle engine to the final rule analysis.

(3) Non-HEV Atkinson Mode Engines

Manufacturers use a variety of designs and technologies to obtain an engine's highest thermal efficiency while maintaining drivability and performance. While the Otto cycle has historically been used by the vast majority of gasoline based engines, one way to improve thermal efficiency is by using alternative combustion cycles. One such alternative combustion cycle that can be used in place of the Otto cycle to achieve a higher maximum thermal efficiency is the Atkinson cycle. Atkinson cycle operation is achieved by modifying the Otto cycle engines' crank and valvetrain mechanics to maintain compression ratio while increasing expansion ratio.⁷⁹⁸ Specifically, in Otto cycle operation, the exhaust valve is opened near the end of the power stroke, allowing exhaust gases out of the cylinder. The pressure in the cylinder is still about three to five atmospheres.⁸⁰¹ Currently, there are two common approaches to achieving Atkinson Cycle operation: Either the exhaust valve timing or the intake valve timing are modified. In the first instance, the exhaust valve is not opened until enough expansion has occurred for the cylinder pressure to be equivalent to atmospheric pressure. The energy that typically is lost when the exhaust valve opens in Otto cycle is captured in the Atkinson cycle, leading to higher

thermal efficiency. Modifying the intake valve timing, the most common way to achieve Atkinson cycle operation, involves allowing the intake valve to stay open during some portion of compression stroke. As a result, some of the fresh charge is driven back into the intake manifold by the raising piston so the cylinder is never completely filled with air, allowing optimized capture of combustion-created pressure.

While Atkinson cycle engines have higher theoretical thermal efficiency compared to Otto cycle engines, the Atkinson cycle engine delivers that higher efficiency at the cost of power density.⁸⁰² The reduced power density is because of lower operation pressures in the cylinder than in a typical Otto cycle engine. Accordingly, Atkinson cycle engines have been ideal for hybrid vehicles because their electric motor can make up for lost power density.

As vehicle technologies have become more sophisticated, descriptions of Atkinson cycle engines and Atkinson mode engine technologies have been used interchangeably, and often incorrectly, in association with high compression ratio (HCR) engines by the agencies and stakeholders. Although they both achieve an overall higher thermal efficiency than Otto cycle-only engines, they differ in execution depending on engine load. For the following discussion, Atkinson technologies considered in the analysis can be categorized into three groups: (1) Atkinson engines, (2) Atkinson-mode engines, and (3) Atkinson-enabled engines, which are variable valve timing engines with late intake closing that enables the Atkinson cycle mode. As discussed earlier, because power density is traded for efficiency, there is a limit to where Atkinson technology can be applied. While any vehicle could, theoretically, adopt an Atkinson-mode engine or an engine that enables operating in Atkinson cycle mode, the difference in vehicle application (high-performance versus standard-performance vehicles, towing requirements, trucks) leads to different effectiveness levels. The range of effectiveness appeared to create confusion among stakeholders regarding how the technology is applied to vehicles for compliance modeling and simulation.

Atkinson engines are engines that operate full-time in the Atkinson cycle. As mentioned above, the most common method of operation used by Atkinson engines currently is late intake closing.

⁷⁹⁷ NHTSA–2018–0067–11984 at p. 20 of 37 Figure 8.

⁷⁹⁸ Otto cycle is a four-stroke cycle that has four piston movements over two engine revolutions for each cycle. First stroke: Intake or induction; second stroke: Compression; third stroke: Expansion or power stroke; and finally, fourth stroke: Exhaust.

⁷⁹⁹ Compression ratio is the ratio of the maximum to minimum volume in the cylinder of an internal combustion engine.

⁸⁰⁰ Expansion ratio is the ratio of maximum to minimum volume in the cylinder of an IC engine when the valves are closed (*i.e.*, the piston is traveling from top to bottom to produce work).

⁸⁰¹ Pulkabek. W.W. "Engineering Fundamentals of the Internal Combustion Engine." 2nd edition. Pearson Prentice Hall, at p. 118.

⁸⁰² Power density is the engine power per unit of displacement (= [Engine Power]/[Engine Displacement]).

This approach allows backflow from the combustion chamber into the intake manifold, reducing the dynamic compression ratio, but providing a higher expansion ratio. This improves thermal efficiency but reduces power density. As a result of limited engine operation, these engines tend to have lower specific power.⁸⁰³ The lower specific power tends to relegate these engines to hybrid vehicles applications, as coupling the engines to electric motors can compensate for the lower specific power. The Toyota Prius is an example of a vehicle that uses an Atkinson engine. Typically, vehicles that use an Atkinson cycle engine incorporate various fuel-efficient technologies like aerodynamic improvements, advanced continuously variable transmissions, mass reduction, and many other technologies to minimize engine load and attain high thermal efficiency.⁸⁰⁴ The 2017 Toyota Prius achieved a peak thermal efficiency of 40 percent.⁸⁰⁵

Atkinson-mode engines are engines that use both the Otto cycle and Atkinson cycle during operation, switching between the modes of operation based on engine loads. During high loads the engine will operate in the power-dense Otto cycle mode, while at low loads the engine will operate in the higher-efficiency Atkinson cycle mode. The magnitude of efficiency improvement experienced by a vehicle using this technology is directly related to how much of the vehicle's operation time is spent in Atkinson mode. This means vehicles that typically operate at a high load, like a truck towing a trailer, will spend more time in the Otto mode and less time in the Atkinson cycle mode, and will achieve a lower overall efficiency improvement over a traditional Atkinson engine that operates full-time in the Atkinson cycle. As a result, manufacturers will try to use this type of engine in conjunction with other technologies that reduce engine load, which allows the engine to operate more frequently in Atkinson cycle mode. For example, manufacturers could reduce parasitic losses by incorporating more efficient accessory technologies, or reducing overall vehicle mass and aerodynamic drag. These

technologies are enablers for Atkinson-mode engines. When these types of technologies are adopted, it reduces the parasitic losses and, in turn, reduces the time the engine is in high load region. An example of an Atkinson-mode engine is the MY 2017 Mazda 3.

The last type of Atkinson-type engine, the Atkinson-enabled engine, can be characterized by primarily running the Otto cycle, but can achieve Atkinson-mode using variable valve timing (VVT) technology. Some engines use changes in VVT on the intake side to enable Atkinson cycle operation in low load, low speed operation, like city driving. These types of engines are typically used in applications that generally require higher specific power such that it would be infeasible to use Atkinson-mode engines or Atkinson engines. These vehicles tend to have higher load demands due to towing requirements, payload requirements, greater aerodynamic drag from larger frontal areas, greater tire rolling resistance from larger tires and higher driveline losses from four-wheel drive or all-wheel drive (e.g., SUVs and pickup trucks). These higher load demands tend to push these engines more frequently to the less efficient region of the engine map and limit the amount of Atkinson operation. An example of the Atkinson-enabled engine is the Toyota MY 2017 Tacoma 3.5L 6-cylinder engine.

EPA developed two engine maps representing non-hybrid Atkinson engines to support the 2016 Draft TAR, Proposed Determination, and first Final Determination.⁸⁰⁶ Referred to as ATK and ATK2, the engines represented a current non-hybrid Atkinson cycle engine based on the 2.0L 2014 Mazda SkyActiv-G (ATK) engine, and a future Atkinson engine concept based on the Mazda engines, but adding cooled EGR, cylinder deactivation, and an increased compression ratio (14:1) developed for full vehicle modeling and simulation (ATK2). For the 2016 Draft TAR, the agencies adopted EPA's high compression ratio (HCR) engine maps as Eng24 and Eng25, which corresponded to HCR1 and HCR2 in the CAFE modeling.

The Alliance had provided significant comments on the 2016 Draft TAR

regarding the engine maps for HCR engines.⁸⁰⁷ The Alliance detailed concerns regarding the feasibility and effectiveness of Eng24 (HCR1) and Eng25 (HCR2). Many of the comments on the 2016 Draft TAR noted that the modeling projected an implausible rapid fleet penetration for these technologies, and overestimated effectiveness. Commenters stated the overestimation was due largely to modeling with use of high-octane fuel and the addition of other technologies like cEGR and cylinder deactivation (DEAC) using theoretical assumptions that exceed the bounds of operation of components. In contrast, other commenters had stated that EPA's work on the future Atkinson concept "has shown this pathway to be a promising alternative way to match the levels of improvement from a 27-bar BMEP turbocharged engine," and that "it is prudent to assume that the robust body of evidence EPA is putting together based on benchmarking and modeling data is a reasonable assessment of the technology's potential."⁸⁰⁸

For the NPRM analysis, the agencies included EPA's engine maps. The agencies allowed HCR1 to be applied only for a few manufacturers that indicated they would pursue this technology pathway versus alternative pathways, such as downsized turbocharged engines. The agencies were also careful to maintain vehicle performance and utility attributes when considering the application of Atkinson-type technologies. Current Atkinson capable engines have incorporated other technologies to reduce load in order to maximize time in Atkinson operation and to offset the power loss partially. This includes improved accessories, addition of friction reduction technologies, and other technologies that reduce engine load. Although modern improvements to engines have allowed Atkinson operation to occur more often (because of lower engine loads) for passenger cars, larger vehicles capable of carrying more cargo and occupants, and towing larger and heavier trailers, have more limited potential Atkinson operation. Those

⁸⁰³ Specific power is the maximum power produced per displacement typically in units of hp/l or kw/l.

adoption features are discussed further in Section VI.C.1.e) Adoption Features, below.

As stated in the NPRM, the agencies excluded the HCR2 concept engine from the central analysis for several reasons. First, the concept was not subjected to validation to assess its technical feasibility. The concept was only modeled with high octane Tier 2 fuel. The HCR2's capability to operate on regular octane Tier 3 fuel was assessed using non-cycle specific operation, necessitating adjustments to the final results to account for Tier 3 fuel properties from Tier 2 operation, instead of simply operating the engine on Tier 3 to generate effectiveness estimates.⁸⁰⁹ As discussed further above and in Section VI.C.1.a), fuel octane affects engine durability, performance, drivability, and noise, vibration and harshness. Assumptions about compression ratio, EGR rates, and use of cylinder deactivation were not adequately validated. PRIA Chapter 6.3.2.2.20.18 discussed many questions about HCR2 technology's practicability as specified, especially in high load, low engine speed operating conditions. There also has been no observable physical demonstration of the technology assumptions. Many manufacturer engine experts questioned its technical feasibility and commercial practicability during the model years covered by the rulemaking. Stakeholders like the Alliance had previously asked for the engine to be removed from the rulemaking analyses until the performance could be validated with engine hardware.⁸¹⁰ For these reasons, the agencies considered the HCR2 engine too speculative to include in the NPRM central analysis. However, the agencies did provide a sensitivity analysis that included the HCR2 engine.

Comments on HCR1 and HCR2 varied, with commenters split on issues like whether HCR2 was speculative or real, whether there was technology in the fleet that could adequately be represented by HCR2, and the effectiveness of HCR2 in the analysis.

The Alliance commented in support of the decision to exclude HCR2 from the analysis, citing previous comments to the Draft TAR and proposed determination "detailing concerns of feasibility and effectiveness of the non-hybrid Atkinson engine technology packages, including cooled exhaust gas recirculation ("CEGR") and cylinder deactivation."⁸¹¹ Specifically, the

Alliance's comments "noted that the modeling projected an implausibly rapid fleet penetration of this complex engine technology and overestimated its effectiveness, due largely to modeling with high-octane fuel and the theoretical addition of CEGR plus cylinder deactivation." The Alliance concluded that "the inexplicably high benefits ascribed to this theoretical combination of technologies has not been validated by physical testing." Ford commented that previous assessments had "over-estimated both the effectiveness and near-term penetration of advanced Atkinson technology powertrains," stating that "[t]he effectiveness of the 'futured' Atkinson package (HCR2) that includes cooled exhaust gas recirculation (CEGR) and cylinder deactivation (DEAC) is excessively high, primarily due to overly-optimistic efficiencies in the base engine map, insufficient accounting of CEGR and DEAC integration losses, and no accounting of the impact of 91RON Tier 3 test fuel. Given the speculative and optimistic modeling of this technology combination, Ford supports limiting the use of HCR2 technology to reference only, as described in the Proposed Rule."⁸¹² Separately, in support of its overarching comments that the NPRM modeling better reflected reality over prior regulatory assessments, Toyota commented that the effectiveness estimates for Atkinson cycle engine technology in the NPRM may still have been overstated.⁸¹³

In contrast, CARB, ICCT, Meszler Engineering Services, UCS, and other stakeholders commented in different respects, with the broad themes being: (1) That the change in approach towards HCR engines from the Draft TAR and Proposed Determination to the NPRM was not justified, was inadequately justified, or was based on justification from the industry and not the agencies' own independent judgment; (2) that HCR2 as defined by EPA does exist and therefore should be used in the analysis; and (3) that even if HCR2 technology does not exist exactly as EPA defined it, other technologies in the fleet provide the same level of efficiency improvement as HCR2 and therefore it should be used in the analysis. Many of these commenters stated that if HCR2 had been allowed in the compliance analysis, as shown in the NPRM sensitivity analysis allowing HCR2 to be applied, compliance costs would have been reduced dramatically, "on par with

NHTSA and EPA estimates in the TAR."^{814 815}

Specifically, ICCT, CARB, and UCS took issue with the agencies' description of HCR2 technology as speculative, stating that description contrasted with how EPA described the technology in prior documents. ICCT commented that "in the Draft TAR and Final Determination, EPA observed the real-world advances toward production vehicles using HCR2 technology, and determined that that technology could be adopted by automakers during the compliance period."⁸¹⁶ ICCT stated that in the NPRM, "without rational explanation, the agencies now describe this technology as 'speculative' and have omitted the technology from their primary compliance scenarios altogether." CARB similarly commented that "[t]he fact that the Agencies, especially EPA, make [a statement that HCR2 is entirely speculative] is genuinely impossible to credit."⁸¹⁷ In support, all three commenters referenced EPA's hardware testing of a European Mazda engine,⁸¹⁸ with ICCT stating that HCR2 was dismissed as entirely speculative "despite the careful benchmarking of improved HCR engines by EPA," while CARB and UCS similarly cited this hardware testing to rebut the Alliance's assertion that the effectiveness values for HCR2 was "seriously overestimated."

ICCT also took issue with the NPRM statements that "many engine experts questioned [HCR2's] technical feasibility and near-term commercial practicability,"⁸¹⁹ and that "[s]takeholders asked for the engine to be removed from compliance simulations until the performance could be validated with engine hardware," with references to comments from Fiat-Chrysler (stating "Remove ATK2 from OMEGA model until the performance is validated" and "ATK2—High Compression engines coupled with Cylinder Deactivation and Cooled EGR are unlikely to deliver modeled results, meet customer needs, or be ready for commercial application."),⁸²⁰ and comments from the Alliance of Automobile Manufacturers, stating that

⁸¹³ NHTSA–2018–0067–12150.

“[There] is no current example of combined Atkinson, plus cooled EGR, plus cylinder deactivation technology in the present fleet to verify EPA’s modeled benefits and . . . EPA could not provide physical test results replicating its modeled benefits of these combined technologies.”⁸²¹ ICCT stated that the agencies did not identify any such comments or evidence from engine experts, or agency analysis of them. ICCT stated that “it is clear that NHTSA is deferring to stakeholders, and that EPA has been forced to defer to NHTSA.”

ICCT also cited interagency review documents where EPA stated “[t]here are Atkinson engine vehicles on the road today (2018 [Toyota] Camry and Corolla with cooled EGR and the 2019 Mazda CX5 and Mazda6 with cylinder deac) that use high geometric compression ratio Atkinson cycle technology that is improved from the first generation, MY2012 vintage “HCR1” technology. While it is true that no production vehicle has both cooled EGR and cylinder deac, as the EPA “HCR2” engine did, nonetheless, these existing engines demonstrate better efficiency than estimated by EPA. Therefore, it would be appropriate to continue to use EPA’s cooled EGR + deac engine map to represent “HCR2” engines.”⁸²²

More specifically regarding the technical specifications of the HCR2 engine, ICCT and others stated that EPA had already addressed concerns brought by the Alliance⁸²³ on (1) the base engine fuel consumption maps used as the foundation of the HCR2 engine map;⁸²⁴ (2) practical limitations for

cEGR to limit engine knock;⁸²⁵ (3) the reliance on the availability of cylinder deactivation at unrealistic speed and load operating points; (4) the impact of 91 RON market and certification test fuels; and (5) the ability to implement HCR2 technology in existing vehicle architectures.⁸²⁶

CARB, UCS, and ICCT all stated, in different terms, that even if HCR2 technology does not exist exactly as EPA defined it, other technologies that exist in the fleet provide the same level of efficiency improvement as HCR2, specifically referencing the MY 2018 Toyota Camry engine and various Mazda engines, and claiming that HCR2 should therefore be used in the analysis. Specifically, CARB stated that these engines “are already achieving similar efficiency as the modeled HCR2 package even though they don’t have the full complement of technologies (*i.e.*, CEGR and DEAC) used in the HCR2 package.”⁸²⁷ CARB stated that these engines’ “existence as production engines today certainly speaks to the feasibility of this technology for modeling that goes out to 2030MY.”⁸²⁸ Similarly, UCS stated that while the 2018 Toyota Camry engine “does not have all of the features of the HCR2 package constructed by EPA, it achieves similar levels of performance, thus rendering the agencies’ rationale for excluding HCR2 moot—this is a production vehicle using Tier 3 fuel which achieves performance equivalent to HCR2.”⁸²⁹ Similarly, ICCT cited their own analysis of the 2018 Toyota Camry for the propositions that the package of technologies on the Camry exceeds the efficiency gains projected by EPA’s

OMEGA model, meaning that EPA’s projections for the HCR2 engine might understate its effectiveness, and the early problems with low-end torque losses associated with Atkinson cycle engines have been completely solved.⁸³⁰ ICCT stated that “[t]his evaluation of a real world vehicle that comes close to meeting all of the elements of an HCR2 engine makes it clear that HCR2 engines are far from a speculative technology.”

ICCT and CARB also took issue with the agencies’ justification for not using the HCR2 engine map as a simulation proxy for other new engine technology, specifically the statement that:

It is important to conduct a thorough evaluation of the actual new production engines to measure the brake specific fuel consumption and to characterize the improvements attributable to friction and thermal efficiency before drawing conclusions. Using vehicle level data may misrepresent or conflate complex interactions between a high thermal efficiency engine, engine friction reduction, accessory load improvements, transmission technologies, mass reduction, aerodynamics, rolling resistance, and other vehicle technologies.⁸³¹

Both commenters also took issue with the agencies’ statement that existing technologies in the NPRM version of the CAFE model could work together appropriately to represent an HCR1 engine with additional efficiency improvements.⁸³²

ICCT stated that the complexity associated with the package of improvements in the Camry engine was common to all of the technology packages included in either OMEGA or CAFE modeling, and was neither a new issue nor an issue that precludes making reasonable engineering judgments. ICCT stated that the agencies projected efficiency estimates for other technology packages without engine maps from a production engine, citing the agencies’ approach to modeling ADEAC technology, and concluded that the purpose of full vehicle simulation modeling is to project the efficiency impact when several different parts of the vehicle are simultaneously upgraded. ICCT stated that “[i]f reasonable estimates could be made for ADEAC without fully validated engine maps, there is no reason to exclude other technologies on these grounds, especially considering the deep expertise by the agencies and their state-of-the-art technology simulation capabilities with the ALPHA modeling.” Similarly, HDS noted that in contrast to the agencies’ exclusion of HCR2 due to

⁸²¹ Id. (citing EPA-HQ-OAR-2015-0827-6156).

⁸²² NHTSA-2018-0067-11741, Attachment3_ICCT 15page summary and full comments appendix, at I-10 (citing Docket Entry; E.O. 12866 Review Materials for The Safer Affordable Fuel-Efficient (SAFE) Vehicles Rule for Model Years 2021–2026 Passenger Cars and Light Trucks NPRM, Docket ID EPA-HQ-OAR-2018-0283-0453 (hereinafter “EO12866 Review Materials”), File: “EO_12866_Review_EPA_comments_on_the_NPRM_sent_to_OMB_June_29_2018” at 82, <https://www.regulations.gov/document?D=EPA-HQ-OAR-2018-0283-0453>).

⁸²³ EPA-HQ-OAR-2015-0827-4089; EPA-HQ-OAR-2015-0827-6156.

⁸²⁴ NHTSA-2018-0067-11741 (“EPA showed how its “difference” engine maps validly represented performance of the ATK2 [HCR2] packages including on different fuels (pp. 301–02); and that the difference maps submitted in the industry comment “provided no information to compare vintage or application of the actual engine or engines tested, and did not state whether or not testing was conducted,” lacking any information on “test and/or analytical methods, assumptions, fuel properties, environment test conditions, how the engine was controlled or how control was modeled, the number of data points gathered to generate the AAM ‘difference map’ to assure that identical testing and a sufficient fit of data was performed”

(p. 301). In addition, EPA showed that concerns about knock due to use of cooled exhaust gas recirculation had been considered and resolved by ignition improvements (p. 302).”).

⁸²⁵ NHTSA-2018-0067-12039 (“The agencies appear to have relied upon the differences between anti-knock properties of Tier 2 and Tier 3 fuels, mistakenly focusing solely on octane while ignoring ethanol content. . . . this fails to acknowledge the anti-knock benefit of charge cooling related to ethanol, which more than compensates for the change in octane. HCR2 therefore should not be omitted out of concerns around knock.”).

⁸²⁶ NHTSA-2018-0067-11741. ICCT stated that EPA had previously concluded that existing engine architectures were “well adapted for [HCR] technology, and well adapted for the emerging next level HCR2 package of technologies, since the foundational technologies of gasoline direct injection, increased valve phasing authority, higher compression ratios, and cooled exhaust gas recirculation are already in widespread use.” ICCT also commented that “EPA correctly observed that there was sufficient lead time to adopt the HCR2 technology before MY2022 and that it could be incorporated without requiring major vehicle redesigns.”

unresolved issues associated with knock mitigation and cylinder deactivation, “the 2018 analysis included Advanced Cylinder De-activation (ADEAC) which has recently come to market readiness.”⁸³³

Merriam-Webster’s dictionary defines speculative as “involving, based on, or constituting intellectual speculation,” and also, “theoretical rather than demonstrable.”⁸³⁴ To be clear, most engines maps used in this analysis—IAV engine maps included—are theoretical, although they are built based on benchmarked engine data, and additional fuel-economy-improving technologies are added through modeling and simulation. But that does not mean that these engines are speculative. Although the IAV engine maps are not meant to model any manufacturer’s particular engine, many, if not all, technology combinations have been implemented in real-world engines.

The agencies qualified the HCR2 engine as speculative because “no production engine as outlined in the EPA SAE paper has ever been commercially produced or even produced as a prototype in a lab setting. Furthermore, the engine map has not been validated with hardware and bench data, even on a prototype level (as no such engine exists to test to validate the engine map).”⁸³⁵ It is important to distinguish theoretical engines maps with technology combinations that have been proven through real-world testing and operation, from the HCR2 engine map, that was created using a combination of validated individual component models, but the resulting engine system model and generated engine map were not fully validated against actual hardware.

The Alliance and individual automakers have repeatedly provided comments on agency actions with their assessment of the feasibility of the HCR2 engine, including comments ICCT referenced, stating the EPA had addressed concerns brought by the Alliance in the Proposed Determination Technical Support Document.⁸³⁶ The agencies agree with ICCT that EPA

provided responses to comments about HCR2 assumptions and engine maps in the Technical Support Document, the Proposed Determination, and the 2017 Final Determination. However, the agencies considered the matter further after receiving extensive comments on HCR2 for the NPRM. The agencies have concluded responses did not directly and fully address the technical concerns raised by the Alliance. Further, new data and information has become available since the Proposed and Final Determination that is directly relevant to the use of EPA’s engine maps in this analysis.

First, it is important to provide background information about ICCT’s comments referencing previous discussions from the TAR, Proposed Determination and Final Determination. For the 2016 Draft TAR, EPA initially created the ATK1 and ATK2 engine maps based on the MY 2014 Mazda 2.0L SKYACTIV-G engine. The EPA benchmarked the Mazda engine, then modeled increasing the efficiency of the Mazda engine map by simulating the application of additional technologies using GT-Power models. The Alliance and FCA commented on the 2016 Draft TAR suggesting the EPA’s development of the ATK1 and ATK2 engine maps were flawed because the maps were developed based on optimistic baseline engine characterization of the Mazda engine. The Alliance provided evidence of the flaws in EPA’s characterization by comparing EPA’s published base engine data, developed using Tier 2 certification gasoline, to engine data benchmarked by USCAR. USCAR benchmarked their own Mazda Skyactiv engine map using a 91 RON fuel. The comparison resulted in the creation of a “difference map” that showed where the two data sets diverged. The “difference map” implied there were areas of significant divergence, calling into question the data upon which the ATK1 and ATK2 models are based. The EPA responded stating “[the Alliance] did not provide data or other information to substantiate its claim that EPA’s engine dynamometer fuel consumption measurements using a MY2014 Mazda OEM production 2.0L SKYACTIV-G, upon which the ATK2 packages from the TAR analysis are based, were in any way unrepresentative of this engine’s actual performance.”⁸³⁷ ICCT cited in their NPRM comments that the EPA’s discussion of these “difference maps” supported their statement that “[i]n fact, in the Technical Support Document for EPA’s Proposed and 2017 Final

Determination, EPA addressed all these concerns brought forth by the Alliance [regarding HCR2] (including the costs and effectiveness impacts of using regular octane fuel instead of premium fuel).”

It is understandable why ICCT may have thought this discussion addressed concerns raised about the HCR2 map; however, review of the Alliance’s original Draft TAR comments makes it clear the Alliance’s initial comments addressed the *benchmarking* of the MY 2014 Mazda 13:1 SKYACTIV-G engine itself. The Alliance’s original comments, expressed concern over the modeled effectiveness of the advanced Atkinson technology packages because of the baseline engine data used. The Alliance suggested the effectiveness is likely overestimated due to multiple flaws in the benchmarking and modeling approaches taken by EPA. Only the benchmarking is addressed by EPA’s response to the “difference maps,” not the concerns about modeling approach.

The Alliance’s concerns about modeling included the accuracy of the base engine fuel consumption maps (to the extent the baseline engine maps were overly optimistic, the modeled ATK maps were optimistic), limitations for cEGR to mitigate engine knock, limitations of cylinder deactivation, and the impact of fuels.⁸³⁸ After further review, the agencies determined the Alliance’s concerns were not fully addressed, resulting in a closer review of the ATK model development process.

Review of the engine model development showed the engine map was generated assuming the use of high octane fuel, and the follow-up engine dynamometer validation testing also used high octane fuel.⁸³⁹ The characterization of the baseline Mazda Skyactiv engine showed 1–3 percent increase in thermal efficiency across a large portion of the engine map when operated on Tier 2 fuel versus lower octane fuel.^{840 841} The increase in engine

⁸³⁸ EPA-HQ-OAR-2015-0827-4089.

⁸³⁹ Ellies, B., Schenk, C., and Dekraker, P., “Benchmarking and Hardware-in-the-Loop Operation of a 2014 MAZDA SkyActiv 2.0L 13:1 Compression Ratio Engine,” SAE Technical Paper 2016-01-1007, 2016, doi:10.4271/2016-01-1007.

⁸⁴⁰ The engine was first run on LEVIII-compliant certification fuel which has a 7 psi vapor pressure and 88aki. This fuel is similar to Tier 3 fuel with exception of the vapor pressure which is required to be 9 psi to meet Tier 3 certification. It was then tested on Tier 2 certification fuel (93aki) to assess effects of higher octane fuel on engine operation and efficiency.

⁸³⁴ Definition of “speculative,” <https://www.merriam-webster.com/dictionary/speculative>.

⁸³⁵ 83 FR 43038.

⁸³⁶ Also important to note regarding ICCT’s comment, the Alliance comment cited in the NPRM came from a section of the Alliance’s comments titled, “EPA’s Response to Alliance Comments Regarding Atkinson Cycle Engine Technology Benefits is Inadequate,” which seems to suggest that EPA did not address concerns brought by the Alliance in the Proposed Determination Technical Support Document.

⁸³⁷ EPA PD TSD at 2-299.

thermal efficiency, caused by the higher octane fuel, is anticipated to be amplified when applying ATK technologies. ATK technologies increase efficiency by increasing the pressure in cylinder during combustion; however, at the same time the increased pressure increases risk of knock. For more discussion on engine knock, see Section VI.C.1.a). Ultimately, it is expected that the ATK1 and ATK2 engines would show a larger improvement in thermal efficiency as a result of being developed assuming a high-octane fuel versus the 1–3 percent improvement observed on the baseline Mazda Skyactiv engine.

A further limitation was revealed during the agencies review of the ATK model development. The limitation was in how COV of IMEP, an important indicator of combustion stability, was not accounted for directly in the model. The 0–D/1–D models used for investigating cEGR effectiveness could not adequately simulate changes to COV of IMEP. To compensate for the lack of an appropriate model, limits on cEGR were based on literature values for unrelated engine technologies.⁸⁴² As a result, there was no direct evaluation of combustion stability while evaluating the feasibility of the engine concept.

In contrast, for the NPRM and final rule analysis, IAV engines were optimized using Tier 3 fuel, to balance performance and fuel consumption. The majority of baseline vehicles are specified to operate on 87 AKI fuel, therefore lower octane fuel was used to maintain baseline functionality. The IAV engine maps were all derived from a consistent baseline engine and were also optimized using a validated kinetic knock model, and using a COV of IMEP threshold of 3 percent.

These differences in model construction caused an inconsistency that resulted in unrealistic improvements in fuel economy and CO₂ emissions for the HCR engine technologies, whereas the IAV engine maps reflect more realistic accounting for the improvements. The use of high octane fuel and lack of combustion stability modeling are complimentary issues that have compounded effects when combined. For example, the use of high octane fuel allows more advanced spark timing which both increases

efficiency and improves combustion stability, allowing higher cEGR rates before reaching acceptable limits for drivability. The compound effect is greater than the simply adding together individual effects, causing a potentially further unrealistic increase in effectiveness. At a minimum, it is uncertain how using Tier 3 fuel in the HCR2 engine would impact the BSFC of the engine, as there was no direct evaluation of the feasibility of the engine concept's ability to operate on regular octane fuel. The cost for the effectiveness of the HCR2 technology also is inconsistent with the cost of the effectiveness improvement values for the technologies in the 2015 NAS report.⁸⁴³ In considering all of this information, the agencies, believe the HCR2 engine map overstates the capabilities of the technology and decided not to use that engine map for the final rule analysis.

However, the agencies believe the HCR1 engine map does reflect improvements that are representative of the technology in the rulemaking timeframe. For the final rule, to reflect better the incremental effectiveness for a low-cost version of HCR technology, the agencies added the HCR0 engine for the analysis. The specification of this engine was provided in the NPRM PRIA as Eng22b. Using this engine improves the estimated incremental effectiveness because the incremental engine changes from were directly specified for the modeling. HCR0 is the first engine in the HCR path that a manufacturer could adopt. Accordingly, the non-HEV Atkinson engine maps used for the NPRM and final rule central analysis fit into the three defined categories as follows: (1) Eng26 is an HEV Atkinson Cycle engine; (2) in the NPRM analysis, Atkinson-mode engines were characterized by Eng24 (HCR1), and for the final rule analysis, Atkinson-mode engines are characterized by Eng22b (HCR0) and Eng24 (HCR1); and (3) Atkinson-enabled engines are characterized by the different VVT engine technologies identified earlier in basic engine discussions and shown on Table VI–41 and Table VI–42.

Regarding the ability of manufacturers to adapt the engine architecture to practical use, the agencies see merit in observations from both manufacturers and other groups. ICCT is correct in their observation that some production engines have integrated combinations of the technologies, including SGDI, VVT and cEGR. Furthermore, the agencies agree with ICCT that an engine could be built integrating all the technologies

represented in the HCR2 engine model. However, the agencies also agree with the Alliance's comments to the 2016 Draft TAR that applying all the technologies to an engine that only has some of the technologies would require a significant redesign of the powertrain package. The redesign would need to accommodate the new hardware integration, controls and emissions calibration, OBD development and other major efforts. As discussed further in Section VI.C.1.e), the agencies believe these considerations impact how quickly and widely the technology could be implemented in the rulemaking timeframe.

The agencies also disagree with commenters that the HCR2 engine map should be used as a proxy for other vehicles in the fleet that achieve high thermal efficiency. None of the existing vehicles that commenters cited, like the 2019 Toyota Camry and Corolla with cEGR or the 2019 Mazda CX5 and Mazda 6 with cylinder deactivation, include the same combination of technologies as the HCR2 engine. Unlike other engine technologies in the NPRM and the final rule analysis, no engines in the market or in prototype stages exist that have the combined technology specifications of the HCR2. Accordingly, there is no production vehicle that demonstrates the combination of technologies as applied in the HCR2 engine that (1) is feasible, and (2) can achieve the same effectiveness as the modeled HCR2 engine. The NPRM highlighted concerns about using the HCR2 engine map as a proxy for new engine technologies that achieve high thermal efficiency, specifically that:

It is important to conduct a thorough evaluation of the actual new production engines to measure the brake specific fuel consumption and to characterize the improvements attributable to friction and thermal efficiency before drawing conclusions. Using vehicle level data may misrepresent or conflate complex interactions between a high thermal efficiency engine, engine friction reduction, accessory load improvements, transmission technologies, mass reduction, aerodynamics, rolling resistance, and other vehicle technologies.⁸⁴⁴

The agencies continue to believe this is true, and Toyota's comments that the Camry improvements were due to more than just the engine improvements, as discussed further below, provide further support to this conclusion.

Several commenters cited EPA's SAE paper discussing the use of the HCR2 engine model and comparing it to the benchmarking of a 2018 Toyota Camry

⁸⁴² Schenk, C. and Dekraker, P., "Potential Fuel Economy Improvements from the Implementation of cEGR and CDA on an Atkinson Cycle Engine," SAE Technical Paper 2017-01-1016, 2017, doi:10.4271/2017-01-1016.

⁸⁴³ Schenk, C. and Dekraker, P., "Potential Fuel Economy Improvements from the Implementation of cEGR and CDA on an Atkinson Cycle Engine," SAE Technical Paper 2017-01-1016, 2017, doi:10.4271/2017-01-1016.

⁸⁴⁴ 2015 NAS at p. 90 and 91.

⁸⁴⁴ 83 FR 43038.

2.5L engine.⁸⁴⁵ The commenters cited the HCR2 engine's similarities to the Toyota Camry engine as a reason to employ the technology model broadly across the entire vehicle fleet, including applying it to pickup trucks such as the Toyota Tacoma. In the paper, EPA benchmarked a 2018 Toyota Camry 2.5L Atkinson cycle engine equipped with cEGR. EPA created a full vehicle model (the exemplar vehicle) based on the benchmarked data for use in the ALPHA modeling tool. The full vehicle simulation was used to compare the HCR2 engine to the Camry's 2.5L engine, and showed some similarities. The paper implied that it is possible to adopt more technologies to the MY 2018 Camry, like cylinder deactivation, to meet future standards.

This paper, and the comments relying on it—specifically that it shows that additional technologies can be added to the MY 2018 Camry engine to meet future standards—were the subject of considerable debate in the rulemaking docket. Toyota provided supplemental comments regarding issues Toyota had with the modeling and simulation. These included a detailed discussion on why HCR2 is not a reasonable model of the 2018 Toyota Camry engine. Toyota identified other technologies that contributed to the overall thermal efficiency of the 2018 Camry compared to previous generation.⁸⁴⁷ Toyota stated that the 2018 Toyota Camry employed numerous technologies like SGDI, cEGR, optimized intake system, optimized exhaust system, optimized piston design, laser-cladded valve seats, VVT, engine friction reduction, variable oil pump, and electric coolant pump, that all contributed to the engine's improved efficiency over the previous version.⁸⁴⁸

In addition, Toyota stated:

[T]he 2018 Exemplar Vehicle that is based on the baseline 2018 Toyota Camry was equipped with engine start stop that doesn't exist on the production vehicle. Cylinder deactivation was added to the 2025 exemplar vehicle as a protentional enhancement. We acknowledged that adding cylinder

deactivation to the Atkinson-cycle engines is technically possible and would provide some fuel economy benefits. However, the primary function of cylinder deactivation is to reduce engine pumping losses which the Atkinson cycle and EGR already accomplish. The diminishing return on the cylinder deactivation, Atkinson cycle and EGR are further exaggerated by smaller 4-cylinder engines.

This assessment aligns with the 2015 NAS committee report that estimated a 0.7 percent fuel consumption improvement for adoption of cylinder deactivation for DOHC and SOHC V6 and V8 engines.⁸⁴⁹ The agencies agree with Toyota and the NAS assessment that applying cylinder deactivation in small cylinder count engines is subject to diminishing returns.

The agencies agree with Toyota that the presence of the advanced technologies, in addition to the HCR technology, contributed to the performance of the Camry. The analysis already provides benefits for the other advanced technologies individually, and risks, if not ensures, double counting these benefits if the HCR2 model is used (as discussed above and in VI.B). Likely double counting of technology effectiveness further supported the agencies' choice not to use the HCR2 model for the final rule analysis.

The agencies disagree that the approach taken to modeling ADEAC technology should similarly apply to modeling the HCR2 engine, or that because ADEAC just recently entered the market and was employed in the modeling, HCR2 should be as well. As discussed further below, the effectiveness estimates for ADEAC were based on extensive discussions with suppliers and manufacturers that provided CBI data, and technical publications.⁸⁵⁰ The effectiveness estimates provided for ADEAC represented the effects of applying a single technology, and not a combined estimate for several technologies applied at once. Moreover, as commenters noted, ADEAC had recently “come to market readiness,”⁸⁵¹

compared to the HCR2 technology which cannot be found, as modeled, in the market, or even in prototype form. As discussed throughout this document, the preferred approach for the NPRM and final rule was to isolate the effectiveness improvement attributable to specific technologies and apply those

through full vehicle simulations to capture technology synergies and dis-synergies appropriately.

The agencies also disagree with ICCT's comment that the agencies were simply deferring to stakeholders, or that EPA was simply deferring to NHTSA regarding the feasibility of the HCR2 engine. It is reasonable to assume that the automobile manufacturers that belong to the Alliance employ some engine experts that are qualified to speak on the feasibility of an engine. Not just one or two manufacturers objected to the HCR2 engine; the Alliance commented on behalf of its members in support of the exclusion of the engine from the analysis,⁸⁵² and this exclusion was further supported by comments from individual automakers as well. Toyota, the automaker cited by several commenters as closest to implementing HCR2 technology stated in supplemental comments that (1) the HCR2 is not representative of its engine technology;⁸⁵³ and (2) Toyota believes there are diminishing returns for implementing the HCR2 technologies.⁸⁵⁴ The agencies received no comments from stakeholders that manufacture engines in support of the HCR2 technology's feasibility and potential future adoption.

For HCR technology, the agencies carefully considered comments to the NPRM and the available data, and concluded it is appropriate to include HCR0 and HCR1 engine models for the final rule analysis. The engine maps for those technologies provide the best estimates for the effectiveness of HCR technology relative to the engine maps for the other engine technologies used for the analysis. The agencies have reconsidered issues associated with the HCR2 engine models and maps. The agencies find that significant technical questions and issues remain and the engine maps very likely overstate the feasible amount of effectiveness that could be achieved by the represented technologies. Therefore, HCR2 technology is not included for the final rule analysis.

(4) HEV Atkinson Cycle Engines

Three types of Atkinson technology were discussed in the previous section.

⁸⁵¹ NHTSA–2018–0067–11985.

HEV Atkinson cycle engines fall in the first category, operating solely or primarily in Atkinson mode, supported by an electric drive.

Engine map 26 (Eng26) is the model of the HEV/PHEV Atkinson cycle engine used for the NPRM and final rule analysis. The engine was based on Argonne's Advanced Mobility Technology Laboratory (AMTL) 2010 Toyota Prius test data and published literature.⁸⁵⁵ Argonne's AMTL is continuously involved in research and testing of advanced technologies, especially in areas of electrification, and has a large existing database of test data from advanced technology vehicles.⁸⁵⁶ As a result of Argonne's continued research, a 2017 Toyota Prius was characterized for an independent project. Argonne updated the HEV Atkinson cycle engine using the new Prius data to reflect the 41 percent thermal efficiency of the new 2017 system.⁸⁵⁷ The electrification technology groups that used Eng26 include powersplit hybrid vehicles (SHEVPS) and plug-in powersplit hybrid vehicles (PHEV20/50).

(5) Advanced Cylinder Deactivation Technologies

Advanced cylinder deactivation (ADEAC) systems, also known as rolling or dynamic cylinder deactivation systems, allow a further degree of cylinder deactivation than the base DEAC. ADEAC allows the engine to vary the percentage of cylinders deactivated and the sequence in which cylinders are deactivated, essentially providing "displacement on demand" for low load operations.

ADEAC systems may be integrated into the valvetrains with moderate modifications on OHV engines. However, while the ADEAC operating concept remains the same on DOHC engines, the valvetrain hardware configuration is very different, and application on DOHC engines is projected to be more costly per cylinder due to the valvetrain differences.

The agencies discussed assumptions and effectiveness for the ADEAC package in the NPRM preamble.⁸⁵⁸ The

initial review of this technology was based on a technical publication that used a MY 2010 engine design that had incorporated a SOHC VVT basic engine.⁸⁵⁹ Other preproduction 8-cylinder OHV prototype vehicles with ADEAC were briefly evaluated for this analysis, but no production versions of the technology have been studied.⁸⁶⁰ For ADEAC fuel consumption effectiveness values, no engine map was available at the time of the NPRM analysis. Accordingly, the agencies took the effectiveness values as predicted by full vehicle simulations of a DEAC engine with SGDI, VVL, and VVT, and added 3 percent or 6 percent respectively for I-4 engines and V-6 or V-8 engines, and cross-referenced CBI data to quality check this approach.

The agencies noted two potential approaches to including advanced cylinder deactivation in the full-scale Argonne simulation modeling analysis for the final rule. First, the agencies proposed using IAV Eng25a, which was developed to capture the maximum benefits of advanced cylinder deactivation with several constraints that could include emissions, cold start, NVH, and durability. Second, the agencies proposed using a technique developed by Argonne in coordination with NHTSA to split the overall engine data into individual cylinder data and compute overall torque and the fuel consumption rate by accounting for whether each cylinder is active or inactive. The agencies sought comment on using either approach in the final rule analysis to capture best the benefits of advanced cylinder deactivation.

CARB, ICCT, Meszler Engineering Services, HDS, and UCS provided a mixed set of comments on numerous aspects of ADEAC in the NPRM analysis.⁸⁶¹ Broadly, HDS commented on a need to describe ADEAC technology better: "The 2018 analysis also utilized Advanced Cylinder Deactivation in its analysis but the

package components were not completely explained in the PRIA."⁸⁶² Other stakeholders provided comments on ADEAC adoption features, effectiveness, and cost, which are discussed below.

The agencies discussed assumptions and effectiveness for the ADEAC package in the NPRM preamble.⁸⁶³ The initial review of this technology was based on a technical publication that used a MY 2010 engine design incorporating SOHC and VVT.⁸⁶⁴ After determining the MY2010 engine design was not representative of the analysis fleet, the agencies used effectiveness values based on CBI data. The MY2017 baseline fleet reflects technology updates such as SGDI and DEAC that could adopt ADEAC incrementally in the final rule analysis. The cost and effectiveness for ADEAC reflects the baseline engine. The 2015 NAS Committee estimated an 0.7 percent fuel consumption improvement for adoption of cylinder deactivation for V6s and V8s engines.⁸⁶⁵ ⁸⁶⁶

The agencies requested comments on alternative methods to estimate ADEAC effectiveness but received no comments regarding either approach mentioned in the NPRM. For the final rule analysis, the agencies used effectiveness values as predicted by full vehicle simulations of a DEAC engine with SGDI, VVL, and VVT, and added 3 percent or 6 percent respectively for I-4 engines and V-6 or V-8 engines for the naturally aspirated engines. Effectiveness for turbocharged engines used 1.5 percent and 3 percent values, as predicted by full vehicle simulation of a TURBOD engine for I4 and V6/V8, respectively. Without sufficient data to simulate ADEAC, both the IAV and Argonne methodologies described in the NPRM provided questionable estimates for ADEAC. These errors would have propagated across other technology combinations in the analysis. The estimates used for ADEAC and TURBOD for the final rule analysis are also in line with EPA

estimates discussed in their SAE technical publications.⁸⁶⁷

For the final rule analysis, the agencies used the same effectiveness values for ADEAC applied to naturally aspirated engines as in the NPRM, and incorporated estimated effectiveness values for TURBOAD to represent ADEAC on downsized turbocharged engines.

(6) Miller Cycle Engines

In the proposed rule, the agencies provided two engine maps representative of Miller cycle and Eboost engines with 48V battery systems. The Miller cycle engine (Eng23b) and Miller cycle engine with Eboost (Eng23c) specifications were provided in the PRIA but were not used in the NPRM analysis,⁸⁶⁸ although the agencies sought comment on the specifications used for the modeling.

Roush on behalf of CARB, ICCT, Meszler Engineering on behalf NRDC, HDS, and UCS, commented that the agencies did not consider the combination of turbocharging and Miller cycle.⁸⁶⁹ Specifically, Roush argued that the agencies' omission of an engine that utilizes a combination of turbocharging and Miller cycle was unreasonable because it is already in production, specifically on the VW 2.0L EA888 Gen3B—DI. Roush stated this omission would limit the effectiveness for turbocharged engines and cause the adoption of more expensive solutions, thereby overstating the cost to achieve target fuel economy levels. Similarly, Roush pointed to the omission of an engine that uses a variable geometry turbocharger as an error in the agencies' model; Roush pointed to VW's EA211 TSI Evo engine available in Europe in 2017 as an example of an engine in production that enables cost-effective Miller cycle applications.

In response to these comments, the agencies added and used both Miller cycle-type engines and Miller cycle engines with electric assist for the final rule analysis. Discussed earlier in this section, the agencies developed engine maps for additional combinations of technologies for the final rule, including engine maps that became available after the NPRM analysis was completed but before the NPRM was published. For the final rule analysis, the agencies have

included a Miller cycle engine, Eng23b (VTG), as another available engine technology. The specification of this engine was discussed in PRIA Chapter 6.3.2.2.20.20.2.2 and the costs are based on the 2015 NAS estimates for this technology.

(7) Variable Compression Ratio Engines

Variable compression ratio (VCR) engines work by changing the length of the piston stroke of the engine to operate at a more optimal compression ratio and improve thermal efficiency over the full range of engine operating conditions. Engines using VCR technology are currently in production, but appear to be targeted primarily towards limited production, high performance and very high BMEP (27–30 bar) applications.

A few manufacturers and suppliers provided information about VCR technologies, and several design concepts were reviewed that could achieve a similar functional outcome. In addition to design concept differences, intellectual property ownership complicates the ability of the agencies to define a VCR hardware system that could be widely adopted across the industry.

For the NPRM analysis, the agencies provided specifications of a VCR engine (Eng26a) in the PRIA for review and comment.⁸⁷⁰ However the VCR engine was not used in the NPRM analysis.

The Alliance commented in support of the exclusion of variable compression ratio engines from the analysis, stating that the technology is still in early development, and too speculative to be included at this time. The Alliance also stated that the technology is unlikely to attain significant penetration in the MY 2026 timeframe due to intellectual property protection associated with early implementations and its likely application primarily to high-performance vehicles. The Alliance also cited the technology's price as a potential barrier to adoption.⁸⁷¹ Similarly, Ford commented that:

[VCR technology] is likely to be adopted only for premium/limited-market vehicles in the near future. We also agree that intellectual property protections on early implementations will further inhibit significant fleet penetration. Incorporation of VCR requires a new or highly modified engine architecture, necessitating major investment from both the engineering and manufacturing standpoints. Sharing/

commonality across engine families would be greatly limited.”^{872 873}

Similarly, other automakers commented on a confidential basis that several main hurdles prevented them from employing VCR engines, including the complexity of VCR engines and the associated cost of those complex parts.

UCS commented that the agencies did not consider VCR engine technologies in the NPRM analysis.⁸⁷⁴ They stated that the technology was not modeled, nor was it incorporated into the CAFE model. UCS argued that Nissan's VC-Turbo engine is part of a strategy to improve fuel efficiency for Nissan's luxury vehicles by 30–35 percent over previous models, which would be enough to exceed the vehicle's regulatory targets without any credits. UCS concluded that given VCR technology is being put into production in a high-volume vehicle, there is no reason for the agencies to exclude its adoption.

The agencies agreed with comments to include VCR engine technologies in the final rule analysis and on further technical consideration, the agencies have added a VCR engine to the engine technologies list manufacturers could adopt. However, the agencies limited the adoption of the VCR engine technology to Nissan only. VCR engines are complex, costly by design, and synergetic with mainstream technologies like downsize turbocharging, making it unlikely that a manufacturer that has already started down an incongruent technology path would adopt VCR technology.

(8) Diesel Engines

Diesel engines have several characteristics that result in superior fuel efficiency over traditional gasoline engines, including reduced pumping losses due to lack of (or greatly reduced) throttling, high pressure direct injection of fuel, a combustion cycle that operates at a higher compression ratio, and a very lean air/fuel mixture relative to an equivalent-performance gasoline engine.⁸⁷⁵ However, diesel technologies requires additional enablers, such as a NO_x adsorption catalyst system or a urea/ammonia selective catalytic reduction system, for control of NO_x emissions.

For the NPRM, the agencies modeled one diesel engine, represented by

⁸⁶⁷ Kargul, J., Stuhldreher, M., Barba, D., Schenk, C. et al., “Benchmarking a 2018 Toyota Camry 2.5-Liter Atkinson Cycle Engine with Cooled-EGR,” SAE Int. J. Adv. & Curr. Prac. in Mobility 1(2):601–638, 2019, <https://doi.org/10.4271/2019-01-0249> at pp. 19–21.

⁸⁷⁵ Diesel cycle is also a four-stroke cycle like the Otto Cycle, except in the Intake stroke no fuel is injected and fuel is injected late in the compression stroke at higher pressure and temperature.

Eng17,⁸⁷⁶ which was termed “ADSL” in the CAFE modeling. DSLI, a more advanced diesel engine, was modeled using a 4.5 percent fixed effectiveness improvements over ADSL.

CARB commented that diesel technologies are essentially locked out of being selected in the CAFE model because of the high cost.⁸⁷⁷ They state that diesel technology is only selected in rare instances.

The agencies agree that diesel technology is rarely selected. The technologies required to meet diesel emissions standards are costlier compared to gasoline technologies, particularly in the rulemaking timeframe. For example, the 2015 NAS report determined that in the current market, “vehicles with diesel engines are priced an average of more than \$4,000 more than comparably equipped gasoline vehicles.”⁸⁷⁸ Furthermore, the NAS report stated that the “Carbon Penalty” makes it harder for manufacturers to meet CO₂ standards because of the higher carbon density in the diesel fuel compared to gasoline that results in higher CO₂ per gallon.⁸⁷⁹ In addition, the market for diesel vehicles has stagnated at around 1 percent for many years after it peaked at 5.9 percent in 1981, according to the EPA Trends Report.⁸⁸⁰ The agencies believe that the modeled cost of diesel engines appropriately prevents their widespread adoption in the analysis.

UCS commented that the agencies restricted cylinder deactivation technologies to only naturally aspirated gasoline engines.⁸⁸¹ In response to this and other comments, the agencies have allowed diesel engines to adopt ADEAC for this final rule analysis. These engines were designated as DSLIAD to represent diesel engines with ADEAC, and were modeled using a 7.5 percent fixed effectiveness improvement on top of DSLI. This effectiveness improvement of ADEAC on diesel engines is based on the review of technical publications discussed earlier in Section VI.C.1.c)(5).

(9) Alternative Fuel Engines

CNG engines use compressed natural gas as a fuel source. The fuel storage and supply systems for these engines differ tremendously from gasoline, diesel, and

flex fuel vehicles. CNG engines were a baseline-only technology and were not applied to any vehicle that was not already CNG-based in NHTSA’s analysis, per EPCA/EISA’s restrictions on considering dedicated alternative fueled vehicles to set fuel economy standards.⁸⁸² However, for the EPA program the agencies allowed any vehicle to adopt CNG engines. The NPRM MY 2016 analysis fleet did not include any dedicated CNG vehicles to simulate in the CAFE Model.

In addition, for the NPRM and this final rule analysis, NHTSA modified the CAFE model to include the specific provisions related to AFVs under the CO₂ standards. In particular, the CAFE model now carries a full representation of the production multipliers related to electric vehicles, fuel cell vehicles, plug-in hybrids, and CNG vehicles, all of which vary by year through MY 2021.

(10) Emerging Gasoline Engine Technologies

Manufacturers, suppliers, and researchers continue to create a diverse set of fuel economy technologies, some of which are still in the early stages of the development and commercialization process. Due to uncertainties in the cost and capabilities of emerging technologies, some new and pre-production technologies are not a part of the CAFE model simulation. As discussed throughout this section and in VI.B.3, the agencies declined to include technologies in the analysis where the agencies did not believe those technologies would be feasible in the rulemaking timeframe, or the agencies did not have appropriate data upon which to generate an estimate of how effective the technology is that could be applied across the ten vehicle classes. Evaluating and benchmarking promising fuel economy technologies as they enter production-intent stages of development continues to be a priority as commercial development matures.

UCS and ICCT commented that the agencies should consider novel engine

designs.⁸⁸⁴ Specifically, ICCT stated that the agencies should consider a more advanced HCR technology called HCCI (similar to Mazda’s Skyactiv-X) by estimating efficiency and cost to EPA’s process that assigned effectiveness estimates using LPM. They stated that “the agencies developed estimates for ADEAC in the NPRM and the associated modeling even without conclusive and independently verifiable effectiveness.”

In response to comments, a number of technologies were added for the final rule analysis, and adoption features were refined accordingly, as discussed further in Section VI.C.1.e). New engine technologies and combinations include Atkinson engine technology allowed with P2 HEV, new high compression ratio engine (HCR0), variable compression ratio engine, variable geometry turbo engine, variable geometry turbo with electric assist engine, diesel with advanced cylinder deactivation engine, turbo with cylinder deactivation engine, diesel with manual transmission, diesel with start-stop, and PHEV-turbo with 20 mile range, and PHEV-turbo with 50 mile range.

The agencies also disagree with ICCT’s comment that because ADEAC was developed without “conclusive and independently verifiable effectiveness” estimates, and as such the agencies should allow HCCI technology as well. First, conclusive estimates for ADEAC effectiveness were based on CBI data from both manufacturers and suppliers, technical publications, and engineering judgement. The references can be reviewed in the previous Section VI.C.1.c)(5) Advanced Cylinder Deactivation Technologies. In addition, the agencies benchmarked the first prototype vehicle equipped with skip-fire, and discussed potential application of it for other engines. A similar level of data has not been made available for HCCI engine technologies.

The agencies also believe that the technology associated with Mazda SkyActiv-X has been mischaracterized by ICCT and other commenters, and declined to include a specific representation of the SkyActiv-X family of technologies in the analysis for two reasons. The engine known as Skyactiv-X is characterized by Mazda as a unique spark plug controlled compression ignition (SPCCI) technology, 2-liter displacement, 4-cylinder engine with mechanical compression ratio of 16.3:1 operating on 95 RON fuel (91 AKI) with

⁸⁸¹ Docket ID NHTSA–2018–0067–12039, at p. 3.

⁸⁸² NHTSA’s provisions for dedicated alternative fuel vehicles in 49 U.S.C. 32905(a) state that the fuel economy of any dedicated automobile manufactured after 1992 shall be measured based on the fuel content of the alternative fuel used to operate the automobile. A gallon of liquid alternative fuel used to operate a dedicated automobile is deemed to contain 0.15 gallon of fuel. Under EPCA, for dedicated alternative fuel vehicles, there are no limits or phase-out for this special fuel economy calculation, unlike for dual-fueled vehicles, as discussed below.

⁸⁸³ EPA’s provisions for dedicated alternative fuel vehicles that are able to run on compressed natural gas (CNG) currently are eligible for an advanced technology multiplier credit for MYs 2017–2021.

UCS, Comment, Docket No. NHTSA–2018–0067–12039, at pp. 6 & 7.

a mild hybrid system.⁸⁸⁵ The NPRM and this final rule analysis may not have the exact technology combination associated with this vehicle, but the analysis does include technologies that are representative of them, that could enable the benefits employed by the Mazda engine. A mild hybrid system is available for adoption in both the NPRM and this final rule analysis.

Also, the effectiveness associated with this engine was from European test cycles and cannot be compared for U.S. application. European compliance tests are significantly different than those in the U.S., especially when it comes to fuel type and test cycles. Any effectiveness data provided for this engine or any non-U.S. engine cannot be used for U.S. vehicle application without an adjustment for fuel and emissions. For example, the higher-octane fuel used in Europe enables engines to operate at higher compression ratios across wider areas of engine operation.

The agencies further believe that with the technology additions for the final rule discussed in previous sections, the analysis reasonably represents the suite of engine technologies that could be available in the rulemaking time frame. Manufacturers, suppliers, and researchers continue to create a diverse set of fuel economy technologies. However, due to the uncertainties in the cost, manufacturing, and intellectual property concerns like those identified by commenters, the agencies did not consider prototype technologies in the final rule analysis.

(11) Engine Lubrication and Friction Reduction Technologies

Manufacturers have already widely adopted both lubrication and friction reduction technologies. Previous agency analysis considered these improvements in combination as Improved Low Friction Lubricants and Engine Friction Reduction (LUBEFR). The NPRM analysis included advanced engine maps that already assume application of low-friction lubricants and engine friction reduction technologies, and

therefore additional levels of friction reduction were not considered. Low-friction lubricants including low viscosity and advanced low-friction lubricant oils are now available, and widely used. Manufacturers may make engine changes and conduct durability testing to accommodate the lubricants. The level of low-friction lubricants exceeded 85 percent penetration in the MY 2016 fleet.⁸⁸⁶ Reduction of engine friction can be achieved through low-tension piston rings, roller cam followers, improved material coatings, more optimal thermal management, piston surface treatments, and other improvements in the design of engine components and subsystems that improve efficient engine operation.

Meszler Engineering on behalf of NRDC commented that “the NPRM CAFE model no longer considers advanced lubricants and evolutionary friction reduction (LUBEFR) to be adoptable. As a result, no fuel efficiency improvement credits are available. Engine friction reduction is an ongoing evolutionary process that should generate benefits on the order of 5 percent or so increase in fuel economy over a multiyear forecast period, with costs totaling approximately \$100. Moreover, the technology is a benefit of ongoing industry research and evolutionary engine improvements so that it is easily ‘adoptable’ and deployed throughout the fleet. Accordingly, NHTSA should revise the NPRM CAFE model to reinstate the ability to adopt evolutionary friction reduction technology.”⁸⁸⁷

The agencies disagree with Meszler that a five percent fuel economy improvement attributable to lubricants and evolutionary friction reduction is continuously feasible. The MY 2017 baseline vehicles have incorporated many technologies like low viscosity engine oil, integrated exhaust manifold for faster oil warmup, and internal component friction reduction.^{888 889 890}

The LUB and EFR technologies are a legacy of the existing rulemaking work going back to the 2010 CAFE and CO₂ rule for MY 2012 to MY 2016.⁸⁹¹ The agencies believe that many of these technologies have been incorporated in many of the engines in the baseline fleet, and therefore the engine maps used for the NPRM and final rule analysis incorporated them as well. Furthermore, manufacturers have raised concerns over issues with further decreasing oil viscosity; specifically, manufacturers have articulated concerns that damage caused by low speed pre-ignition (LSPI)⁸⁹² can damage an engine.^{893 894 895}

In response to the comment that engine friction reduction technology is evolutionary technology, the agencies introduced one level of friction reduction (EFR) for the final rule analysis. The agencies estimated a 1.4 percent effectiveness for this type of technology based on the 2015 NAS report assessment of further improvements in lubrication and friction.⁸⁹⁶

⁸⁹² LSPI is an abnormal combustion event in which the fuel-air mixture ignites before intended, causing excessive pressures inside the engine’s cylinders. In mild cases, this can cause engine noise, but when severe enough, LSPI can cause engine damage. There are several factors that contribute to LSPI, of which lubricating oil has been observed to be one.

Manufacturers have made significant improvements in fuel economy and CO₂ emissions reductions since the MY 2012 rulemaking analysis.^{897 898} The agencies expended substantial effort to update the analysis fleet from the MY 2016 representative fleet used for the NPRM to a MY 2017 analysis fleet used for this final rulemaking to capture the technologies manufacturers have used to increase their fleet's fuel economy and CO₂ emissions performance. Detailed discussion of the model year 2017 fleet development and application can be found in VI.B.1. The agencies extensively updated the new MY 2017 fleet engine technologies using available manufacturer final model year CAFE compliance submissions to the agencies, as well as manufacturer press release specifications, agency-sponsored vehicle benchmarking studies, review of available technical publications, and through manufacturer CBI.⁸⁹⁹

The data for each manufacturer was used to determine which platforms shared engines and to establish the leader-follower relationships between vehicles. Within each manufacturer's fleet, engines were assigned unique identification designations based on configuration, and technologies applied, along with other characteristics. The data were also used to identify the most similar engine among the IAV engine maps, as discussed in Section VI.C.1.

Just like the real-world vehicle variants, the CAFE model considers differences between each vehicle like base performance and higher performance levels. For example, the 2017 Ford F150 has many variants with different types of engines like the 2.7L turbocharged V6, 3.3L naturally-aspirated V6, 3.5L turbocharged V6, and 5L naturally-aspirated V8. In contrast to the LPM, the CAFE model rosters each variant level and powertrain application individually. This variation is accounted for as engine technologies are assigned in the analysis fleet.

As a result of new information available since publication of the NPRM and comments received to the NPRM, the agencies included additional engine technologies in the compliance analysis, expanding the total number of engine

technologies available from 16 to 23. This expansion is a direct result of comments received to the NPRM and further enables the agencies' capabilities to accurately and, realistically, characterize the technologies present on an engine found in the analysis fleet. This collection of technologies represents the best available information the agencies have, at the time of this action, regarding both currently available engine technologies and engine technologies that could be feasible for application to the U.S. fleet during the rulemaking timeframe. The agencies believe this effort has yielded the most technology-rich and accurate analysis fleet utilized by the CAFE model to date.

In some cases, however, it was necessary for the agencies to substitute an engine map that closely represented an engine technology that were effectively the same, or, based on engineering judgement, were the best available proxy at the time of the analysis. For example, many manufacturers offer their own proprietary VVT engine technologies and so the agencies assigned the same engine map for all of these VVT in the baseline fleet. The CAFE model uses compliance CAFE and CO₂ values for baseline vehicles and so it's not as relevant to have exact technology assignment type as it more important to provide the advanced vehicle have adopted to date. For further discussion of this see section VI.A.3 Fuel-Savings Technologies. This substitution was necessary, in some cases, where an "exact-match" engine map was not available for application to a specific vehicle and/or vehicle specific engine application. The agencies leveraged a series of engine operating characteristic maps developed by industry suppliers and, in some cases, the agencies themselves, to assign the closest baseline engine map for the analysis.

As discussed in Section VI.C.1.b), these engine maps provide operational characteristics such as horsepower, torque, or efficiency at a specified point in an engine's operational range. These operational maps are developed based on a given set of engine characteristics and technologies applied to that engine. Engine maps are closely held by vehicle manufacturers and are typically considered intellectual property. As such, vehicle manufacturers are not typically willing provide the operational maps to the agencies, where it would ultimately be in the purview of competitors. In some instances, manufacturer engine maps are published in media such as technical papers or conference presentation

materials. However, these publicly available engine maps are, in nearly all instances, void of critical information that would enable their use for meaningful simulation and modeling.

Therefore, the agencies are generally limited to the catalog of engine maps they have developed through contracts and, where possible, in-house which, in turn, yields the need for sound, engineering judgement-based substitution of an engine map as a proxy for an engine application in the marketplace. Unfortunately, this is necessary as the agencies are unable to fund the development of engines maps for every possible engine and technology combination available for sale. However, it is important to note the agencies do have a substantial catalog of engine maps to leverage and continue to fund the development of new maps as new technologies enter the marketplace. Additional information on the agencies' catalog of engine maps used for this final rulemaking can be found in Section VI.C.1.b).

Some engine technologies are designated in the CAFE Model as "baseline only" technologies, meaning these are characteristics such as engine configuration, architecture, or a technology that is considered inherent to the fleet for the given model year, an example for the MY 2017 fleet used in this analysis is variable-valve-timing (VVT). Beyond the aforementioned configurations and technology, engine technologies that can be applied to a future engine and, eventually, to a vehicle in the compliance modeling are only available at a vehicle redesign. As such, a vehicle will only adopt a new engine according to the application schedule defined as a CAFE model input.

e) Engine Adoption Features

Engine adoption features are defined through mechanisms like technology path logic or the application of selection logic, refresh and redesign cycles, and phase-in capacity limits. Most of the technology adoption features from the NPRM have been carried over for the final rule analysis. However, the final rule analysis also included adoption features for the new technologies incorporated in the final rule analysis. For a detailed discussion of CAFE model path logic for the final rule analysis, including technology supersession logic and technology mutual exclusivity logic, please see Section IV.

Figure VI-18 and Figure VI-19 below show the engine technology paths used for the NPRM and this final rule analysis, respectively. The engine

technology paths have increased to incorporate new advanced technologies

manufacturers could adopt into their fleet.

BILLING CODE 4910-59-P

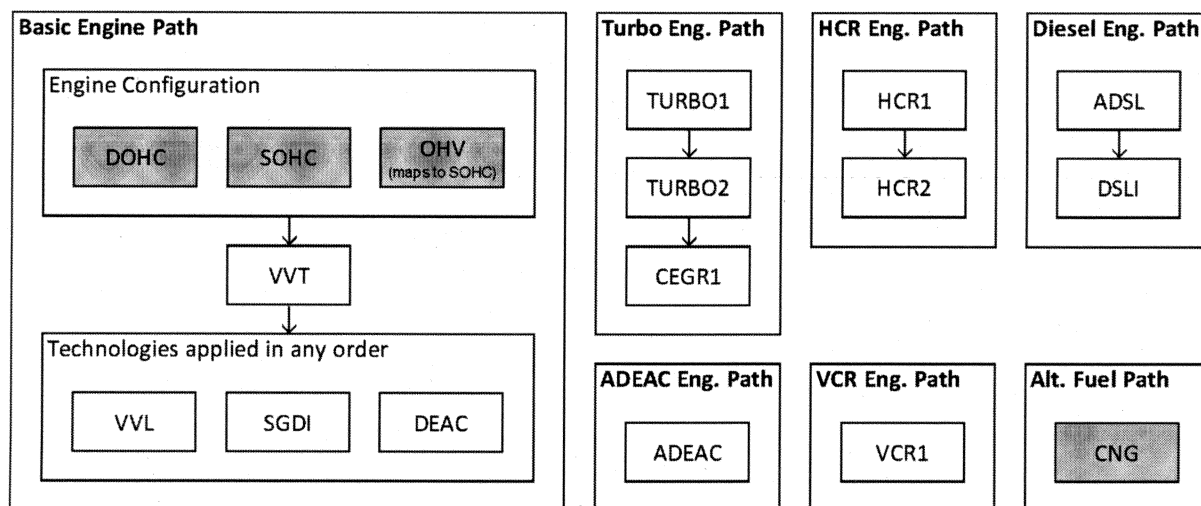

Figure VI-18 – Engine Paths Used for the NPRM Analysis

Figure VI-19 – Engine Paths Used for the Final Rule Analysis

BILLING CODE 4910-59-C

Similar to the 2012 final rule for MYs 2017–2025, this final rule analysis also considered real-world limits when the defining the rate at which technologies can be deployed.⁹⁰⁰ During the rulemaking timeframe, manufacturers are expected to go through the normal automotive business cycle of redesigning and upgrading their light-

duty vehicle products. This allows manufacturers the time needed to incorporate fuel economy improving and CO₂ reducing technologies into their normal business cycle. This is important because it has the potential to avoid the much higher costs that could occur if manufacturers need to add or change technology at times other than their scheduled vehicle redesigns. This time period also provides manufacturers the opportunity to plan for compliance

using a multi-year time frame, again consistent with normal business practice.

Section II.G.3.a of the NPRM provided substantial discussion of how an “application schedule” is used by the CAFE model to determine when manufacturers are assumed to be able to apply a given technology to a vehicle. The NPRM application schedule for engine technologies is reproduced in Table VI-43, which shows that all of the

⁹⁰⁰ 77 FR 62712.

engine technologies may only be

applied (for the first time) during redesign.

BILLING CODE 4910-59-P

Table VI-43 – NPRM CAFE Model Engine Technologies Application Schedule

| Technology | Application Level | Application Schedule | Description |
|-------------------|--------------------------|-----------------------------|--|
| SOHC | Engine | Baseline Only | Single Overhead Camshaft Engine |
| DOHC | Engine | Baseline Only | Double Overhead Camshaft Engine |
| OHV | Engine | Baseline Only | Overhead Valve Engine (maps to SOHC) |
| VVT | Engine | Baseline Only | Variable Valve Timing |
| VVL | Engine | Redesign Only | Variable Valve Lift |
| SGDI | Engine | Redesign Only | Stoichiometric Gasoline Direct Injection |
| DEAC | Engine | Redesign Only | Cylinder Deactivation |
| HCR | Engine | Redesign Only | High Compression Ratio Engine |
| HCR2 | Engine | Redesign Only | High Compression Ratio Engine with DEAC and CEGR |
| TURBO1 | Engine | Redesign Only | Turbocharging and Downsizing, Level 1 (18 bar) |
| TURBO2 | Engine | Redesign Only | Turbocharging and Downsizing, Level 2 (24 bar) |
| CEGR1 | Engine | Redesign Only | Cooled Exhaust Gas Recirculation, Level 1 (24 bar) |
| ADEAC | Engine | Redesign Only | Advanced Cylinder Deactivation |
| CNG | Engine | Baseline Only | Compressed Natural Gas Engine |
| ADSL | Engine | Redesign Only | Advanced Diesel Engine |
| DSLI | Engine | Redesign Only | Diesel engine improvements |

For this final rulemaking action, a similar schedule is employed, and has been updated with information gathered

since the NPRM and through comments provided to the agencies.

Table VI-44 presents the engine technology application schedule used for the final rule CAFE modeling.

Table VI-44 – Final Rule CAFE Model Engine Technologies Application Schedule

| Technology | Application Level | Application Schedule | Description |
|-------------------|--------------------------|-----------------------------|---|
| SOHC | Engine | Baseline Only | Single Overhead Camshaft Engine |
| DOHC | Engine | Baseline Only | Double Overhead Camshaft Engine |
| OHV | Engine | Baseline Only | Overhead Valve Engine (maps to SOHC) |
| EFR | Engine | Redesign Only | Improved Engine Friction Reduction |
| VVT | Engine | Redesign Only | Variable Valve Timing |
| VVL | Engine | Redesign Only | Variable Valve Lift |
| SGDI | Engine | Redesign Only | Stoichiometric Gasoline Direct Injection |
| DEAC | Engine | Redesign Only | Cylinder Deactivation |

| VTGE | Engine | Redesign Only | Variable Turbo Geometry (Electric) |
| TURBOD | Engine | Redesign Only | Turbocharging and Downsizing with DEAC |
| TURBOAD | Engine | Redesign Only | Turbocharging and Downsizing with ADEAC |
| ADSL | Engine | Redesign Only | Advanced Diesel |
| DSLI | Engine | Redesign Only | Diesel Engine Improvements |
| DSLIAD | Engine | Redesign Only | Diesel Engine Improvements with ADEAC |
| CNG | Engine | Baseline Only | Compressed Natural Gas Engine |

Fuel economy improving and CO₂ reducing technologies for vehicle applications vary widely in function, cost, effectiveness, and availability. Some of these attributes, like cost and availability, vary from year to year. New technologies often take several years to become available across the entire market. The agencies use phase-in caps to manage the maximum rate that the CAFE model can apply new technologies. Phase-in caps are intended to function as a proxy for a number of real-world limitations in deploying new technologies in the auto industry. These limitations can include but are not

limited to, engineering resources at the OEM or supplier level, restrictions on intellectual property that limit deployment, and/or limitations in material or component supply as a market for a new technology develops. Without phase-in caps, the model may apply technologies at rates that are not representative of what the industry is actually capable of producing, which would suggest that more stringent standards might be feasible than actually would be. Table VI-45 and Table VI-46 below shows the phase-in caps between the NPRM and this final rule analysis, respectively.

Most engine technologies are available at a rate of 100 percent in MY2017 for the final rule analysis. Some advanced technologies that have been recently introduced for one or two vehicle models are phased in at lower rates. Technologies such as ADEAC and TURBOD are phase in at rates that represent manufacturers' adoption capability and typically have complementary effectiveness compared to other advanced technologies. These lower phase-in caps also represent intellectual property and functional performance concerns.

BILLING CODE 4910-59-P

Table VI-45 – NPRM CAFE Model Engine Phase-in Caps

| Name | Technology Description | Technology Pathway | Phase-in Cap | Phase-in Start Year |
|-------------|---|---------------------------|---------------------|----------------------------|
| VVT | Variable Valve Timing | Basic Engine | 100% | 2000 |
| VVL | Variable Valve Lift | Basic Engine | 100% | 2000 |
| SGDI | Stoichiometric Gasoline Direct Injection | Basic Engine | 100% | 2000 |
| DEAC | Cylinder Deactivation | Basic Engine | 100% | 2004 |
| TURBO1 | Turbocharging and Downsizing, Level 1 | Turbocharged Engine | 100% | 2004 |
| TURBO2 | Turbocharging and Downsizing, Level 2 | Turbocharged Engine | 100% | 2010 |
| CEGR1 | Cooled Exhaust Gas Recirculation, Level 1 | Turbocharged Engine | 100% | 2010 |
| HCR1 | High Compression Ratio Engine, Level 1 | HCR Engine | 100% | 2016 |
| HCR2 | High Compression Ratio Engine, Level 2 | HCR Engine | 100% | 2016 |
| VCR | Variable Compression Ratio Engine | VCR Engine | 100% | 2019 |
| ADEAC | Advanced Cylinder Deactivation | Advanced DEAC Engine | 100% | 2019 |
| ADSL | Advanced Diesel | Diesel Engine | 100% | 2010 |
| DSLI | Diesel Engine Improvements | Diesel Engine | 100% | 2010 |

BILLING CODE 4910-59-C

Comments received on engine adoption features were mixed, with manufacturers generally supporting the NPRM methodology, and CARB and NGOs opposing it. Several manufacturers commented, both in their public comments or on a CBI basis, that many of the emerging engine technologies had the potential to improve vehicle fuel economy, but were technically complex and addressed many of the same issues as other existing engine technologies.

We agree with manufacturers that broadly, there are technologies that, in theory, present large potential effectiveness improvements like VCR, ADEAC, and others. However, the agencies believe it is important to assure realistic adoption of these technologies into the fleet in the rulemaking time frame, so that the rulemaking analysis accurately represents the costs and benefits of different regulatory

alternatives considered. If the agencies were to select stringency based on an assumption that an emerging technology would see widespread adoption, and then it does not, the benefits of that stringency level would not be realized. The agencies have taken steps in the NPRM and this final rule analysis to consider the manufacturability and feasibility of these technologies for different vehicle types and manufacturers. Discussed earlier, the analysis considers these and other concerns by accounting for product cadence, and by implementing phase-in caps and skips, and by designating technology phase-in and phase-out years. Similar to the 2012 final rule, this final rule analysis employed these strategies to reflect better the real-world considerations faced by manufacturers.

EDF commented, referencing EPA's statutory command prescribed in Section 202(a) of the Clean Air Act that:

EPA's task is thus to identify the major steps necessary for 'development and application of the requisite technology,' and then the respective standard 'shall take effect.' These individual decisions are highly consequential: As noted above, without changing anything else about the agencies' analysis, allowing HCR2 would reduce augural compliance costs by \$619—or about 30% of the total difference between the augural and rollback scenarios. The proposal's rejection of these technologies nowhere justifies how the (unfounded and cursorily justified) concerns accord with the agency's limited discretion under Section 202(a)(2) and duty to 'press for the development and application of improved technology rather than be limited by that which exists today.' If the agency is to predict more than the results of merely assembling pre-existing components, it must have some leeway to deduce results that are not represented by present data.⁹⁰¹

CARB also commented that the CAFE Model prevents manufacturers "from

⁹⁰¹ NHTSA-2018-0067-12108 at 104.

switching between a turbocharged and HCR pathways under the premise that manufacturers either would not develop both or would be committed irreversibly to one path or the other. This assumption is not based in reality and is not reflective of actual industry practice—manufacturers who have pursued turbocharging have also already pursued HCR engines for other vehicles in their line-up. For example, General Motors (GM) utilizes downsized turbocharging in some vehicles, such as the newly designed 2019MY Silverado pick-up and the Malibu sedan which has two different turbocharged engine options. GM also has a third offering in the Malibu sedan which is an HCR naturally aspirated 1.8L equipped with cooled exhaust gas recirculation (CEGR) mated to a hybrid electric system.”⁹⁰²

CARB’s observation was true for the NPRM analysis, however for the final rule analysis the agencies allowed manufacturers to adopt engine technologies from alternate tree paths, when incorporating electrification technology, see Section VI.C.3.c). The agencies still believe that if manufacturers have invested in one type of engine technology for their vehicles that they would not transition to another technology except in the case of a major vehicle powertrain redesign, such as the inclusion of an HEV system. Additional discussion on this issue is presented in Section VI.B.1.

The following sections discuss adoption features specific to individual engine technologies, including comments received and updates (or not) for the final rule analysis.

(1) Basic Engines

Most vehicles in the MY 2017 analysis fleet that are DOHC or SOHC/OHV spark ignited engines and are not downsized turbocharged engines have any two combinations of VVT, VVL, SGDI or DEAC.⁹⁰³ For the NPRM, only engines with 6-cylinders or more could adopt DEAC and ADEAC.

HDS on behalf of CARB commented that in the NPRM analysis VVL, which is cost ineffective compared to other conventional technologies, was always included in an adopted technology package.⁹⁰⁴ HDS further stated that the “effectiveness of VVL is even smaller when the technology is combined with turbocharged downsized engines.” Accordingly, HDS stated that removing

VVL from the base pathway would save \$314 but reduce fuel economy by only 1.4 percent, according to the LPM.

The agencies did not agree with HDS’ assessment of the NPRM analysis. The agencies do not agree VVL was forced to be adopted in the analysis fleet and do not agree with how technology effectiveness values compare to LPM estimates. As discussed earlier in the effectiveness and modeling section, each engine technology was modeled independently and the CAFE model was allowed to adopt the most cost effective technology. Therefore, it is inaccurate to state, a technology is less effective, especially when comparing LPM. Particularly because VVL technologies reduce pumping losses in engines, so it is realistic that other technologies, that also reduce pumping losses, have synergetic effect. This is specifically true for turbocharged engines.

ICCT commented that DEAC technology should be available for every engine, and should not be limited to 6-cylinder and higher cylinder count engines. ICCT and CARB also commented that DEAC should be allowed on turbocharged engines. ICCT also commented that ADEAC should be widely available as it can be a viable technology application for various other powertrain technology combinations.⁹⁰⁵ Furthermore, CARB commented “automakers will combine technologies like turbocharging, HCR and DEAC as well as more technologies when they have cost-effectiveness synergies.”⁹⁰⁶

The agencies agree with ICCT that DEAC and ADEAC could be applied to additional engine types, including turbocharged engines. However, the agencies disagree with ICCT that ADEAC should be widely applied to all powertrain technology combinations in this analysis. The agencies have updated the final rule analysis to allow DEAC and ADEAC for various engine cylinder counts and for turbocharged engines.

For the final rule analysis, both DEAC and ADEAC technologies can be adopted by any naturally aspirated engine. Similarly, any turbocharged engine can also adopt cylinder deactivation technology, as characterized by TURBOD and TURBOAD in the CAFE model. In this final rule analysis, the agencies distinguished cylinder deactivation technologies between naturally aspirated and forced air induction systems.

For the final rule analysis, the agencies allow any combination of VVT, VVL, SGDI and DEAC to be adopted for any engine displacement and cylinder count. Figure VI–18 below shows the basic engine paths a vehicle could traverse for the final rule analysis. Similar to the NPRM, the agencies have not changed the adoption features of the technologies shown in Figure VI–18, with one exception. Vehicles that are SOHC or DOHC configuration that do not have VVT in the baseline can now adopt it.

Finally, the agencies disagree with ICCT and CARB that these DEAC, ADEAC, TURBOD, and TURBOAD should apply beyond these configurations. DEAC’s fundamental benefits are driven by reducing pumping losses and by enabling the engine to operate in a more thermal efficient region of the engine fuel map. Conventional spark-ignited engines control airflow into the cylinders via a throttle operated by the driver to provide the level of power that is delivered.⁹⁰⁷ In an 8-cylinder engine, when driving in light load conditions such as highway driving, there are lower engine power requirements. In a throttle controlled system, engine pumping losses increase as air flow decreases. A way to reduce pumping loss in an engine is by increasing the airflow into the cylinders. By deactivating a set of cylinders, the same power output can be delivered by a “smaller” engine. Many technologies modeled for this analysis work to reduce pumping losses, but through other mechanisms like VVT, VVL, downsized engines with turbochargers, high compression Atkinson mode cycle, and Miller Cycle.⁹⁰⁸ Transmissions with a higher number of gears also provide the opportunity to reduce pumping work of the engine.⁹⁰⁹

As discussed earlier, DEAC can reduce pumping losses, so when combined with other technologies that also reduce pumping losses, like downsized turbocharged engines, the benefits for cylinder deactivation are lower than for naturally aspirated engines because downsized turbocharged engines already have lower pumping losses due to having a downsized engine.⁹¹⁰

⁹¹⁰ 2015 NAS at p. 34.

(2) Turbocharged Downsized Engines

About 23 percent of vehicles in the MY 2017 baseline fleet had turbocharged engines. For the final rule analysis, the agencies allowed any basic engine to adopt turbo engine technology (TURBO1, TURBO2 and CEGR1) from the Turbo path similar to the NPRM analysis. This includes any combination of VVT, VVL, SGDI and DEAC for both SOHC and DOHC configurations. Vehicles that have turbocharged engines in the baseline fleet will stay on the turbo engine path to prevent unrealistic engine technology change in a short timeframe considered in the rulemaking analysis. Turbo path is a mutually exclusive technology in that it cannot be adopted for HCR, diesel, ADEAC, CNG and powersplit PHEVs.

(3) Non-HEV Atkinson Mode Engines

The NPRM analysis allowed limited application of HCR engines (HCR1 and HCR2) to vehicles in the MY 2016 baseline fleet.⁹¹¹ As discussed above, applying HCR1 or HCR2 technologies to a vehicle resulted in overstated effectiveness values relative to the baseline VVT engine,⁹¹² because of differences in how those maps were developed compared to the IAV engine maps used for the majority of the technology analysis. In an attempt to avoid unrealistic results in the NPRM, adoption of HCR1 (Eng24) technology was limited to only manufacturers that demonstrated existing use of high compression ratio technology. HCR was disallowed for other manufacturers that demonstrated an intent to develop other advanced technologies incompatible with HCR technology. In addition, the agencies disallowed HCR engines from being applied to vehicles with greater performance requirements, like 6- and 8-cylinder vehicles, because the higher load requirements from these vehicles would force the engine to exit the Atkinson mode, where maximum efficiency is achieved.

The Alliance commented in agreement with the application restrictions for HCR1 in the NPRM, listing the following justifications: “Packaging and emission constraints associated with intricate exhaust manifolds needed to mitigate high load/low revolutions per minute knock; Inherent performance limitations of Atkinson cycle engines; and Extensive capital and resources required for manufacturers to shift to HCR from other established technology pathways

(e.g., downsized turbocharging).”⁹¹³ Ford similarly commented in support of “the more restrained application of HCR1 in the Proposed Rule, an approach that recognizes the investment, packaging, performance and emissions factors that will limit penetration of this technology.”⁹¹⁴

In contrast, CARB stated that the constraint on HCR1 engines was inappropriate and did not reflect reality,⁹¹⁵ and stated that the agencies failed to supply any detailed rationale as to why HCR applications were so constrained in the CAFE Model. Specifically, CARB took issue with the justification that HCR1 is limited in the CAFE model because it is “not suitable for MY 2016 baseline vehicle models that have 8-cylinder engines and in many cases 6-cylinder engines.”⁹¹⁶ CARB stated that “the HCR1 technology is declared not suitable on 207 of the 288 engines cumulatively used by all of industry including over 50 percent of the 4 cylinder engines and nearly 90 percent of the 6 cylinder engines instead of only being restricted from 8 cylinder and ‘in many cases 6 cylinder engines.’” CARB also stated that the implied rationale for not allowing HCR1 to be applied to 6- and 8-cylinder engines because trucks or larger vehicles could not utilize it is unreasonable, as the Toyota Tacoma used a 3.5L V6 HCR Atkinson-like engine since MY 2016. CARB stated that the Toyota Tacoma was properly assigned a HCR1 engine in the MY 2016 analysis fleet file, but the engine was disallowed from other Toyota V6 engines utilized in vehicles like the Sienna minivan and 4Runner SUV. CARB commented that “[i]f the intended rationale is that HCR engines will have insufficient low end torque to satisfy truck-like towing demands, it would be inappropriate to restrict the engine from minivan and SUV applications which have a lower tow rating and lower expected towing demands.” Finally, CARB stated that the HCR1 package restrictions were inappropriate, as there was no mechanism in the CAFE model to represent appropriately the MY 2019 Dodge Ram 1500 5.7L V8 that uses “a higher compression ratio than earlier versions and using its VVT system to reduce pumping losses via delayed, or late, intake valve closing—resulting in an HCR-like engine with an over-expanded or Atkinson cycle.”

Similarly, Meszler Engineering Services, commenting on behalf of

NRDC, commented that HCR1 appears as a baseline technology on vehicles representing about 4 percent of the baseline non-hybrid vehicle market, and is subsequently applied to only 23 percent of the market. Meszler stated that the “relative cost effectiveness of the technology is perhaps best illustrated by the fact that the market penetration of HCR technology on non-hybrid vehicles under the augural standard is modeled to be 27 percent of 2032 sales, exactly equal to the baseline penetration of 4 percent and the allowable adoption fraction of 23 percent. In other words, the technology was adopted by every vehicle that was not explicitly prohibited (by NHTSA) from doing so.” EDF commented that “NHTSA has further imposed artificial and unreasonable constraints on the use of certain technologies that does not match how automakers are applying them in vehicles today,” stating that HCR1 represented a technology that had been in the marketplace for many years and had been applied by several manufacturers, “[y]et, even for MY 2030 vehicles and beyond, NHTSA only allows the use of HCR1 by about 30 percent of the U.S. fleet.”⁹¹⁷

In considering the comments, the agencies agree with commenters that the HCR1 engine application was overly limited for the NPRM analysis. As a result, the agencies have expanded the availability of HCR1 technology for the final rule analysis. The refined adoption features for HCR1 are discussed below. The new adoption features do maintain considerations for performance neutrality. Comments about how the characterization of engine technologies in the analysis fleet impacted HCR technology adoption in subsequent model years are addressed in Section VI.C.1.d) Baseline Fleet Engine Tech.

Regarding HCR2, the Alliance commented in support of “the decision to exclude the speculative HCR2 technology from the analysis.”⁹¹⁸ The Alliance continued, “[a]s previously documented in Alliance comments, the inexplicably high benefits ascribed to this theoretical combination of technologies has not been validated by physical testing.” Similarly, Ford stated that “[t]he effectiveness of the ‘futured’ Atkinson package (HCR2) that includes cooled exhaust gas recirculation (CEGR) and cylinder deactivation (DEAC) is excessively high, primarily due to overly-optimistic efficiencies in the base engine map, insufficient accounting of CEGR and DEAC integration losses, and no accounting of the impact of 91RON

Tier 3 test fuel. Given the speculative and optimistic modeling of this technology combination, Ford supports limiting the use of HCR2 technology to reference only, as described in the Proposed Rule.”⁹¹⁹

In contrast, several commenters disagreed with the agencies’ decision to limit the adoption of HCR2 engines, stating that the technology was clearly applicable during the rulemaking timeframe, as the technology was already being applied by manufacturers, and that the technology was cost-effective, as shown by the agencies’ own modeling.

ICCT commented that “[i]t is clear that the agencies have artificially excluded a known technology that is applicable in the timeframe of the rulemaking.”⁹²⁰ ICCT commented that “[d]espite the facts that (as discussed above) the agencies have cost and effectiveness data for this technology, many automakers are already deploying the HCR1 technology, and the 2018 Camry has already put most of the HCR2 technologies into production, the agencies did not allow any application of HCR2 by 2025.”⁹²¹ ICCT concluded that the “only explanations . . . for the agencies’ system of omissions and constraints are that the agencies have biased the analysis against including all the viable technologies by inserting their own artificial constraints (either for lack of research, lack of analytical effort, or not fully utilizing all the agencies’ best analytical tools and data) or that the auto industry is providing information that erroneously suggests their innovation is far less than what is demonstrated both above and in the agencies’ own previous analyses.” ICCT stated that “[t]he great lengths the agencies have gone to artificially impose ‘skip’ constraints for HCR in the CAFE modeling system demonstrates that the agencies have exerted an explicable and apparently deliberate bias towards forcing most of the automaker compliance technology toward higher cost, non-HCR turbocharging paths.”⁹²²

Several commenters also stated that HCR should not have been restricted because it is clearly a cost-effective technology, citing the sensitivity runs conducted that allowed unrestricted HCR application in the analysis. For example, ICCT commented that allowing HCR2 application across the fleet reduced total per-vehicle cost of compliance with the augural standards by \$690, which “shows that the

agencies intentionally excluded a highly cost-effective technology (by their own analysis) in the rulemaking analysis.”⁹²³ Similarly, EDF performed software modifications of the CAFE model, including allowing the use of both HCR1 and HCR2 technology for all manufacturers by MY 2028. The analysis performed by EDF using their modified version of the CAFE model, showed reductions in the per-vehicle compliance cost projections by nearly \$600.⁹²⁴

ICCT concluded that “[t]he only reasonable and technically valid assumption is that HCR be allowed for application to all vehicle models’ engine redesigns through all the model years of the compliance modeling analysis.”⁹²⁵ ICCT stated that “[f]or the agencies to constrain HCR technology for use by other automakers, they have a responsibility to demonstrate why each of the other automakers cannot adopt this known technology in their fleet.”

The agencies agree with commenters’ observations about the results of the sensitivity runs performed as part of the NPRM analysis. However, the agencies also believe the adoption features for HCR1 and HCR2 were appropriate for the NPRM analysis. Had the agencies not applied adoption features in that way, the agencies would have shown unrealistic pathways for compliance for manufacturers that would have understated costs and overstated benefits of potential CAFE and CO₂ standards.

The agencies disagree with commenters’ statements that HCR has been widely available in the automotive market and that the HCR technology accordingly should not be limited in the CAFE model. For reasons discussed in the NPRM and explained in more detail in Section VI.C.1.c)(3), depending on vehicle type and use, Atkinson cycle operation may be enabled for low and moderate engine demand conditions, whereas Otto cycle operation may be needed for higher load conditions to meet performance needs, such as to move more passengers, cargo, or for towing. In addition, there may be issues on some platforms to package the larger exhaust manifolds needed to enable Atkinson operation, particularly with V6 and V8 engines. Manufacturers have applied Atkinson technologies in unique ways to meet the needs and capabilities of their vehicles to operate using the Atkinson and Otto cycles. The agencies agree with comments from stakeholders, including Toyota, who

observed HCR technology is not suitable for all vehicle configurations, and may not meet performance requirements for high-load applications. As discussed earlier, the agencies believe the variation of technologies can be categorized into three different forms of Atkinson engine technologies for this analysis: (1) Atkinson engines, (2) Atkinson-mode engines, and (3) Atkinson-enabled engines using variable valve timing with late intake closing. Manufacturers typically apply one of these technologies and tune that technology for specific applications. Some commenters have consistently conflated the technologies and asserted the capabilities of all three types of Atkinson technologies can be represented by a single engine model. The agencies do not agree with stakeholder assertions that a single HCR engine map should be applied to every technology class or vehicle platform.

To reflect better the incremental effectiveness for a low-cost version of HCR technology, the agencies added the HCR0 engine for the analysis. The specification of this engine was provided in the NPRM PRIA as Eng22b. Using this engine improves the estimated incremental effectiveness because the incremental engine changes were directly specified for the modeling and are relative to the other engine technologies in the analysis.⁹²⁶ HCR0 is the first engine in the HCR path that a manufacturer could adopt. HCR0 represents technology that could incrementally be adopted to the VVT engine, increasing compression ratio and adding Atkinson cycle capability. The use of the HCR0 technology, applied in the final rule analysis, allowed the agencies to update HCR adoption features. Once a basic engine adopts HCR technology (i.e., HCR0 and HCR1 for the central analysis, or HCR2 for a sensitivity case) the vehicle will not switch to a different engine technology path. For example, if a vehicle had adopted HCR or is equipped with HCR technology it is not allowed to adopt turbocharged engine technologies. The HCR0 technology appropriately captures the benefits of applying transitional Atkinson technologies to conventional basic engine technologies. The agencies note that VVT technology valve control has late intake valve closing under some operating conditions to take some advantage of Atkinson cycle-like operation; however, that operation is not as extensive as HCR technology and is not coupled with a higher

⁹²⁶ PRIA 6.3.2.2.21.20.2.1 IAV Engine 22b—High Compression Atkinson Cycle Engine at p. 307.

compression ratio as is the case for HCR technologies.

The agencies also allowed all 4-cylinder engines on the basic engine path to adopt HCR technology similar to turbocharged technologies. This allowed any small and midsize vehicles, including small and midsize SUVs, that had any combinations of basic engine path technologies to move to the HCR path. However, there are two exceptions to this feature, including: (1) When the vehicle is a pickup including both standard and performance class; and (2) when the base engine is shared with a pickup including both standard and performance class. The agencies discussed earlier in the non-HEV Atkinson section why HCR technology cannot be applied to all vehicle applications.

Finally, engines with advanced engine technology already in the baseline vehicle such as turbocharged engines are not allowed to adopt HCR technology. The agencies continue to believe this constraint is reasonable given the extensive capital resources and stranded capital that would be involved if a manufacturer who focused on and invested heavily in non-HCR advanced technologies were to abandon those technologies abruptly and switch to HCR technologies.⁹²⁷ For example, Ford has incorporated turbocharged engines across 75 percent to 80 percent of their fleet in MY2017, and these engines are shared across multiple technology classes.⁹²⁸ The abovementioned modeling, limitation for this analysis assumes that manufacturers will not change advanced engine technology applied to a platform due to the high cost and lead time required for research and development, and for the development and implementation of new manufacturing plants and equipment to implement an entirely new powertrain in the rule making time frame. For further discussion see Section VI.B.1.

In response to ICCT's comment that agencies must discuss the reasoning for allowing and disallowing HCR technology for each individual manufacturer, these updated adoption features now allow more manufacturers to adopt HCR engine technology. The agencies no longer apply adoption features based on manufacturer, but now base them on individual platforms. The agencies believe a manufacturer that has already invested in advanced engine technologies for a specific platform would face very high costs and

incur significant stranded capital to switch that platform to another advanced technology. And doing so would not be reasonable given the small incremental fuel economy improvement that would be gained, for example, for switching from advanced turbocharging to HCR technologies. Specifically, manufacturers that have invested in turbocharging technology for certain platforms, like Honda, Ford, and the German manufacturers, would incur unreasonable costs to switch to another advanced technology path. However, manufacturers that use turbo technology on one platform are not precluded from implementing HCR technology on another of its platforms. HCR adoption is still limited for all manufacturers based on vehicle performance requirements discussed earlier.

(4) Advanced Cylinder Deactivation Technology

In the NPRM, any basic engine technology could adopt ADEAC. Commenters stated that the agencies restricted ADEAC technologies in the NPRM analysis to naturally aspirated engines.

ICCT provided a broad comment regarding the treatment of advanced technologies, including ADEAC, and criticized how the NPRM "removed many technologies that are viable and being actively deployed by the auto industry." ICCT specifically criticized "cases where viable technology combinations are disallowed" such as "turbocharging and cylinder deactivation (DEAC)." ⁹²⁹

UCS also commented on how ADEAC technology was applied in the NPRM, stating "While the agencies have acknowledged the existence of dynamic cylinder deactivation, they have not appropriately included it as an available technology, dramatically limiting its availability." UCS specifically disagreed with adoption features of the ADEAC, noting the technology "is restricted to naturally aspirated, low-compression ratio engines—it cannot be combined with turbocharged engines, high compression ratio engines, or variable compression ratio engines due to pathway exclusivity in the Volpe model." ⁹³⁰ CARB and Meszler mirrored these concerns.⁹³¹

The agencies agreed with commenters and in response have allowed both naturally aspirated engines and turbocharged engines to adopt ADEAC in the final rule analysis. The new Advanced Turbocharging path includes

TURBOD and TURBOAD, while naturally aspirated engines use the same ADEAC engine designation. There is some potential for this type of technology to improve fuel economy and reduce CO₂ emissions, however, the technology provides diminishing returns if it is included with engine downsizing or other technologies that already reduce pumping losses. Accordingly, once a vehicle has adopted ADEAC, TURBOD, or TURBOAD, the agencies did not allow further adoption of other engine technologies that reduce pumping losses such as VCR and VTG.

(5) Miller Cycle Engines

Miller cycle engine technologies (VTG and VTGe) are new for this final rule analysis, and VTG engines could be applied to any basic and turbocharged engine. Discussed earlier, the VTGe technology is enabled by the use of a 48V system that presents an improvement from traditional turbocharged engines, and accordingly VTGe could only be applied with a mild hybrid system.

(6) Variable Compression Ratio Engines

In the NPRM analysis, variable compression ratio (VCR) technology was not available for adoption, but the engine map and specifications were provided for review. For this final rule analysis, VCR engines are included in the analysis and can be applied to basic and turbocharged engines, however the technology is limited to Nissan. VCR technology requires a complete redesign of the engine, and in MY2020, only two of Nissan's models had incorporated this technology. In addition, the technology showed lower fuel savings than expected.⁹³² The agencies do not believe any other manufacturers will invest to develop and market this technology in their fleet in the rulemaking time frame.

(7) Diesel Engines

Diesel engine adoption and features have been carried from the NPRM analysis for this final rule analysis for ADSL and DSLI. Any basic engine technologies (VVT, VVL, SGDI, and DEAC) can adopt ADSL and DSLI engine technologies. New for the final rule analysis is the adoption of advanced cylinder deactivation for diesel engines (DSLAD). Any basic engine and diesel engine can adopt this technology in the final rule analysis;

⁹³² VanderWerp, D. "Why Nissan's Holy-Grail VC-T Engine Doesn't Achieve Better Fuel Economy," C/D Nov 1, 2018. Available at <https://www.caranddriver.com/features/a24434937/nissan-new-vc-t-engine-fuel-economy/>. Last accessed Dec. 19, 2019.

⁹²⁷ 83 FR 43038.

⁹²⁹ NHTSA-2018-0067-11741 at p.6.

⁹³⁰ NHTSA-2018-0067-12039 at p.4

⁹³¹ NHTSA-2018-0067-12039 at p.4.

however, the agencies have applied a phase in cap and year for this technology at 34 percent and MY 2023, respectively. In the agencies' engineering judgement, the agencies have concluded that this is a rather complex and costly technology to adopt and think that it could take significant investment to develop. For more than a decade, diesel engine technologies have been used in less than one percent of the total light-duty fleet production,⁹³³ and the investment for this cylinder deactivation technologies may not be justifiable.

(8) Alternative Fuel Engines
Adoption features for alternative fueled compressed natural gas (CNG) engines have been carried over from the NPRM for this final rule analysis. Because CNG is considered an alternative fuel under EPCA/EISA, it cannot be adopted during the rulemaking timeframe for NHTSA's standard setting analysis. The EPA analysis was modeled separately in the CAFE model without such constraints.

(9) Engine Lubrication and Friction Reduction
Finally, new for this analysis is the addition of EFR. The agencies allow

EFR to apply to any engine technology except for DSLI and DSLIAD. DSLI and DSLIAD inherently have incorporated engine friction technologies from ADSL. In addition, friction reduction technologies that apply to gasoline engines cannot necessarily be applied to diesel engines due to the higher temperature and pressure operation in diesel engines.

f) Engine Effectiveness Modeling and Effectiveness Values
Figure VI-20 below shows the effectiveness estimates from all the vehicle types for the NPRM analysis using Autonomie full vehicle modeling and simulation.

Figure VI-20 – NPRM Technology Effectiveness by Engine Technologies Relative Base

Roush commented that they had observed wide variations in estimated incremental effectiveness associated with individual technology packages

between the 2016 Draft TAR and NPRM analysis.⁹³⁴
The agencies agree that to predict potential incremental improvements in fuel efficiency accurately, it is extremely

important to understand the nature of the improvements being sought by each increment (improved thermodynamics, reduced friction, reduced vehicle weight, etc.). The technology modeling

⁹³³ The 2018 EPA Automotive Trends Report Table 4.1 at p. 72.

⁹³⁴ NHTSA-2018-0067-11984. Roush at p. 16.

and large scale simulation used for the proposal and updated for the final rule does exactly that. In fact, the NPRM and final rule use these methods more expansively than any previous CAFE and CO₂ rulemaking, including the 2016 Draft TAR and 2016 EPA Proposed Determination.

One commenter stated the effectiveness for ADEAC was overestimated for the NPRM, and that data from compliance shows much lower effectiveness. The agencies disagree with this comment, as it is invalid to compare effectiveness of full vehicle compliance data directly to the incremental effectiveness modeled for ADEAC. For reasons discussed in Section VI.B.3 data from full vehicle benchmarking cannot be used as a

comparison for specific technology effectiveness. The effectiveness estimated for this technology is in line with test data, CBI, and engineering analysis.⁹³⁵

Engine effectiveness estimates remained the same for most technologies from the NPRM analysis, with the exception of some technologies that had characteristics updated, and the new added engine technologies. For the final rule analysis, the agencies used the same effectiveness values for ADEAC applied to naturally aspirated engines as in the NPRM, and incorporated estimated effectiveness values for TURBOAD to represent ADEAC on downsized turbocharged engines.

Other technology-specific comments and the agencies' responses are provided within the discussion of each technology throughout this section, as those comments tended to be predicated on issues surrounding the engine maps used to model technologies or technology-specific adoption features. For the final rule analysis, the technical merits of the substantive comments and any accompanying publications and information were carefully considered and discussed in the subsections where appropriate.

Figure VI-21 below shows the effectiveness estimates from compact car and midsize car vehicle types for the final rule analysis using Autonomie full vehicle modeling and simulation.

BILLING CODE 4910-59-P

Figure VI-21 – FRM Technology Effectiveness Estimates by Engine Technologies Relative to Base for compact and midsize vehicle class

g) Engine Costs

Discussed in the PRIA, the agencies spent millions of dollars sponsoring research to determine direct

manufacturing costs (DMCs) for fuel saving technologies since the 2012 rule.⁹³⁶ Because a major objective of the studies was to consider costs in the rulemaking timeframe, the agencies

believed that these costs were appropriate to use for the NPRM and final rule analysis. Table VI-47 below shows the DMC used for IC engine technologies for the NPRM analysis.

⁹³⁵ Boha, Stani. "Benchmarking and Characterization of a Full Continuous Cylinder Deactivation System." EPA. April 10–12, 2018 SAE World Congress. <https://www.epa.gov/sites/production/files/2018-10/documents/deact-sae-world-congress-boha-2018-04.pdf> last access Feb 12, 2020.

⁹³⁶ FEV prepared several cost analysis studies for EPA on subjects ranging from advanced 8-speed transmissions to belt alternator starter, or Start/Stop systems. NHTSA also contracted with Electricore, EDAG, and Southwest Research on teardown studies evaluating mass reduction and transmissions. The 2015 NAS report on fuel

economy technologies for light-duty vehicles also evaluated the agencies' technology costs developed based on these teardown studies, and the technology costs used in this proposal were updated accordingly. These studies are discussed in detail in Chapter 6 of the RIA accompanying the NPRM proposal.

CARB commented that costs associated with IC engines were not excluded from the final costs of BEV vehicles.⁹³⁷ CARB continued, stating that “the final costs of BEV vehicles are higher due to the inclusion of the base absolute costs, to which the assigned BEV incremental cost would be added.”

The agencies agree with CARB that inclusion of IC engine costs in the BEV

cost was an error in the analysis. In response to this comment, the agencies have developed absolute costs for baseline engines for the CAFE model in order to account for appropriate cost of removing engines from BEVs. In the final rule analysis, once a vehicle adopts BEV technology, the costs associated with powertrain systems are removed.

Due to the extensive variations in engine technologies in real world production, the agencies relied on discrete publication costs and historical studies to assign costs for base engines.^{938 939} For this final rule analysis, the agencies have included these costs for base engines shown in Table VI–48.

Table VI-48 – Examples of Absolute Costs for Engines in 2018 Dollars

| | I4 | V6 | V8 |
|-------------|-----------------|-----------------|-----------------|
| SOHC | 5,013.49 | 5,675.87 | 6,306.65 |
| DOHC | 5,090.94 | 5,830.76 | 6,461.54 |

BILLING CODE 4910–59–C

Commenters compared engine cost data from the NPRM to other sources, in many cases to support their comments that the technology costs used in the NPRM were too high. ICCT commented that the agencies did not consider the latest reports on technology cost data, and specifically referenced an ICCT-sponsored FEV cost study for the European EU6b regulations in MY 2025,⁹⁴⁰ as well as prior EPA cost estimates for several engine technologies including SGDI, cEGR, HCR, and others, to point out differences in cost.⁹⁴¹ ICCT also commented on the difficulty they had in locating the cost data used in the NPRM, stating that “because the agencies present cost data in so many different ways in dozens of different places in the NPRM, impact assessment, and supporting data files, the precise agencies’ costs are obscured and not transparent.” ICCT stated that “[w]ithout a clear explanation of the methodology, it is unclear precisely how price increases are determined, as well as the relationship between technology costs, fines, and price increases.” Despite this claim, ICCT was able to provide several pages comparing engine technology costs.

In the NPRM PRIA Chapter 6.3.2.2.20.22, the agencies provided DMCs for all engine technologies in 2016 dollars without inclusion of RPE and learning for review. In the same chapter, the agencies also provided absolute costs that incorporated costs in 2016 dollars, RPE and learning data as

used by the CAFE model to assess cost effectiveness for future MY vehicles. Where appropriate, the agencies discussed in the individual technology sections where costs were updated for this final rule analysis with the latest data. This also includes cost data for new technologies available in the CAFE model for the final rule analysis.

Some engine costs were carried over from prior rulemakings, but may have looked different because they were updated to current dollars (2016 for the NPRM and 2018 for the final rule), and for engine architecture and cylinder count. In addition, costs were updated based on appropriate vehicle class. This was important to consider to maintain performance neutrality, as technology effectiveness associated with one engine technology type for a vehicle class cannot be used for the same engine technology for higher performance vehicle class. This affected total costs. For further discussion on the cost-effectiveness metric used in the CAFE model, see discussions in the Section VI.A Overview of the CAFE model and VI.B.3 Technology Effectiveness Values.

The agencies do not believe that the FEV report referenced by ICCT is applicable for this analysis for a few reasons. First, the primary focus of the FEV study “is the European Market according to the EU6b regulation as well as the consideration of emissions under both the NEDC and WLTP test procedures.” This final rule analysis specifically considered the U.S. automotive market during the rulemaking timeframe based on U.S.-

specific regulatory test cycles. Accordingly, the costs reflect incremental technology effectiveness for achieving improvements as measured through U.S. regulatory test methods. The agencies had discussed these test cycles and methods further in Section VI.B.3 Technology Effectiveness Values.

Second, FEV did not conduct original teardown studies for this report, as indicated by project tasks, but rather used engineering judgement and external studies in assessing incremental costs.⁹⁴² The FEV report did not provide sources for each individual cost and it is unclear how costs in many scenarios were developed since no teardowns were used. Note that for this final rule analysis, the agencies have used previously conducted FEV cost teardown studies and the referenced 2015 NAS costs that referenced FEV teardowns. The agencies are not concluding that FEV is an unreliable source. The agencies preferred to specifically identify incremental costs of adding technology to account appropriately for the costs of those technologies in the analysis.

Finally, the cost for different vehicle classes identified by the FEV study does not line up with the vehicle classes discussed in the NPRM and this final rule analysis. FEV stated specifically, “the configuration of the vehicles has not been optimized for the US market and may not be representative of this market.”⁹⁴³ The agencies have discussed the importance of aligning the CAFE vehicle models with the U.S. market earlier in Section VI.B.3

Technology Effectiveness Values and Section VI.C.1.d) Baseline Fleet. All of these factors make it difficult to compare directly the agencies' estimates and estimates presented in the FEV report cited by ICCT in their comments.

HDS provided a variety of costs and effectiveness comparisons between the NPRM and previous 2012 final rule and the 2016 Draft TAR.⁹⁴⁴ Specifically, HDS stated that the data presented in the 2016 TAR indicated a \$60 per CO₂/mile reduction for most conventional engine technologies.

Although the comparison was technically sound, there are significant differences between the Draft TAR and NPRM analyses that clearly account for the differences in engine cost. First, the NPRM analysis used the MY 2016 fleet

as a starting point to model manufacturers' potential responses to CAFE and CO₂ standards, whereas the 2012 final rule and Draft TAR used older baseline fleets. Vehicles in the MY 2016 fleet already included more advanced technologies than their predecessors in prior MY fleets, which would make it more expensive for vehicles that have already adopted advanced technologies to adopt more advanced technology. Second, the agencies refined the engine modeling from previous analysis to the NPRM to account for engine configurations and cylinder count more precisely. For the final rule analysis, the same approach was taken to account appropriately for costs for different type engine designs and configurations.

Aside from these updates, engine costs were carried over from the NPRM analysis, except for newly added technologies, where costs were obtained from various sources such as NAS studies, technical publications, and CBI data. Finally, the cost estimates have been updated to account for dollar year (updated from 2016 dollars to 2018 dollars), and learning rate.

(1) Basic Engines

DMCs used for the final rule analysis for basic engine technologies were the same as NPRM costs. Table VI–49 below shows the basic engine DMC used for this final rule analysis.

(3) Non-HEV Atkinson and Atkinson Engines

DMCs used for the final rule analysis for HCR0 and HCR1 were based on HCR1 and HCR2 from NPRM, respectively. Discussed in Section VI.C.1.c).(3), the agencies aligned the cost of HCR technologies to align with 2015 NAS effectiveness and costs.

Stakeholders commented on the costs of HCR technology compared to previous analysis. ICCT compared the NPRM costs to EPA's Proposed Determination costs, stating that "[t]his is a clear case where the agencies appear to have not used the best available data from EPA which has extensively analyzed this technology and its associated cost, nor have the agencies justified how they have increased the associated costs, apparently by a factor of three." Similarly, Roush Industries commenting on behalf of CARB stated that the costs for implementing HCR

technology were 5–6 times the 2016 Draft TAR estimated costs, which are "extremely high" and "will significantly overstate the incremental cost and bias technology pathways."⁹⁴⁵ HDS also commented that the costs for HCR technology were higher than the costs from the 2016 Draft TAR, and speculated that was due to "the bulky exhaust system used in the Mazda ATK1 engine, which apart from being expensive also requires the vehicle to be modified to accommodate the exhaust system."⁹⁴⁶ HDS cited the 2018 Camry as an example of a vehicle that does not use the same exhaust system, but stated the sources of the new cost data were not documented in the PRIA. ICCT stated that "[t]he agencies should reinstate the better justified and more deeply analyzed original Proposed Determination HCR cost numbers from EPA for this rulemaking."

The NPRM analysis and the final rule analysis used the same DMCs established by the 2015 NAS report for

the Atkinson cycle technologies. However, because there are many various engine configurations in the market, the agencies do not use the same fixed costs that were set for each type of vehicle described in the 2015 NAS report, such as pickup and sedan. The agencies have expanded costs by taking into account the type of technology in the baseline, like SGDI, and the configuration of the engine, such as SOHC versus DOHC. In addition, the cost used in the NPRM also included updated dollar year, learning rate, and RPE. Although EPA also used costs from the 2015 NAS report for the Proposed Determination analysis, they used a different approach to account for components.⁹⁴⁷ For the final rule analysis the agencies continued to use the same DMC for HCR technologies. Table VI-55 below shows HCR DMCs used for the final rule analysis in 2018 dollars.

(4) Advanced Cylinder Deactivation Technologies

DMCs used for the final rule analysis for the advanced cylinder deactivation technologies were the same as NPRM costs.

Roush commented that in the NPRM analysis, the agencies did not properly

consider the “very cost-effective benefits of skip-fire technology,” referred to in the analysis as ADEAC. Roush stated that “due to extremely high estimated cost (\$1,250.00 in MY2016), the benefits of this technology will likely not be chosen in any reasonable technology pathway. If included, the predicted cost for that pathway will be overestimated by \$750–\$1,000.”⁹⁴⁸ Similarly, Meszler commented on the cost for the ADEAC system stating “advanced cylinder deactivation paths are assumed (by NHTSA) to be expensive, and are selected only in rare instances.”⁹⁴⁹ ICCT also stated “The agencies estimated a greatly exaggerated cost of advanced cylinder deactivation for that level of the technology.”⁹⁵⁰

The agencies do not agree with the commenter’s statement that the analysis did not consider ADEAC as a cost effective technology or that the agencies overestimated costs for the technology. The agencies considered the most up to date information and data for the NPRM and final rule analysis.⁹⁵¹ The agencies

rely on the CAFE model to determine technology cost effectiveness, and if the technology was cost effective for a manufacturer to adopt, then the model would apply it to a manufacturer’s vehicle. The adoption of ADEAC was applied to vehicles with corresponding technology combinations to reflect appropriate cost and effectiveness, as discussed in the paragraph above. The purpose of ADEAC is to reduce pumping losses, but if the engine has been downsized, or has already incorporated technologies that also reduce pumping loss, then it is likely the ADEAC has reached a point of diminishing return. As far as the agencies are aware, Roush did not provide alternative DMCs for ADEAC technology. Table VI–58 below shows the examples of advanced cylinder deactivation DMC used for both naturally aspirated and turbocharged engines for the final rule analysis in 2018\$.

(5) Miller Cycle Engines

The agencies estimated costs for Miller cycle engines with VTG from 2016 ICCT-sponsored FEV technology cost assessment report. The agencies considered costs from 2015 NAS study that referenced a NESCCAF 2004 report,⁹⁵²⁹⁵³ but believed that the

reference material from the ICCT report had more updated cost estimates for this technology that represented what was discussed in the NPRM and modeled in the final rule analysis.

NAS estimated the incremental cost for VTG as \$525 in 2010\$, but this cost assumes many of the traditional turbocharged components and adds VVT, VVL and SGDI. In addition, VTG (Eng23b) and VTGe (Eng23c) engines both have similar modeled BMEP levels and a cooled EGR system to CEGR1 (Eng14), implying that the components such as cooling systems and piping will have similar costs.

The NAS template to calculating the final DMCs for the Miller cycle engines for the different engine configuration is the \$525 (2010\$) plus cost of cEGR1 minus cost of VVT, VVL, and SGDI. The agencies estimated the cost for electrically-assisted variable supercharger VTGe (Eng23c) engines based on the 2015 NAS study that uses a cost of \$1050 (2010\$) plus the cost of the mild hybrid battery. For the final rule analysis, the total costs for these technologies are shown below.

(9) Engine Lubrication and Friction
Reduction Technologies

EFR costs used for the final rule analysis are based on the 2015 NAS assessment for low friction lubrication and engine friction reduction level 2

(LUB2_EFR2). The 2015 NAS report provided estimates of \$51 (I4 DOHC), and \$72 (V6 SOHC and DOHC) for midsize cars, in 2015 dollars, relative to level 1 engine friction reduction (EFR1), which costs about \$12 per cylinder. For this analysis, EFR technologies DMCs

are estimated to be \$14.05 per cylinder in 2016 dollars. Total costs were updated to reflect 2018 dollars and MY 2017 learning rate. Table VI-74 shows the EFR DMC used for the final rule analysis in 2018 dollars.

Table VI-74 – Example of EFR DMC Used for this Final Rule Analysis in 2018 Dollars.

| Engine Technologies - Direct Manufacturer Costs (2018\$) for FRM | | | | | | | | | | Incremental To |

2. Transmission Paths

Transmissions transmit torque from the engine to the wheels. Transmissions primarily use two mechanisms to improve fuel efficiency: (1) A higher gear count, as more gears allow the engine to operate longer at higher efficiency speed-load points; and (2) improvements in friction or shifting efficiency (*e.g.*, improved gears, bearings, seals, and other components), which reduce parasitic losses.

There are two major categories of transmission types modeled in the analysis: Automatic and manual. Automatic transmissions automatically select and shift between transmission gears for the driver during vehicle operation. The automatic transmission category is further subdivided into four subcategories: Traditional automatic transmissions, dual clutch transmissions, continuously variable transmissions, and direct drive transmissions. Manual transmissions require direct control by the driver to select and shift between gears during vehicle operation.

Conventional planetary gear automatic transmissions (AT) are the most popular transmission.⁹⁵⁵ ATs typically contain three or four planetary gear sets that provide the various gear ratios. Gear ratios are selected by activating solenoids which engage or release multiple clutches and brakes as needed. ATs with gear counts ranging from five speeds to ten speeds were considered in the NPRM and final rule analysis.⁹⁵⁶

ATs are packaged with torque converters, which provide a fluid coupling between the engine and the driveline, and provide a significant increase in launch torque. When transmitting torque through this fluid coupling, energy is lost due to the churning fluid. These losses can be eliminated by engaging the torque converter clutch to directly connect the engine and transmission (“lockup”).

Conventional continuously variable transmissions (CVT) consist of two cone-shaped pulleys, connected with a belt or chain. Moving the pulley halves

allows the belt to ride inward or outward radially on each pulley, effectively changing the speed ratio between the pulleys. This ratio change is smooth and continuous, unlike the step changes of other transmission varieties. CVTs were not initially chosen in the fleet modeling for the 2012 rulemaking analysis for MYs 2017 and later because of the predicted low effectiveness associated with CVTs (due to the high internal losses and narrow ratio spans of CVTs in the fleet at that time).⁹⁵⁷ However, improvements in CVTs in the current fleet have increased their effectiveness, leading to increased adoption rates in the fleet. In its 2015 report, the NAS recommended CVTs be added to the list of considered technologies. The agencies included CVT technology for the NPRM and this final rule analyses.

Dual clutch transmissions (DCT), like automatic transmissions, automate shift and launch functions. DCTs use separate clutches for even-numbered and odd-numbered gears, allowing the next gear needed to be pre-selected, resulting in faster shifting. The use of multiple clutches in place of a torque converter result in lower parasitic losses than ATs. However, DCTs are seeing limited penetration in the fleet, and because of the low penetration rate, only two DCTs were considered in the analysis.

Direct drive (DD) transmissions are a direct connection between the wheels and a drive motor. In a DD transmission, the ratio between wheel speed and motor speed remains constant. A DD transmission is only used in battery electric vehicles, and in the NPRM the agencies provided the specification for comments.⁹⁵⁸

Manual transmissions (MT) are transmissions that require direct control by the driver to operate the clutch and

shift between gears. Manual transmissions have seen a significant reduction in application by automakers over recent years. As a result of the reduced market presence, only three variants are used in the analysis.

a) Transmission Modeling in the CAFE Model

The NPRM analysis modeled pathways for applying improved technology for each of the transmission categories and subcategories, except for the direct drive, which was only available in the battery electric vehicles. The MT and DCT pathways only included increasing gear counts (*e.g.*, 5-speed manual transmission, 6-speed manual transmission, and 7-speed manual transmission) as improved technologies.

The traditional ATs and CVTs included both increased gear counts and high efficiency gearbox (HEG) technology improvements as options. HEG improvements for transmissions represent incremental advancement in technology that improves efficiency, such as: Reduced friction seals, bearings and clutches, super finishing of gearbox parts, and improved lubrication. All these advancements are aimed at reducing frictional and other parasitic loads in transmissions to improve efficiency. Three levels of HEG improvements are considered in this analysis, based on 2015 NAS recommendations and based on CBI data.⁹⁵⁹ HEG efficiency improvements were applied to ATs and CVTs, as those transmissions inherently have higher friction and parasitic loads related to hydraulic control systems and greater component complexity, compared to MTs and DCTs.

In total, 18 unique transmission technology combinations were simulated, using explicit input values for gear ratios, gear efficiencies, gear spans, shift logic, and transmission architecture.⁹⁶⁰ ⁹⁶¹ Table VI–77 shows a list of the multi-gear transmissions used for the NPRM.⁹⁶²

BILLING CODE 4910–59–P

⁹⁵² The NPRM and final rule also included a direct drive transmission (single ratio) for BEVs.

⁹⁶³ Comments from Environmental Defense Fund, Attachment B, NPRM Docket No. NHTSA–2018–0067–12108, at 70.

⁹⁵⁶ Specifically, the agencies considered five-speed automatic transmissions (AT5), six-speed automatic transmissions (AT6), seven-speed automatic transmission (AT7), eight-speed automatic transmissions (AT8), nine-speed automatic transmissions (AT9), and ten-speed automatic transmissions (AT10).

| Continuous variable transmission level 2HEG | CVTL2A/2B |
| 5-speed manual transmission | MT5 |
| 6-speed manual transmission | MT6 |
| 7-speed manual transmission | MT7 |

The technologies that made up the four transmission/level paths defined by the modeling system for the NPRM analysis are shown in Figure VI-22. Each vehicle model in the analysis fleet is assigned an initial transmission type and level that most closely matches its configuration and characteristics. The baseline-level technologies (AT5, MT5 and CVT) appear in gray boxes and are

only used to represent the initial configuration of a vehicle's transmission in the analysis fleet. Because there are only a few manual transmissions with less than five forward gears in the analysis fleet, for simplicity, all manual transmissions with five forward gears or fewer were designated MT5 for the analysis. Similarly, all automatic transmissions with five forward gears or

fewer have been assigned the AT5 technology. For the NPRM analysis, the agencies included a 7-speed automatic and a 9-speed automatic to account for effectiveness of those transmissions in the analysis fleet. These two transmissions were not available for adoption but were available as initial configurations, and appear in gray boxes in Figure VI-22.

⁹⁶² The NPRM and final rule also included a direct drive transmission (single ratio) for BEVs.

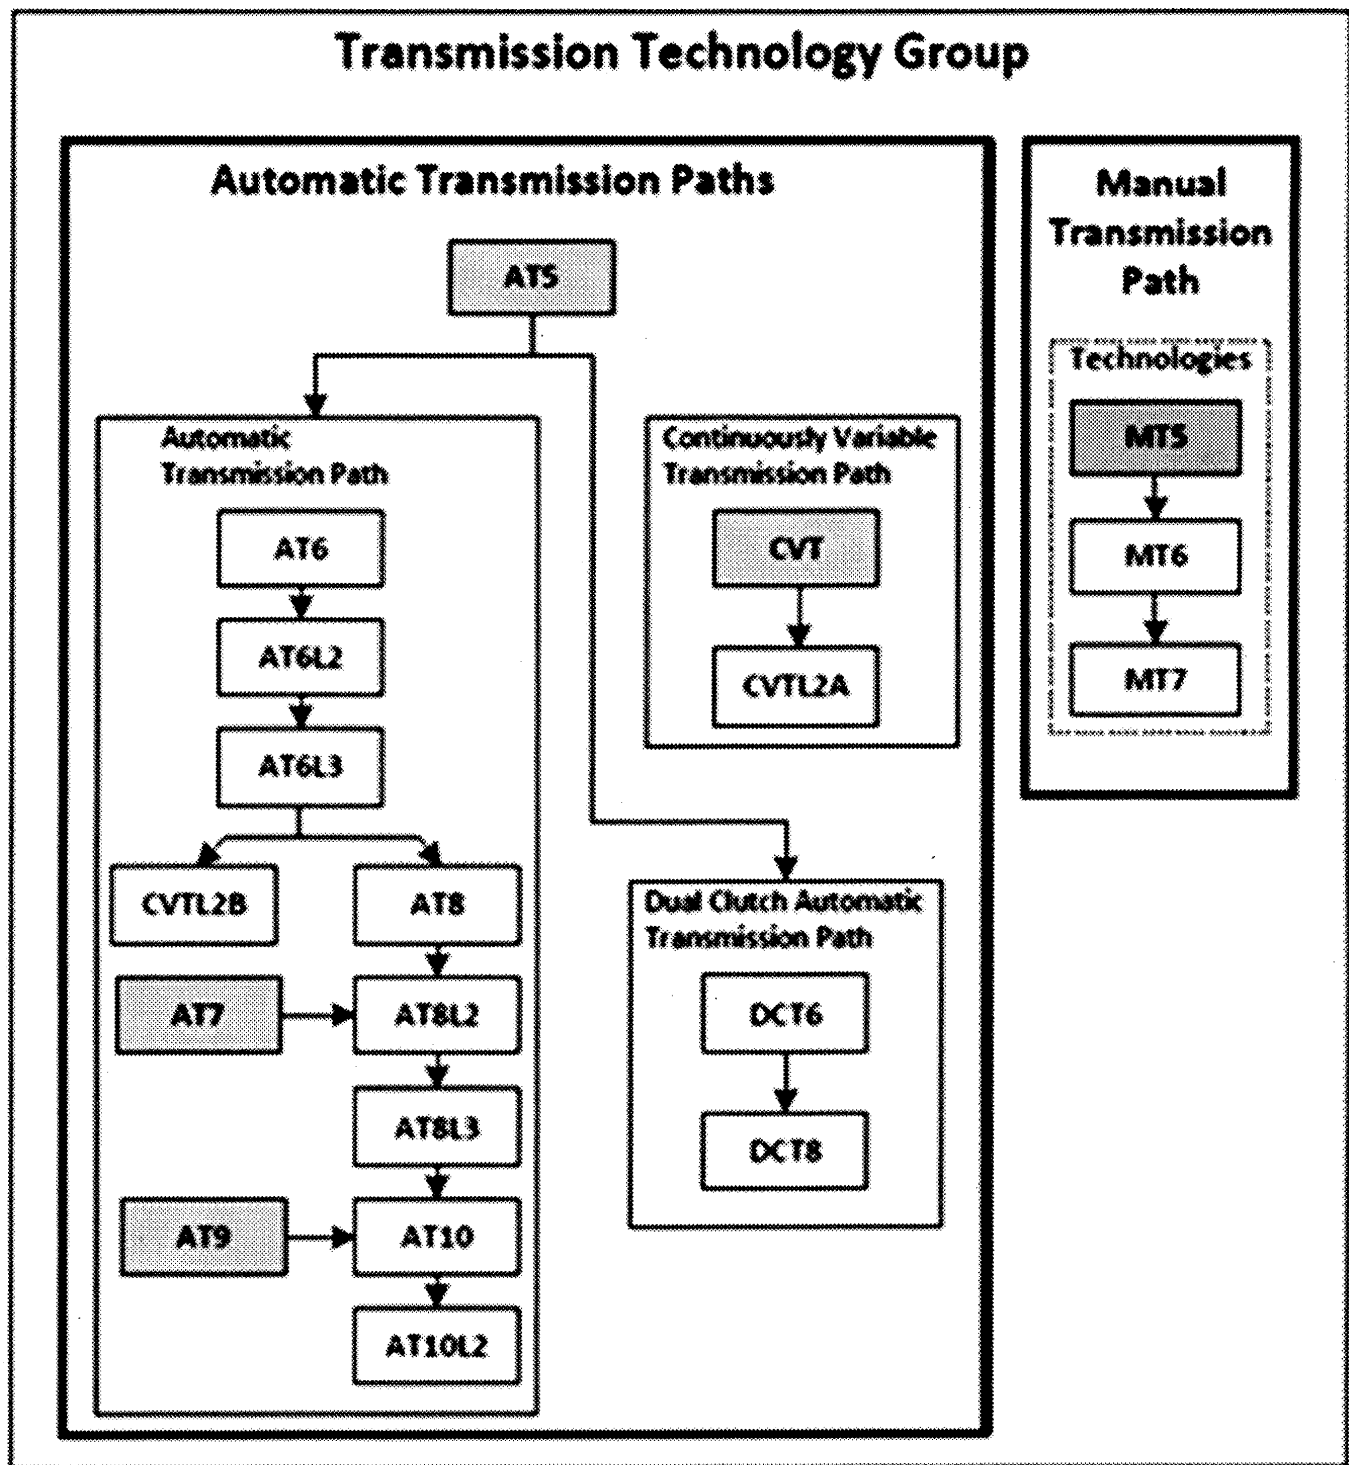

Figure VI-22 – NPRM Transmission Paths

BILLING CODE 4910-59-C

The model generally may apply any of the more efficient transmission technologies that are contained within the pathway of the baseline vehicle initial transmission configuration. The

model prohibits manual transmissions from becoming automatic transmissions. Automatic transmissions may become CVT level 2 after progressing through the 6-speed automatic, as shown in Figure VI-22. While the structure of the model

could allow automatic transmissions to consider applying a DCT, the market data file was used to preclude the application of DCTs to automatic transmission vehicles, as discussed

further in Section VI.C.2.c) Transmission Adoption Features, below.

The model does not attempt to simulate “reversion” to less advanced transmission technologies, such as replacing a 6-speed AT with a DCT and then replacing that DCT with a 10-speed AT. The agencies invited comment on whether the model should be modified to simulate “reversion” and, if so, how this possible behavior might be practicably simulated. Richard Rykowski, supporting comments from the Environmental Defense Fund (EDF), broadly discussed the concept of reversion in the CAFE model, and included an example relating to the transmission technology paths.⁹⁶³ Mr. Rykowski stated that it is “possible that the model could add a 10-speed transmission to a vehicle with a very basic engine” and then as the simulation progressed and “the manufacturer required greater fuel or CO₂ emission control, the Volpe Model might move to a TURBO1 or HCR engine” and the vehicle would no longer need the 10-speed transmission to meet standards, and a 6-speed or 8-speed transmission might be more cost effective.

The scenario discussed by Mr. Rykowski is very unlikely. The CAFE model cost optimization algorithm considers both current and future standard requirements when selecting current MY technologies. The algorithm will look multiple years into the future and compare multiple potential technology paths going forward for the most cost-effective path. For a more detailed discussion on the cost

optimization algorithm see Section VI.A.4, Compliance Simulation.

Regarding the types of transmission technologies modeled, Meszler Engineering Services provided a comment criticizing the limited number of manual transmission model options and the limited technology paths available to vehicles with manual transmissions.⁹⁶⁴ The agencies do not agree with Meszler Engineering Service’s assessment. The manual transmission path includes three model options and allows for the vehicles to receive electrification in the form of SS12V and BISG technologies. The agencies believe the technology paths dedicated to manual transmission was appropriate for vehicles that typically represent manufacturers’ specialty performance cars, such as the Subaru STI or BMW M-series, that comprise an overall fleet share of less than 2 percent.

Commenters also discussed potential missing transmission technologies in the NPRM analysis. ICCT stated that the agencies failed to consider transmission warm-up technologies, which are available in 3.7 million new vehicles in the MY 2016 fleet, that are being deployed due to regulatory test-cycle benefits and off-cycle credits.⁹⁶⁵ In addition, the Fiat Chrysler Automobiles (FCA) also expressed concern over the lack of inclusion of thermal bypass devices in the modeling of transmission technologies.⁹⁶⁶

The agencies agree with parts of ICCT’s and the FCAs comments and

disagree with other parts. The agencies do agree with ICCT and the Auto Alliance that the analysis should consider the off-cycle benefits of transmission warm-up technology. For the final rule analysis, the agencies applied off-cycle technologies in the CAFE model. For the final rule analysis, the agencies applied off-cycle technologies at the maximum menu regulatory value of 10 g/mile for all manufacturers by MY 2023. The modeled adoption included benefits of transmission warm-up as a menu item. The modeling of off-cycle technologies is further discussed in Section VI.C.8. The agencies disagree with ICCT and the Auto Alliance comments that transmission warm-up technologies were not included in the NPRM on-cycle analysis. For the NPRM, and for the final rule, the HEG level 2 technology package includes rapid transmission oil warm-up technology.⁹⁶⁷ The inclusion of the HEG2 technology package in AT and CVT models accounts for impacts of this technology to performance on the standard test-cycle.

For the final rule analysis the transmission model paths are shown in Figure VI–23. For the final rule analysis, the baseline-only technologies (MT5, AT5, AT7L2, AT9L2, and CVT) are grayed and are only used to signify initial vehicle transmission configurations. For simplicity, all manual transmissions with five forward gears or fewer are assigned the MT5 technology in the analysis fleet. Similarly, all automatic transmissions with five forward gears or fewer are assigned the AT5 technology.

⁹⁶⁶ Comments from Fiat Chrysler Automobiles, Attachment 1, NPRM Docket No. NHTSA–2018–0067–11943, at 97.

⁹⁶⁷ 2015 NAS Report, at 191.

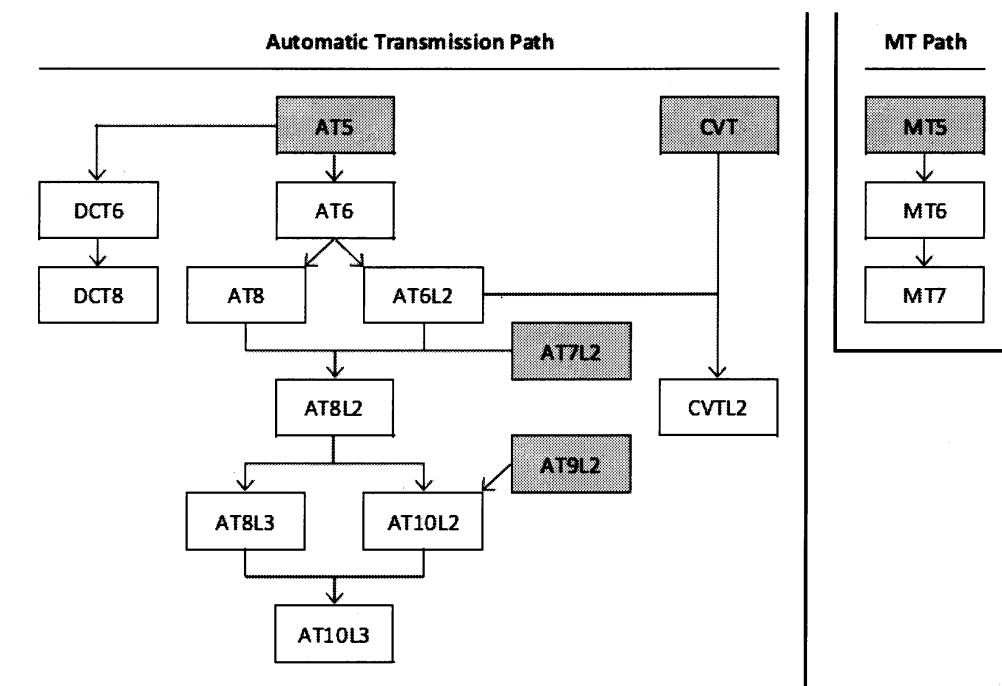

Figure VI-23 – The Transmission CAFE Model Pathways for Transmission Technologies

Since the Manual Transmission path terminates with MT7, the system assumes that all manual transmissions with seven or more gears are mapped to the MT7 technology. Moreover, all dual-clutch (DCT) or auto-manual (AMT) transmissions with five or six forward gears are mapped to the DCT6 technology, and all DCTs or AMTs with seven or more forward gears are mapped to DCT8.

For the final rule analysis, the naming convention for the transmission technology models was updated to identify better the technologies

represented in each transmission. Although the technologies in each transmission configuration were described in the NPRM, there appears to have been confusion among some commenters about the technology content of some transmission configurations. Some commenters compared the NPRM AT10 to the NPRM AT8, and commented on unexpected differences in effectiveness relative to the differences in transmission gear count.⁹⁶⁸ For the given example, the NPRM AT8 represented a baseline 8-speed automatic transmission, with

level 1 HEG technology applied, and the NPRM AT10 represented a 10-speed automatic transmission with level 2 HEG technology applied. A direct comparison of gear count would occur by comparing the NPRM AT8L2 to the NPRM AT10. The updated naming convention identifies the transmission technology type, gear count and HEG technology level. Table VI-78 shows the final rule names for transmission models compared to the names used for the NPRM analysis.

BILLING CODE 4910-59-C

b) Transmission Analysis Fleet Assignments

The agencies discussed in the NPRM the process for developing the 2016 analysis fleet, including how the agencies weighed using confidential business information versus publicly-releasable sources, the use of compliance data, and decision to use a 2016 analysis fleet over other alternatives.⁹⁶⁹ As discussed above, this final rule analysis used the 2017 vehicle fleet as the analysis fleet input, and the agencies followed largely the same process for assigning initial transmission assignments as in the NPRM.

For the 2017 analysis fleet, transmission data was gathered from the manufacturer final model year CAFE compliance submissions to the agencies as well as manufacturer press releases. The data for each manufacturer was used to determine which platforms shared transmissions and to establish the leader-follower relationships between vehicles. Within each manufacturer fleet, transmissions were assigned unique identification designations based on technology type, drive type, gear count, and technology version. The data were also used to identify the most similar transmission

among the Autonomie transmission models, as discussed further below.

The transmission characteristics of vehicles in the analysis fleet show manufacturers use transmissions that are the same or similar on multiple vehicle models. Manufacturers have told the agencies they do this to control component complexity and associated costs for development, manufacturing, assembly, and service. Both the NPRM and final rule analyses account for this sharing. To identify common transmissions, the agencies considered the transmission type (manual, automatic, dual-clutch, continuously variable), number of gears, and vehicle architecture (front-wheel-drive, rear-wheel-drive, all-wheel-drive based on a front-wheel-drive platform, or all-wheel-drive based on a rear-wheel-drive platform). If multiple vehicle models shared these attributes, the transmissions were treated as single group for the analysis. Vehicles in the analysis fleet with the same transmission configuration adopted transmission technology together.

For ATs and CVTs, the identification of the most similar Autonomie transmission model required additional steps beyond just assigning gear count for ATs, or just assigning the CVT model. A review of the age of the transmission design, relative performance versus previous designs,

and technologies incorporated was conducted, and the information obtained was used to assign a HEG level. Engineering judgment was used to compare the technologies and performance improvements reported versus descriptions of HEG technology discussed in the NAS report.⁹⁷⁰

In addition, no automatic transmissions in the 2017 analysis fleet were determined to be initially at a HEG Level 3. However, all 7-speed automatic transmissions, all 9-speed automatic transmissions, all 10-speed automatic transmissions and some 8-speed automatic transmissions were found to be advanced transmissions operating at a Level 2 HEG equivalence. All other transmissions were assigned at the minimum level.

c) Transmission Adoption Features

The agencies included several transmission adoption features in the NPRM that have been carried over for the final rule analysis. For a detailed discussion of path logic applied in the final rule analysis, including technology supersession logic and technology mutual exclusivity logic, please see FRM CAFE Model Documentation Section S4.5, Technology Constraints

⁹⁶⁹ 83 FR 43003.

⁹⁷⁰ 2015 NAS Report, at 191.

(Supersession and Mutual Exclusivity).⁹⁷¹

(1) Automatic Transmissions

Automatic transmission technology adoption is defined by path logic and technology availability. The transmission path precludes adoption of other transmission types once a platform progresses past an AT6. This restriction is used to avoid the significant level of stranded capital that could result from adopting a completely different transmission type shortly after adopting an advanced transmission, which would occur if a different transmission type was adopted after AT6 in the rulemaking timeframe. Stranded capital is discussed in more detail in Section VI.B.4.c), Stranded Capital Costs. In addition, any automatic transmissions that use HEG3 technology cannot be phased in until the 2020 model year. The technology phase-in year is based on the estimated availability of HEG3 technology from the NAS (2015) report and confidential data obtained from OEM's and suppliers. Finally, all P2HEVs are paired with an AT8 transmission, which is also discussed further in Section VI.C.3.c).

One commenter expressed concern that all P2HEVs were paired with an AT8 transmission, and argued that the full slate of transmission technology should be available for adoption with that powertrain technology.⁹⁷² The commenter correctly observed a limit of transmission technologies for use only with the P2HEV technology option; all other HEV based technology options did not have this limitation.

The agencies disagree that a greater variety of transmission technologies are necessary to model the P2HEV technology reasonably. The P2HEV demonstrated limited response to transmission technologies beyond the AT8L2, and access to those technologies were limited to reflect the diminishing returns anticipated for higher gear counts used in conjunction with the P2 system, and trends in industry.⁹⁷³ Adopting P2HEV to a conventional vehicle provides a significant fuel consumption improvement, agnostic of

transmission type, based on the agencies' full vehicle simulation results.

(2) Continuously Variable Transmissions

Application of CVTs in the NPRM and final rule analysis was not allowed for high torque vehicle applications. The launch, acceleration, and ratio variation characteristics of powertrains with CVTs may be significantly different than ATs leading to potential consumer acceptance issues and/or complaints. Several manufacturers have told the agencies that they employ strategies that mimic AT shifting under some conditions to address these issues. Some manufacturers have also encountered significant engineering challenges in employing CVTs for use in high torque or high load applications.

In addition, the CVT adoption was limited by technology path logic. CVTs cannot be adopted by vehicles that do not start with a CVT or by vehicles beyond the AT6 in the baseline fleet which have a greater number of gear ratios and therefore increased ability to operate the engine at a highly efficient speed and load. Once on the CVT path the platform is only allowed to apply improved CVT technologies. This restriction is used to avoid the significant level of stranded capital that could result from adopting a completely different transmission type shortly after adopting an advanced transmission, which would occur if a different transmission type was adopted in the rulemaking timeframe. Stranded capital is discussed in more detail in Section VI.B.4.c), Stranded Capital Costs.

The Alliance commented that the analysis "appropriately restricts the application of CVT technology on larger vehicles."⁹⁷⁴ The agencies concurred with the Alliance's observations and thus the limitations on CVT application were continued in the final rule analysis.

(3) Dual Clutch Transmission

For DCTs, while the structure of the model could allow automatic transmissions to consider applying a DCT, the market data file was used to preclude the application of DCTs to vehicles that had already adopted an automatic transmission with six or more gears (e.g., AT6 through AT10). The model allows baseline vehicles that have DCTs to apply an improved DCT (if opportunities to do so exist), and allows vehicles with an AT5 to consider DCTs. This was done to ensure vehicle functionality is maintained as

technologies are applied, and accounts for consumer acceptance issues related to the drivability and launch performance tradeoffs. These issues with DCTs resulted in a low relative adoption rate over the last decade.⁹⁷⁵ It also is broadly consistent with manufacturers' technology choices.

(4) Manual Transmissions

Manual transmission technology adoption in the CAFE model remained unchanged from the NPRM and is only limited by the technology path limits discussed above. Manual transmissions cannot be adopted by vehicles that do not start with a manual transmission in the analysis fleet. Vehicles with manual transmissions cannot receive an alternate transmission technology, and may only progress to more advanced manual transmissions. These restrictions are in recognition of the low customer demand for manual transmissions.⁹⁷⁶

d) Transmission Effectiveness Modeling and Resulting Effectiveness Values

For the NPRM and final rule analysis, full vehicle simulation was used to understand how transmissions work within the full vehicle system to improve fuel economy, and how changes to the transmission subsystem influence the performance of the full vehicle system.

The Autonomie tool models transmissions as a sequence of mechanical torque gains. The torque and speed are multiplied and divided, respectively, by the current ratio for the selected operating condition. Furthermore, torque losses corresponding to the torque/speed operating point are subtracted from the torque input. Torque losses are defined based on a three-dimensional efficiency lookup table that has as inputs: Input shaft rotational speed, input shaft torque, and operating condition.⁹⁷⁷

The general transmission models are populated with characteristics data to model specific transmissions. Characteristics data are typically provided in the form of tabulated data for transmission gear ratios, maps for transmission efficiency, and maps for torque converter performance, as applicable. The quantity of data needed

⁹⁷⁷ Detailed discussion of transmission modeling can be found in the ANL Model Documentation at Chapter 4 and Chapter 5.

depends on the transmission technology being modeled. The characteristics data for these models was collected from peer-reviewed sources, transmission and vehicle testing programs, results from simulating current and future transmission configurations, and confidential data obtained from OEMs and suppliers.⁹⁷⁸

The level of HEG improvement applied to a given transmission was modeled by improvements made to the efficiency map of the transmission. As an example, the 8-speed automatic transmission models show how a model can be incrementally improved with the addition of the HEG enhancement. The AT8 is the model of a baseline transmission developed from a transmission characterization report.⁹⁷⁹ The AT8L2 has the same gear ratios as the AT8, however the gear efficiency map has been improved to represent application of the HEG level 2 technologies. The AT8L3 models the application of HEG level 3 technologies using the same principle, further improving the gear efficiency map over the AT8L2 improvements.

The NPRM and final rule analysis, using the Autonomie tool, comprehensively simulated each of the 18 transmission technologies. Each transmission was modeled with explicit gear ratios, gear efficiencies, gear spans, adaptive shift logic, and transmission architecture individually for each of the ten vehicle types. The NPRM and final rule analysis clearly showed the specific contributions to effectiveness provided by each transmission technology combination and the associated cost. This provided greater transparency for public review and comment.

The implementation of the full vehicle simulation approach used in the NPRM analysis, and carried forward to the final rule analysis, clearly defines the contribution of individual transmission technologies and separates those contributions from other technologies. This modeling approach comports with the National Academy of Science 2015 recommendation to use full vehicle modeling supported by application of collected improvements

at the sub-model level.⁹⁸⁰ The approach allows the isolation of technology effects in the analysis which contributes to an accurate cost assessment.

This approach was supported by the Auto Alliance, who commented in support of the agencies' explicit and transparent modeling of the cost and effectiveness for each of the transmission technologies. The Alliance contrasted the NPRM approach with the transmission modeling methodology used in the Proposed Determination—which they strongly objected to—which had lumped together fundamentally different transmission technologies into bundles with identical cost and efficiencies, “making it impossible to fully comprehend the rationale” for the Proposed Determination’s high effectiveness estimates.⁹⁸¹

However, other stakeholders were not supportive of the modeling approach used in the NPRM. The Union of Concerned Scientists (UCS) thought a level of abstraction was necessary to account for unpredictability in the market, such as the failure of the dual-clutch transmission to reach widespread use as anticipated in the agencies 2012 analysis for MYs 2017 and later. UCS thought that keeping the transmission technology generalized would avoid the pitfalls of potentially picking the wrong technology leader, but would still predict the general trend of behavior, stating that “[i]ncidentally, this is an example of why we supported EPA’s move to a more generic representation of transmissions in its OMEGA modeling.”⁹⁸²

The agencies disagree with UCS’s suggestion to generalize the transmission technology groupings for the analysis. By grouping the technologies into overly broad, generic categories, the analysis loses accuracy on the costs and the effectiveness for specific systems. The OMEGA model used general transmission categories, asked for by UCS’s comments, as part of the CO₂ analysis in the Draft TAR and in the Proposed Determination, and the assumptions and limitations were acknowledged at the time.^{983 984} One

assumption used by the OMEGA model approach was “[t]he incremental effectiveness and cost for all automated transmissions are based on data from conventional automatics.”⁹⁸⁵ In response, the Alliance observed that the transmission groups used “do not recognize unique efficiencies of different transmission technologies.”⁹⁸⁶ At the time EPA stated “the potential effectiveness gains between TRX levels, while arising from different technology packages within each transmission type, will be very similar among the transmission types.”⁹⁸⁷ However, as shown in Table VI–81 and Table VI–82, there are nontrivial differences in the costs of different transmission technologies.

The approach used in the NPRM analysis and this final rule analysis is an evolution of the approach used for the Proposed Determination model, and avoids the issue described above. The NPRM and final rule analyses reduce the span of transmission technology groupings, with the intent to provide an increase in fidelity and precision for cost and performance, as was requested by stakeholders such as the Auto Alliance, while including tools to mitigate market effects, which addresses other concerns such as those expressed by UCS. In the analysis for the final rule the transmissions are grouped by technology type (AT, DCT, CVT, etc.) and gear count (5,6,7, etc.). The level of HEG technology applied as a separate factor further subdivided the transmission groups. Defining technology adoption features addresses the potential for market forces, such as those that affected the sales of DCTs, and supports the narrower technology groupings. Technology adoption features are defined through market research, historic and current fleet composition analysis, and dialogue with manufacturers.

Commenters also provided general comments regarding the values of effectiveness for advanced transmissions used for the NPRM

analysis versus values used for the Draft TAR. For example, CARB noted a “2 percent-3 percent lower efficiency assumed for advanced 8- and 9-speed transmissions relative to the data EPA itself previously developed with back to back testing on FCA vehicles,”⁹⁸⁸ with similar concerns expressed by other commenters.⁹⁸⁹ Meszler Engineering Services wondered “why the AT10 technology was being so widely adopted when its associated benefits appeared negligible for a particular vehicle” and noted “[t]he wide ranging effectiveness estimates were unexpected.”⁹⁹⁰ Senator Tom Carper also noted “the most advanced eight speed transmission technology are assigned unrealistically low fuel efficiency effectiveness values for some vehicle types.”⁹⁹¹

The Auto Alliance also provided comments with regards to the larger variation of effectiveness values that were of concern to commenters such as Meszler Engineering Services and Senator Tom Carper. The Auto Alliance acknowledged that the use of full vehicle simulation, with more details, results in greater diversity of results. The comment stated, “Over an entire fleet, a more reasonable expectation is that there will be some vehicles with higher fuel economy than expected for a given technology set and some vehicles with a lower fuel economy than expected for a given technology set. As discussed above, these differences arise for a variety of reasons, and cannot simply be attributed to “less than optimal technology integration.”⁹⁹²

The Auto Alliance also specifically commented on the FCA vehicle study used to support CARB’s comment and used to generate the TAR analysis values. The Auto Alliance pointed out that the vehicles used in the study had other technology differences, however the study still “proceeds to compare the fuel economy of these variants to assert support for its own estimate of transmission effectiveness. This comparison neglects that the 2.4L engines in these variants are not the

same and that the variant with the nine-speed transmission was a redesigned vehicle.” The Alliance concluded, therefore, that “the Chrysler 200 comparison provided by H-D Systems does not compare a transmission change in isolation from other changes that impact fuel economy and likely overestimates the benefits associated with the transmission change.” The Auto Alliance summarized the analysis of the study by noting that “[s]uch differences also impact fuel economy, confounding an analysis which purports to compare the fuel economy benefits associated directly with the transmission.”⁹⁹³

The agencies agree with the Auto Alliance assessment of the 8- and 9-speed FCA vehicles, and have based analysis inputs on alternate information sources.⁹⁹⁴ However, the observations by commenters of a wider range of values for the NPRM effectiveness when compared to the Draft TAR compliance analyses are a direct result of the improvements in modeling approach. As discussed above the NPRM compliance analysis increased the number of transmission technology paths considered by further subdividing the technology groupings. The change resulted in a wider range of effectiveness, as the specific transmission technologies are paired across all the configurations of vehicle technologies. In addition to this greater range, there were also specific effectiveness issues identified for some of the transmission technologies, which are addressed in the sections below.

Commenters may also be observing, with comments like “advanced transmissions have low effectiveness with some vehicles types,” an expected effect when an advanced transmission is coupled to an advanced engine. The National Academy of Science, in their 2015 report, noted that “as engines incorporate new technologies to improve fuel consumption, including variable valve timing and lift, direct injection, and turbocharging and downsizing, the benefits of increasing transmission ratios or switching to a

CVT diminish.”⁹⁹⁵ This is not to say that transmissions are not an important technology going forward, but rather a recognition that advanced engines have larger “islands” of low fuel consumption that rely less on the transmission to improve the overall efficiency of the vehicle. Thus, effectiveness percentages reported for transmissions paired with unimproved engines would be expected to be reduced when the same transmission is paired with a more advanced engine.

Commenters also expressed concern for the transmission gear set and final drive values used for the NPRM analysis, or, more specifically, that the gear ratios were held constant across applications. Roush commented that “all transmissions with a given number of ratios (8-speed, 10-speed) maintain the same individual step ratios” and that this would lead to “powertrain inefficiencies and under-predict potential fuel economy benefits.”⁹⁹⁶ CARB, quoting a report from its contractor, noted that “the final drive ratio was kept constant as powertrains were changed and that transmission gear ratios were not optimized,” and suggested that manufacturers forgoing improvements from gear ratio or final drive ratio changes is unrealistic and results in an underestimation of the benefits from advanced transmissions.⁹⁹⁷

However, the Auto Alliance stated that “[m]anufacturers share major technologies such as transmissions and engines across multiple vehicle models and platforms.” The Auto Alliance also supported the agencies’ approach of not including final drive ratio changes, particularly when only minor system changes are incurred. The Auto Alliance continued further stating that “[i]n the case of passenger cars, the final drive ratio is frequently the same across multiple models that use the same transmission.”⁹⁹⁸

The agencies disagree with Roush, Duleep, and CARB’s assessment. It is an observable practice in industry to use a common gear set across multiple platforms and applications. The most recent example is the GM 10L90, a 10-speed automatic transmission that used the same gear set in both pick-up truck

and passenger car applications.⁹⁹⁹ Optimization of performance is achieved through shift control logic rather than customized hardware for each vehicle line. The use of a single gear set for each transmission technology also supports the overall analysis approach. The level of technology performance modeled must reasonably represent a typical level of performance representative of the industry range of performance. If the systems were over-optimized for the agencies' modeling, such as applying a unique gear set for each individual vehicle configuration, the analysis would likely over-predict the reasonably achievable fuel economy improvement for the technology. Over-prediction would be exaggerated when applied under real-world large-scale manufacturing constraints necessary to achieve the estimated costs for the transmission technologies. Accordingly, the agencies used the NPRM approach for the final rule analysis.

In response to comments related to the effectiveness of micro-HEV systems, which are discussed in Section VI.C.3.d)(2)(a), and comments related to the effectiveness of diesel engines, which are discussed in Section VI.C.1.c)(8), the agencies took a close look at NPRM effectiveness results. Two issues were identified related to the interaction between Autonomie transmission models and other Autonomie powertrain technology models. First, a logic issue was found in a transmission control subroutine and, second, there was an issue with a sub-model input. While these items were caused by issues in the transmission model sub-systems, the effects manifested in the effectiveness of the micro-HEV systems and the diesel engine systems. Autonomie uses a gearbox transient sub-model to control the simulated state of powertrain components during a transmission event, such as shifting or vehicle starting and stopping. The simulated powertrain component states include conditions such as clutch engagement, or engine operation mode. A detailed discussion of the Autonomie control model can be found FRM Argonne Model Documentation file at Section 4.4. Different versions of the sub-model are used for micro-HEV technologies (12VSS and ISG) than for conventional drivetrains, mild-HEV or Strong-HEV systems.

An issue was found in the control logic used in the micro-HEV version related to the sequence of powertrain component modes during shifting events for automatic transmissions, regenerative braking events for automatic transmissions, and stop start events for manual transmissions. While these issues reduced the effectiveness of the micro-HEV technology in the Argonne modeling results, they had very minimal effect on the overall NPRM Analysis. The control logic issue was resolved for the final rule analysis. There also was an issue with the gearbox transient sub-model used for micro HEVs that impacted calculation of the CVT best efficiency operating ratio targets under low torque conditions. This resulted in some negative effectiveness values for certain CVT technology combinations, but had very minimal effect on the overall NPRM results. This software item was also resolved for the final rule analysis.

As discussed in the Autonomie model documentation, FRM Argonne Model Documentation file at Section 4, the full vehicle model is created from a network of subsystem models. The subsystems all interact through data connections transferring outputs from one subsystem model to the inputs of another. An issue was identified with the definition of the connection between the gearbox transient sub-model for DCT's with diesel engines, which impacted the values provided to the diesel control model. This caused reduced effectiveness values for the diesel engines with DCTs in the Argonne modeling results, however it had very minimal effect on the overall NPRM analysis. The data connection issue was resolved for the final rule analysis.

Lastly, the agencies received several comments on transmission shifting logic, which are addressed in the following section.

(1) Shift Logic

Transmission shifting logic has a significant impact on vehicle energy consumption and was modeled in Autonomie to maximize the powertrain efficiency while maintaining acceptable drive quality. The logic used in the Autonomie full vehicle modeling relied on two components: (1) The shifting controller, which provides the logic to select appropriate gears during simulation; and (2) the shifting initializer, an algorithm that defines shifting maps (*i.e.*, values of the parameters of the shifting controller) specific to the selected set of modeled

vehicle characteristics and modeled powertrain components.¹⁰⁰⁰

(a) Shifting Controller

The shift controller is the logic that governs shifting behavior during simulated operation. The shift controller performance was informed by inputs from the model. The inputs included: Specific engine or transmission used, and instantaneous conditions in the simulation. Instantaneous conditions included values such as vehicle speed, driver demand and a shifting map unique to the full vehicle configuration.¹⁰⁰¹ The shift controller logic was consistently applied for all vehicles simulated.

Although no comments were received specifically on shift control logic, the agencies tracked several effectiveness concerns identified by commenters back to how the agencies modeled some transmissions paired with turbocharged engines. Meszler Engineering Services discussed an unexpected range of effectiveness observed for transmissions when coupled to different engine technologies, and concluded that "[m]oreover, the variation across technology combinations is markedly different."¹⁰⁰² Senator Carper's comments mirrored Meszler's, noting that "the more expensive version of an engine technology (TURBO2), which would be expected to be more fuel-efficient, was instead assigned a negative fuel-efficiency value for some types of vehicles."¹⁰⁰³ The Senator also observed the same phenomenon for cooled exhaust gas recirculation (CEGR I), which "was assigned a fuel-efficiency effectiveness of at or near zero." Similarly, UCS noted that "many simulations of improved transmissions and turbocharged engines show little incremental improvement over less complex technologies."¹⁰⁰⁴

In response to the comments, the agencies conducted an in-depth review of these technology combinations. The agencies determined the minimum lugging speed for turbocharged engines, which controls the minimum engine speed allowed before down-shifting, caused the observed behavior. The issue was isolated to some combinations of advanced transmissions and

¹⁰⁰⁴ Comments from UCS, Attachment 1, NPRM Docket No. NHTSA-2018-0067-12039, at 32.

⁹⁹⁹ "GM Global Propulsion Systems—USA Information Guide Model Year 2018" (PDF). General Motors Powertrain. Retrieved 26 September 2019. https://www.gmpowertrain.com/assets/docs/2018R_F3F_Information_Guide_031918.pdf.

turbocharged engines. For the final rule analysis, a modification was made to the shift controller logic of transmissions coupled to turbocharged engines. Specifically, the minimum lugging speed allowed for turbocharged engines was increased in the shift controller. An

increase in lugging speed increases the minimum speed at which the shift controller will allow the engine to operate before down-shifting, resulting in increased operation in better efficiency regions of the engine map.¹⁰⁰⁵ The updated lugging speeds are based

on Argonne benchmarking data of the 2017 F150.¹⁰⁰⁶ The updated values are shown in Table VI-79, the lugging speeds for naturally aspirated engines are shown as reference and remain unchanged from the NPRM.

Table VI-79 – Lugging speeds for transmissions in the final rule analysis

| | 5-speed | 6-speed | 7-speed | 8-speed | 9-speed | 10-speed |
|--|---------|---------|---------|---------|---------|----------|
| Naturally Aspirated Lugging speed (rad/s) | 140 | 130 | 120 | 110 | 110 | 110 |
| Turbocharged Lugging speed (rad/s) | 140 | 130 | 130 | 130 | 130 | 130 |

(b) Shift Initializer

As defined above, the shifting initializer is an algorithm that defines shifting maps (*i.e.*, values of the parameters of the shifting controller) specific to the selected set of modeled vehicle characteristics and modeled powertrain components.

Commenters stated that the model did not customize shifting maps for each transmission application. Roush Industries commented, “[t]he 2018 PRIA analysis assumes that all transmissions with a given number of ratios maintain the same individual step ratios and shift maps.”¹⁰⁰⁷ Roush also commented that the effectiveness of transmissions were understated due to inaccurate transmission maps or “the lack of vehicle system optimization and calibration.”¹⁰⁰⁸ UCS stated that the “transmission shift strategy does not deploy gear-skipping or other more modern control strategies.”¹⁰⁰⁹ HDS

provided similar comments to Roush, observing that the Autonomie models “do not optimize engine efficiency after most changes in tractive load because the model employs fixed shift points, gear ratios, and axle ratios.”¹⁰¹⁰ Finally, CARB expressed that “[f]or the Autonomie modeling, a fixed final drive ratio was utilized and, presumably, a fixed shift logic based on the selected transmission.”¹⁰¹¹

The commenters seem to conflate the practice in the analysis of using the same gear sets across vehicle configuration with using the same shift maps. As commenters stated, they assumed the same maps were applied across vehicle models. However, the shift initializer routine was run for every unique Autonomie full vehicle model configuration and generated customized shifting maps. The algorithms’ optimization was designed to balance minimization of energy

consumption and vehicle performance.¹⁰¹² This balance was necessary to achieve the best fuel efficiency while maintaining customer acceptability by meeting performance neutrality requirements, as discussed in Performance Neutrality, Section VI.B.3.a)(6).

While discussing shift logic, commenters also expressed concern about the capturing of fuel efficiency losses associated with shifting events. Roush stated, “[t]he 2018 PRIA transmission modeling does not accurately capture the losses and FE penalty associated with a shift event.”¹⁰¹³ The agencies disagree with this statement. While losses associated with a shifting event are not modeled as a single factor, the mechanisms that cause the loss are appropriately incorporated in the Autonomie transmission models.

¹⁰¹³ Comments from Roush Industries, Attachment 1, NPRM Docket No. NHTSA-2018-0067-11984, at 14-15.

The automatic transmission models have an associated torque converter model.¹⁰¹⁴ The torque converter model is designed to simulate the inertial and torque loads imposed on an engine because of shift events. Other clutch-based transmission models, MTs and DCTs, apply a general loss of efficiency across transmission efficiency maps to account for losses due to shift events.

(2) Transmission Effectiveness Values

The NPRM technology effectiveness modeling results showed that the effectiveness of a technology often varies with the type of vehicle and the other technologies that are on the vehicle. Figure VI-24 shows the range of effectiveness for each transmission technology across the range of vehicle

types and technology combinations in the NPRM analysis. The data reflect the change in effectiveness for applying each transmission technology by itself while all other technologies are held unchanged. The effectiveness improvement range is over a 5-speed automatic transmission.

Figure VI-24 – Range of Effectiveness for Transmission Technologies in NPRM Analysis

(a) Automatic Transmissions

Regarding AT effectiveness values, commenters pointed out the unusually high level of effectiveness displayed by the AT6L2 transmission. ICCT and UCS both specifically expressed concern with the effectiveness of the AT6L2 compared to other advanced transmissions.¹⁰¹⁵ The performance of the AT6L2 was central to ICCT's analysis of the NPRM inputs, which highlighted the AT6L2 models' performance, showing the cost versus effectiveness of the AT6L2 outperformed more advanced transmission options.¹⁰¹⁷

Evaluation of the AT6L2 transmission model in response to these comments revealed an overestimated efficiency map was developed for the NPRM model. The high level of efficiency assigned to the transmission surpassed benchmarked advanced transmissions.¹⁰¹⁸ To address the issue, the agencies replaced the effectiveness values of the AT6L2 model for the final

rule analysis with AT7L2 effectiveness values.

The updated estimate of effectiveness is supported by values shown in the NAS 2015 analysis.¹⁰¹⁹ The study estimated the difference in effectiveness between a 6-speed automatic transmission and a 7-speed automatic transmission of approximately the same technology level to be 0.8 percent. The difference is reduced further when application of high efficiency gear box technology ranges of effectiveness is applied. Because the 7-speed automatic transmission and the advanced 6-speed automatic transmission technologies are parallel on the technology tree, the agencies felt using the same effectiveness value was reasonable and appropriate.

Commenters also pointed out a lack of skip-shift logic used in the NPRM analysis, and an increase in the shift busyness observed for the high gear count transmissions. Roush commented on the NPRM analysis "not

incorporating the concept of 'Skip shifting' which is important for reducing shift busyness and increasing FE especially in vehicles equipped with transmission with a large number of ratios (8–10)." ¹⁰²⁰ Both CARB and UCS repeated similar concerns.¹⁰²¹

After consideration of the comments and re-evaluation of the NPRM results, the agencies concurred with the commenters. The lack of skip-shift logic and increased shift busyness can result in lower overall efficiency and decreased consumer acceptance. For the final rule analysis, a skip-shift logic was applied to the 10 speed automatic transmissions. The logic was based on the baseline 2017 Ford F150 10-speed transmission benchmarking performed by Argonne.¹⁰²² The introduction of the skip-shift logic impacted effectiveness and reduced the number of shifts by 23 percent for the 10-speed automatic transmission over the UDDS cycle.¹⁰²³

In the NPRM analysis, transmission gear spans increased as the number of

¹⁰¹⁴ See FRM ANL Model Documentation at Paragraph 4.5 and Paragraph 5.4.

¹⁰²³ See FRM ANL Model Documentation file at Paragraph 4.4.5.5. This update reduced the number of shift events from 231 to 178.

gears increased.¹⁰²⁴ However, to address further the comments related to optimization, the gear span of the AT10L3 was increased over the AT10L2, based on gear span data for the Honda 2018 10-speed transmission.¹⁰²⁵ The AT10L3 span was increased to 10.10 in the final rule analysis from 7.34 in the NPRM analysis. However, the efficiency map for the AT10L3 remained the same for the final rule analysis.¹⁰²⁶

Finally, in the agencies' review of NPRM model inputs, a weight discrepancy for the AT10 transmissions was identified. The weight assigned to the AT10 transmission in the NPRM analysis was too high. The weights were corrected for the final rule analysis. The AT10 transmission weights were reduced by 20–45 kg, depending upon vehicle type.¹⁰²⁷

The AT effectiveness values used for the final rule analysis can be seen in

Figure VI–25. For automatic transmission technologies, the effectiveness improvement range is relative to a 5-speed automatic transmission. The new effectiveness values are a result of the aforementioned changes implemented to address comments. To summarize, the changes included an adjustment to the modeled effectiveness of the AT6L2, the use of skip-shift logic on the 10-speed transmissions, and the increase of the AT10L2 gear span.

Figure VI–25 shows the automatic transmission's effectiveness increases progressively in a logical order and behaves in an expected manner. Gains in effectiveness can be observed increasing as gear count increases, and as HEG levels increase. The effects of diminishing returns can be observed as gear count reaches higher levels, and effectiveness effects for increased gear

count are reduced. This agrees with observed data reported by the NAS and industry stakeholders.^{1028 1029}

(b) Continuously Variable Transmissions

For CVTs, the agencies also identified a discrepancy with the NPRM CVT weights. The weight assigned to the CVT class during the NPRM analysis was incorrect. Corrected values were assigned for the final rule analysis. The CVT weights were reduced by 9–10 kg based on vehicle type.¹⁰³⁰

The CVT effectiveness values used for the final rule analysis can be seen in Figure VI–26, shown as an effectiveness improvement over a 5-speed automatic transmission. The effectiveness values were not changed significantly from the values used in the NPRM analysis.

e) Transmission Costs

For the NPRM, the transmission technology costs used as inputs for the CAFE model were retail price equivalent costs with learning curves applied. For a complete discussion on

how the retail price equivalent and learning effects were applied to direct manufacturing costs see Section VI.B.4.b), Indirect Costs, and Section VI.B.4.d), Cost Learning. The direct manufacturing costs for the transmission technologies used in the

NPRM were derived from technical sources and manufacturer’s CBI.¹⁰³¹

Table VI–80 below shows the relative costs of the transmissions used in the NPRM analysis including learning and retail price equivalent.

Figure VI–28 – Effectiveness of Manual Transmissions for Final Rule Analysis

BILLING CODE 4910–59–C

(1) Automatic Transmissions

Several comments were received on technology costs, or cost effectiveness. Meszler Engineering Services noted that “AT10L2 (level 2 ten-speed automatic) transmission technology is another example of an end-of-path technology with very poor cost effectiveness relative to other transmission options.”¹⁰³² A cost analysis by ICCT also showed relative costs of transmission technologies may not be in line with the modeled effectiveness.¹⁰³³

The agencies conducted a review of transmission costs in response to the comments. For the final rule analysis,

adjustments were made to costs of the AT6L2, AT7L2, AT9L2, AT10L2, and the AT10L3. The costs were adjusted based on reviewing the recommended relative costs discussed in the NAS 2015 report. Table VI–81 shows the cost for the automatic transmissions in the final rule analysis.

The direct manufacturing cost (DMC) estimate for the AT6 is drawn from Table 5.7 of the NAS report. The DMC estimate for the AT6L2 is based on the cost of the AT6 with HEG level 2 technology costs applied. This cost change is applied in accordance with the effectiveness adjustment made for the AT6L2.

A DMC estimate for the AT7 was drawn from Table 5.9 of the NAS report and was based on the cost of a system already equipped with HEG technology. The DMC estimate was given in 2007 dollars and relative to an AT5/AT4. The new DMC replaces the DMC from the NPRM, which did not account for the HEG technology.

The DMC for the AT9 technology was drawn from Table 8A.2a of the NAS (2015) report and per the NPRM description of the technology made relative to the AT8L2. The AT9 is assumed to have at least the level 2 HEG technology applied. The NPRM analysis assumed the AT9 cost was only relative

¹⁰³¹ See PRIA Section 6.3.7.3.

(3) Dual Clutch Transmissions

The agencies received one comment on cost learning over time for DCT technologies. Roush Industries “believes that the [actual] learning factors for such systems are significantly better than those estimated by either the 2018 PRIA or the 2016 Draft TAR.” Roush stated

that “eight-speed DCTs (DCT8) are currently in production (MY2018), with quantities increasing significantly,”¹⁰³⁴ but provided no specific supporting data.

The current learning curve for the DCT technologies was established based on recommendations from the NAS 2015 report and on CBI data collected

from manufacturers and suppliers. Since Roush did not supply any data to support its comment, the agencies decided it was reasonable to make no change to the DCT learning curve for the final rule analysis. Table VI-83 shows the cost for the DCTs in the final rule analysis.

Table VI-82 – Summary of Absolute Transmission Cost, including Learning Effects and Retail Price Equivalent for the Final Rule Analysis

| Name | Technology Pathway | C-2017 | C-2021 | C-2025 | C-2029 |
|-------|--------------------|-------------|-------------|-------------|--------------|
| CVT | CVT | \$ 2,341.87 | \$ 2,330.48 | \$ 2,322.63 | \$ 2,3165.55 |
| CVTL2 | CVT | \$ 2,534.64 | \$ 2,514.69 | \$ 2,500.94 | \$ 2,490.29 |

(4) Manual Transmissions

No adjustments were made to the NPRM costs of the manual transmission

technologies for the final rule analysis. Table VI-84 shows the cost for the MTs in the final rule analysis.

BILLING CODE 4910-59-C

3. Electric Paths

The electric paths include a large set of technologies that share the common element of using electrical power for certain vehicle functions that were traditionally powered mechanically by engine power. Electrification technologies thus can range from electrification of specific accessories (for example, electric power steering to reduce engine loads by eliminating parasitic loss) to electrification of the entire powertrain (as in the case of a battery electric vehicle).

Electrified vehicles are considered, for this analysis, to mean vehicles with a fully or partly electrified powertrain. These include several electrified vehicle categories, including: Battery electric vehicles (BEVs), which have an all-electric powertrain and use only batteries for propulsion energy; plug-in hybrid electric vehicles (PHEVs), which have a primarily electric powertrain and use a combination of batteries and an engine for propulsion energy; and hybrid electric vehicles (HEVs), which use electrical components and a battery to manage power flows and assist the engine for improved efficiency and/or performance. HEVs are further divided into strong hybrids (including P2 and power-split hybrids) that provide strong electrical assist and in many cases, can support a limited amount of all-electric propulsion, and mild hybrids (such as belt integrated starter generator (BISG) hybrids, crankshaft integrated starter generator (CISG) hybrids, and 48V mild hybrids) that typically provide only engine on/off with minimum electrical assist.

Fuel cell electric vehicles (FCEVs) are also another form of electrified vehicle having a fully electric powertrain, and are distinguished by the use of a fuel cell system rather than grid power as the primary energy source.

The factors that influence the cost and effectiveness of electrification technologies are their components. These include: Energy storage components such as battery packs; propulsion components such as electric motors; and power electronics components, such as inverters and controllers, that process and route electric power between the energy storage and propulsion components. For the purpose of this analysis, these components are divided into battery components and non-battery components.

Battery components strongly influence the cost of electrified

vehicles.¹⁰³⁵ Because developments in battery technology may apply to more than one category of electrified vehicles, they are discussed collectively in Section VI.C.3.e). That section details battery-related topics that directly affect the specification and costing of batteries for all types of electrified vehicles considered in this analysis.

Non-battery components also have an influence on both the cost and effectiveness of electrified vehicles. The selection and configuration of non-battery technologies distinguish the different architecture among electrified vehicles. Non-battery components largely consist of propulsion components and power electronics.

Propulsion components typically include one or more electric machines (an umbrella term that includes what are commonly known as motors, generators, and motor/generators). Depending on how they are employed in the design of a vehicle, electric machines commonly act as motors to provide propulsion, and/or act as generators to enable regenerative braking and conversion of mechanical energy to electrical energy for storage in the battery.

“Power electronics” refers to the various components that control or route power between the battery system and the propulsion components, and includes components such as: Motor controllers, which issue complex commands to control torque and speed of the propulsion components precisely; inverters and rectifiers, which convert and manage DC and AC power flows between the battery and the propulsion components; onboard battery chargers, for charging the BEV or PHEV battery from AC line power; and DC-to-DC converters that are sometimes needed to allow DC components of different voltages to work together.

Onboard chargers are charging devices permanently installed in electrified vehicles to allow charging from grid electrical power. Onboard chargers travel with the vehicle and are distinct from stationary charging equipment. Level 1 charging refers to charging powered by a standard household 110–120V AC power outlet. Level 2 charging refers to charging at 220–240V AC power.

The agencies included a more extensive overview of charging technology and the state of charging infrastructure in the NPRM and PRIA, however, this was purely qualitative

because charging was not accounted for in any respect in the NPRM analysis. The Alliance commented that “[w]hile the costs of installing chargers and charger convenience were not taken into account within the Volpe model . . . these factors will continue to have an impact on the overall penetration of electrification technologies that the market will be willing to accept.”¹⁰³⁶ In contrast, the National Coalition for Advanced Transportation (NCAT) commented that the qualitative discussion overstated the risks and understated the benefits of electric vehicle charging.¹⁰³⁷ Specifically, NCAT took issue with the characterization of potential risks of charging to the electric grid, stating that “the PRIA’s focus on worst case hypotheticals does not reflect the current capabilities of the grid, nor the dynamic nature of EV charging to mitigate any potential negative impacts. In both in the short-term and long-term, the impact of EVs with respect to the electric grid would have a net-positive impact to society, including the EV owners and utility customers broadly.” NCAT also commented that “[w]hile substantial investments in EV infrastructure have and will be made, the costs and benefits to consumers must be put into the appropriate context.” NCAT cited two studies for the proposition that the average lifetime distribution electric vehicle infrastructure impact is about \$80–\$90 per electric vehicle sold, with the adoption of time of use rates and assuming a diversity of charging rates. NCAT also cited the California Public Utilities Commission 2016–2017 Electric Vehicle Load Research Report in support of their statement that the additional service and distribution system upgrades due to additional plug-in electric vehicle load is minimal, as “of the approximately 275,000 [electric] vehicles estimated to be on the road as of October 2017 in the service areas of California’s three investor-owned utilities, only 460, or 0.16 percent required a service line or distribution system upgrade solely to support the plug-in electric vehicle load at their residential charging location.”¹⁰³⁸

The agencies agree that adding electric vehicle infrastructure will require additional costs, and information about what that cost is and how it can or should be accounted for

¹⁰³⁶ NHTSA–2018–0067–12073.

¹⁰³⁷ NHTSA–2018–0067–11969.

¹⁰³⁸ Citing Joint IOU Electric Vehicle Load Research Report (December 29, 2017), pp. 1–2, 12, available at <http://www.cpuc.ca.gov/zev/> (2016–2017 Load Research Report).

¹⁰³⁵ Battery costs are not necessarily a strong influence on fuel Cell Electric Vehicles, where the cost of the fuel cell technology has a larger influence.

in the analysis is helpful for commenters to submit in order to put those considerations in the appropriate context. For this final rule, the agencies did not incorporate any costs related to electric vehicle charging infrastructure in the technology compliance analysis because those costs are separate from the costs that manufacturers and consumers would directly incur from a manufacturer transitioning part of their fleet to plug-in electric vehicles and consumers paying for those vehicles, even though local electric ratepayers will in all likelihood pay higher rates to upgrade local power grids to accommodate any widespread adoption of electrified vehicles. Accordingly, this means that the actual costs associated with electrified vehicles have been underestimated for the final rule analysis. The agencies did refine the estimates for the value of refueling time for electric vehicles, and that topic is discussed in Section VI.D.1.b)(11)(b). The agencies will continue to explore whether and how charging infrastructure should be incorporated into the analysis for future actions.

The following sections discuss vehicle electrification issues that were accounted for in the analysis, including the agencies' characterizations of electric vehicle technology, additional electric vehicle configurations added for the final rule analysis per commenters' requests, and the sources and methods used to develop battery and non-battery components, which were also refined for this final rule.

a) Electrification Modeling in the CAFE Model

A set of technologies was chosen to represent the spectrum of electrification methods observed in the baseline fleet and that the agencies believed could be applied to vehicles in the rulemaking timeframe. Each technology was placed in a specific electrification pathway, grouping and defining the progression of related technologies. In the NPRM analysis, a total of eleven electrification technologies were contained in four electrification pathways. In consideration of comments received, the electrification technologies and associated pathways were modified for the final rule analysis, resulting in a total of eighteen variants of electrification technologies. Each of these NPRM and final rule technologies, and the electrification pathways they belong to, are detailed below. Operational modes of electrified vehicles are further described in the Argonne Model Documentation for the final rule.

(1) Electrification Technologies

(a) Electric Improvements

The electrification of power steering (EPS) and other accessories (IACC) have the potential of reducing fuel consumption by facilitating power-saving control strategies that avoid parasitic loss of engine power. These accessories traditionally are directly coupled to and driven by the conventional combustion engine; any time the engine is running some energy is continuously consumed by each accessory, even when it is not needed. By decoupling these accessories from the engine and instead driving them "on-demand" with electric motors, a more energy-efficient control strategy can be employed to reduce fuel consumption. EPS and IACC are discussed in detail in Section VI.C.7, Other Vehicle Technologies.

(b) Micro Hybrid

12-volt stop-start (SS12V), sometimes referred to as start-stop, idle-stop or 12-volt micro hybrid, is the most basic hybrid system that facilitates idle-stop capability. In this system, the integrated starter generator is coupled to the internal combustion (IC) engine. When the vehicle comes to an idle-stop the IC engine completely shuts off and, with the help of 12-volt battery, the engine cranks and starts again in response to throttle to move the vehicle, or release of the brake pedal. The 12-volt battery used for the start-stop system is an improved unit capable of higher power, increased life cycle, and capable of minimizing voltage drop on restart. This technology is beneficial to reduce fuel consumption and emissions when the vehicle frequently stops, such as in city driving conditions or in stop and go traffic, and can be applied to all vehicle technology classes.

(c) Mild Hybrids

The belt integrated starter generator (BISG) and crank integrated starter generator (CISG), sometimes referred to as mild hybrid systems, provide idle-stop capability and use a higher voltage battery with increased energy capacity over typical automotive batteries. The higher voltage allows the use of a smaller, more powerful and efficient electric motor/generator, which replaces the standard alternator. In BISG systems, the motor/generator is coupled to the engine via belt (similar to a standard alternator), while the CISG integrates it to the crankshaft between the engine and transmission; both of these systems allow the engine to be automatically turned off as soon as the vehicle comes to a full stop. In addition, these motor/generators can recover

braking energy while the vehicle slows down (regenerative braking) and in turn can propel the vehicle at the beginning of launch, allowing the engine to be restarted later. Some limited electric assist is also provided during acceleration to improve engine efficiency. The CISG system has a higher efficiency, but also higher cost than the BISG.

The agencies received limited high-level comments on CISG systems, with CARB stating that CISG systems are generally considered more capable and more efficient relative to BISG systems because they do not have the same belt-related constraints including maximum torque limitations, load restrictions on the front crank to avoid uneven crankshaft bearing wear, and mechanical energy transfer losses.¹⁰³⁹ CARB also noted that the decision to implement a CISG system is typically made early in the design process because doing so often requires an engine block casting change. CARB stated that the current high costs and larger dimensions, compared to BISGs, will likely delay major market penetration of CISG systems until beyond the MY 2025 timeframe.

For the final rule analysis, the agencies did not include CISG systems. The effectiveness of CISG systems were similar to the BISG, and the high cost of the CISG caused it to be applied infrequently. Other packaging and integration issues make it difficult for most vehicles to adopt CISG technology. Typically, a manufacturer would have to modify the flywheel housing to allow the installation of an electric motor, which must also fit where the system is mounted between the transmission and the engine block. Space in that part of the vehicle also comes at a premium because other components such as exhaust systems and piping systems must also be housed in the same area. In the final rule analysis, all vehicles previously considered to possess CISG technology were instead assigned a BISG system.

(d) Strong Hybrids

A hybrid vehicle is a vehicle that combines two or more sources of propulsion energy, where one uses a consumable fuel (like gasoline), and one is rechargeable (during operation, or by another energy source). Hybrids reduce fuel consumption through three major mechanisms, including (1) potential engine downsizing, (2) optimizing the performance of the engine to operate at

¹⁰³⁹ Roush Industries on behalf of California Air Resources Board, Rogers_Final_Final_NPRM_10.26.2018, Docket No. NHTSA-2018-0067-11984, at 15.

the most efficient operating point and under some conditions storing excess energy such as by charging the battery, and (3) capturing energy during braking and some decelerations that might otherwise be lost to the braking system and using the stored energy to provide launch assist, coasting, and propulsion during stop and go traffic conditions. The effectiveness of the hybrid systems depends on how the above factors are balanced, taking into account complementary equipment and vehicle application. For some performance vehicles, the hybrid technologies are used for performance improvement without any engine downsizing.

The NPRM analysis evaluated the following strong hybrid vehicles: Hybrids with “P2” parallel drivetrain architecture (SHEVP2),¹⁰⁴⁰ and hybrids with power-split architecture (SHEVPS). The parallel hybrid drivetrain, although enhanced by the electric portion, remains fundamentally similar to a conventional powertrain. In contrast, the power-split hybrid drivetrain is novel and considerably different than a conventional powertrain. Although these hybrid architectures are quite different, both types provide start-stop or idle-stop functionality, regenerative braking capability, and vehicle launch assist. A SHEVPS has a higher potential for fuel economy improvement than a SHEVP2, although its cost is also higher.

Power-split hybrid (SHEVPS) is a hybrid electric drive system that replaces the traditional transmission with a single planetary gear set (the power-split device) and a motor/generator. This motor/generator uses the engine either to charge the battery or to supply additional power to the drive motor. A second, more powerful motor/generator is permanently connected to the vehicle’s final drive and always turns with the wheels. The planetary gear splits engine power between the first motor/generator and the drive motor either to charge the battery or to supply power to the wheels. During vehicle launch, or when the battery state of charge (SOC) is high, the engine, which is not as efficient as the electric drive, is turned off and the electric machine propels the vehicle. During normal driving, the engine output is used both to propel the vehicle and to generate electricity. The electricity generated can be stored in the battery

and/or used to drive the electric machine. During heavy acceleration, both the engine and electric machine (by consuming battery energy) work together to propel the vehicle. When braking, the electric machine acts as a generator to convert the kinetic energy of the vehicle into electricity to charge the battery.

The Autonomie simulations assumed all SHEVPS’ used an Atkinson cycle engine (Eng26). Therefore, all vehicles equipped with SHEVPS technology in the CAFE model simulations were assumed to have Atkinson cycle engines. This Atkinson cycle engine with high compression ratio is optimized for efficiency, rather than performance. Accordingly, SHEVPS technology as modeled in this analysis was not suitable for large vehicles that must handle high loads.¹⁰⁴¹ Further discussion of Atkinson engines and their capabilities is discussed in Section VI.C.1 Engine Paths.

P2 parallel hybrids (SHEVP2) are a type of hybrid vehicle that uses a transmission-integrated electric motor placed between the engine and a gearbox or CVT, with a clutch that allows decoupling of the motor/transmission from the engine. Although similar to the configuration of the CISC system discussed previously, a P2 hybrid would typically be equipped with a larger electric machine and battery in comparison to the CISC. Disengaging the clutch allows all-electric operation and more efficient brake-energy recovery. Engaging the clutch allows efficient coupling of the engine and electric motor and, when combined with a transmission, reduces gear-train losses relative to power-split or 2-mode hybrid systems. P2 hybrid systems typically rely on the internal combustion engine to deliver high, sustained power levels. Only low and medium power demands are allowed for electric-only mode.

In the NPRM CAFE modeling, the SHEVP2 system represented a hybrid system paired with an existing engine on a given vehicle, while the SHEVPS removed and replaced the previous engine with an Atkinson cycle engine. The agencies explained that while many vehicles may use HCR1 engines as part of a hybrid powertrain, HCR1 engines may not be suitable for some vehicles, such as high performance vehicles or vehicles designed to carry or tow large loads (this is further discussed in Section VI.C.1, Engine Paths). Many

manufacturers may prefer turbocharged engines (with high specific power output) for P2 hybrid systems, in order to maintain performance. Accordingly, in the NPRM analysis, to satisfy power demands, many SHEVP2 systems were paired with non-HCR powertrains.

ICCT and Meszler Engineering Services commented that as a result of NPRM CAFE model constraints, low-cost, HCR engines were too infrequently paired with SHEVP2 technology. These commenters claimed that frequent pairing of SHEVP2 with downsized turbocharged engines resulted in higher cost and lower effectiveness for these strong hybrids.^{1042 1043}

In consideration of these comments, the final rule analysis includes additional strong hybrids (P2HCR0, P2HCR1, and P2HCR2¹⁰⁴⁴) that use HCR engines in a P2 parallel hybrid system. The SHEVP2 technology allows the engine type to be inherited from the outgoing engine; this is unchanged from the NPRM and provides a good solution for vehicles that need to undergo hybridization but require other engine technologies (such as turbocharging) to meet performance requirements. In addition, this final rule analysis allows any conventional engine technology to go to P2HCR strong hybrid technology within the set performance requirements. This is further discussed in the Section VI.C.3.c), Electrification Adoption Features.

(e) Plug-In Hybrids

Plug-in hybrid electric vehicles (PHEV) are hybrid electric vehicles with the means to charge their battery packs from an outside source of electricity (usually the electric grid). These vehicles have larger battery packs with more energy storage and a greater capability to be discharged than other non-plug-in hybrid electric vehicles. PHEVs also generally use a control system that allows the battery pack to be substantially depleted under electric-only or blended mechanical/electric operation and batteries that can be cycled in charge-sustaining operation at a lower state of charge than is typical of other hybrid electric vehicles. These vehicles generally have a greater all-electric range than the typical SHEVs discussed above. In the NPRM analysis,

¹⁰⁴² Meszler Engineering Services, Attachment 2, Docket No. NHTSA–2018–0067–11723, at 15.

¹⁰⁴³ International Council on Clean Transportation, Attachment 3, Docket No. NHTSA–2018–0067–11741, at I–25.

¹⁰⁴⁴ P2HCR2 was included in simulations used for sensitivity studies, but was excluded in the central analysis simulations for reasons surrounding the HCR2 engine, as discussed in Section VI.C.1.

¹⁰⁴⁰ Depending on the location of electric machine (motor with or without inverter), the parallel hybrid technologies are classified as P0—motor located at the primary side of the engine, P1—motor located at the flywheel side of the engine, P2—motor located between engine and transmission, P3—motor located at the transmission output, and P4—motor located on the axle.

¹⁰⁴¹ Kapadia, J., Kok, D., Jennings, M., Kuang, M. et al., “Powersplit or Parallel—Selecting the Right Hybrid Architecture,” SAE Int. J. Alt. Power. 6(1):68–76, 2017, <https://doi.org/10.4271/2017-01-1154>.

PHEVs with two all-electric ranges—a 30 mile and a 50 mile all-electric range (AER)—were included as technologies that vehicles could adopt. The PHEV30 represented a “blended-type” plug-in hybrid, which can operate in all-electric (engine off) mode only at light loads and low speeds, and must blend electric machine and engine power together to propel the vehicle at medium or high loads and speeds. The PHEV50 represented an extended range electric vehicle (EREV), which is capable of travelling in all-electric mode even at higher speeds and loads.

Unlike other alternative fuel systems that require specific infrastructure for refueling or recharging (e.g., hydrogen vehicles or rapidly charged battery electric vehicles), PHEV batteries can be charged using existing infrastructure, although widespread adoption may require upgrades to electrical power distribution systems.¹⁰⁴⁵ PHEVs are considerably more expensive than conventional vehicles and more expensive than SHEVPS technologies because of larger battery packs and charging systems capable of connecting to the electric grid.

Commenters, such as CARB, stated that in the NPRM analysis the PHEV motors were oversized and overpowered, and that model-built PHEV30s have excessive battery pack size and electric range when compared to actual production vehicles.¹⁰⁴⁶ In response to such comments, the agencies, in collaboration with Argonne, conducted further market study to confirm CARB’s observations and determined that replacing PHEV30 (with a nominal 30 mile AER) with PHEV20 (with a nominal 20 mile AER) would more closely characterize the PHEVs actually in production.¹⁰⁴⁷ The agencies therefore elected to replace PHEV30 with PHEV20 in the final rule.

The final rule also includes four additional types of plug-in hybrids; two additional plug-in hybrids were added to allow the use of turbocharged engines (PHEV20T, PHEV50T), and two additional plug-in hybrids were added to provide maximum efficiency by utilizing an Atkinson cycle engine (PHEV20H, PHEV50H).

In practice, many PHEVs recently introduced in the marketplace use turbocharged engines in the PHEV system, and this is particularly true for

PHEVs produced by European manufacturers and for other PHEV performance vehicle applications. However, the NPRM Autonomie simulations (and thus all the CAFE model simulations) assumed all PHEVs used a naturally aspirated, Atkinson cycle engine. The agencies determined through continued marketplace observation that PHEV vehicles should indeed be allowed to adopt or retain turbocharged engines. Also, BorgWarner commented that modeling of PHEVs should include turbocharged engines, since these engines can be downsized to reduce vehicle mass and fit into smaller engine compartments, and offer efficiency and performance advantages especially when paired with a higher expansion ratio.¹⁰⁴⁸ Thus, in addition to the PHEV20 and PHEV30, the final rule analysis included PHEV20T and PHEV50T variations which are, respectively, 20 and 50 mile all electric range PHEVs with turbocharged engines.

This final rule also added PHEV20H and PHEV50H, although effectively these are not used by the model simulations. These plug-in types represent 20 and 50 mile all electric range plug-in hybrids that use particularly efficient high-compression, Atkinson cycle engines. These were added with the intent to provide PHEVs with a maximum level of fuel economy at a lower cost. However, they proved to be too similar to existing plug-in technology choices and were thus assigned identical characteristics as the PHEV20 and PHEV50. In this final rule analysis, PHEV20 and PHEV50 sizing were updated and so the similarities in performance between different engines converged. For further discussion on PHEV sizing, see Section VI.C.3.d), Electrification Effectiveness Modeling and resulting Effectiveness values.¹⁰⁴⁹ The PHEV20H and PHEV50H technologies are still considered by the CAFE model but they remain as

“placeholders” for potential incorporation in future analyses.

(f) Battery Electric Vehicles

Electric vehicles (EVs), or battery electric vehicles (BEVs) are equipped with all-electric drive and with systems powered by energy-optimized batteries charged primarily from grid electricity. The range of a battery electric vehicle depends on the vehicle’s class and the battery pack size. The NPRM analysis included BEVs with a range of 200 miles.

Following the NPRM, the agencies conducted continued market analysis of production BEVs, and observed a growing number of vehicles with nominal ranges above 200 miles. CARB also commented that certain BEVs modeled as BEV200 in the NPRM in fact had “well over 200 miles of range.”¹⁰⁵⁰ The agencies thus concluded that a 300-mile-range BEV300 should be included in the final rule to represent better these higher-range electric vehicles as well as a potential future range alternative more comparable to IC engines. The agencies still believe that, in the rulemaking timeframe, BEV300 will be the most cost effective extended range BEVs that could be available for adoption. Longer-range electric vehicles could have been modeled in the analysis, but the compliance simulation would likely not have selected the longer-range vehicle if lower-range vehicles were still available. This is because the CAFE model only applies technologies until a manufacturer meets its CAFE or CO₂ standard, and the BEV200 and BEV300 vehicles operate functionally the same in helping a manufacturer towards meeting its compliance obligations. The only difference between these vehicles is cost. As discussed further in Section VI.C.3.c), the agencies used phase-in caps to control expected BEV200 and BEV300 penetration based on the current trend and future assumption that consumers will transition towards longer-range electric vehicles.

(g) Fuel Cell Vehicles

Fuel cell electric vehicles (FCEVs or FCVs) utilize a full electric drive platform but consume hydrogen fuel to generate electricity in an onboard fuel cell. Fuel cells are electrochemical devices that directly convert reactants (hydrogen and oxygen via air) into electricity, with the potential of achieving more than twice the efficiency of conventional internal combustion engines. High pressure gaseous hydrogen storage tanks are used by most

¹⁰⁴⁵ See above for a discussion of electrical vehicle infrastructure.

¹⁰⁴⁶ California Air Resources Board, Attachment 2, Docket No. NHTSA–2018–0067–11873, at 150, 153.

¹⁰⁴⁷ “ANL response on NPRM comments (PHEV sizing)- 181112.pptx,” available in Docket No. NHTSA–2018–0067.

¹⁰⁴⁸ BorgWarner, Attachment 2, Docket No. NHTSA–2018–0067–11873, at 150, 153.

¹⁰⁴⁹ This final rule analysis used Atkinson Engine for PHEVPS electrified vehicles. The components such as electric motor and engine power in these hybrid systems were sized in ways to meet vehicle class performance characteristics and efficiency. And after these vehicle components were sized, the Atkinson engines in these vehicles were operating in similar efficiency as HCR engines as the full vehicle modeling and simulation. As discussed in PO 06 C.1.c.1 Non-HEV Atkinson Engine Modes, power-split hybrid-based Atkinson engines attempt to operate in the most efficient regions while using electric motors to meet deficiencies in performance. And so, PHEV20H and PHEV50H HCR engines compared to PHEV20 and PHEV50 Atkinsons engines would have been sized to operate in the most efficiency regions and the thermal efficiency between these two set of combinations would have had similar efficiency for this analysis.

¹⁰⁵⁰ California Air Resources Board, Attachment 2, Docket No. NHTSA–2018–0067–11873, at 147.

automakers for FCEVs. These high-pressure tanks are similar to those used for compressed gas storage in more than 10 million CNG vehicles worldwide, except that they are designed to operate at a higher pressure (350 bar or 700 bar vs. 250 bar for CNG), and to contain the very small, and very flammable, gaseous hydrogen molecule. FCEVs are currently produced in limited numbers and are available in limited geographic areas.

(2) Electrification Pathways

The electrification technologies described above were applied in the

CAFE model through a number of technological pathways. Three main electrification technology pathways were modeled: The Electric Improvements Path, the Electrification Path, and the Hybrid/Electric Path. These three electrification pathways are evaluated in parallel by the CAFE model; the model can consider any of the three right away, and does not need to go “through” one pathway in order to begin evaluating another. Any superseded technology is also disabled whenever a succeeding technology is applied to a vehicle, even if a specific

superseded technology was not previously utilized on that vehicle. As previously explained, this requirement exists so that the modeling system does not downgrade technologies during analysis.

The Electric Improvements Path defined in the NPRM and final rule is shown in Figure VI–29 below, which starts with EPS and progresses to IACC. While these two electrified-accessory technologies are mutually exclusive, either one can be modularly paired with any other technology, including those in the other electrification pathways.

Figure VI-29 – NPRM and FRM Electric Improvements Path

The Electrification Path shown in Figure VI–29 allows a conventional powertrain to become a micro-hybrid with SS12V, or a mild hybrid with BISG, or CISG (which is no longer available for the final rule analysis, as discussed previously) technologies. All three of the Electrification Path technologies are mutually exclusive with respect to all conventional

powertrain technologies, as well as technologies contained in the Hybrid/Electric path discussed below. The model first evaluates SS12V, and then progresses to BISG or CISG (NPRM-only). The conventional engine technology CONV is grayed out to indicate that the model uses information about the previous conventional (non-electrified) powertrain to map properly

to simulation results found in the vehicle simulation database. Although the adoption of these technologies will classify a vehicle as a micro/mild hybrid (MHEV) and no longer a conventional (CONV), the vehicle is allowed to retain the engine and transmission technologies possessed before entering the Electrification Path.

Figure VI-30 – NPRM (Left) and Final Rule (Right) Electrification Pathways

The Hybrid/Electric Pathways are shown in Figure VI–30. Both the NPRM and final rule Hybrid/Electric paths begin at the “strong hybrid” technology types, each of which is mutually exclusive of the others; once one is chosen, the other is eliminated from

future selection for that vehicle. The paths then progress into plug-in hybrids and then culminate with the mutually exclusive battery electric vehicles or fuel cell vehicles. The additional final rule technologies described above can be found in the final rule Hybrid/

Electric pathway on the right side of Figure VI–31, in comparison to the NPRM technologies shown on the left

side of the figure.¹⁰⁵¹ The hybrid/electric pathways contains multiple “roots,” or starting points, which force a vehicle to remain within the branches of a chosen root. For example, the final rule hybrid/electric pathway has three roots: SHEVP2, SHEVPS, and P2HCR0. If a vehicle uses SHEVPS, then SHEVP2 technology and the entire P2HCR0

through PHEV50H branch will be disabled from further consideration. In other words, from one technology in the pathway, a vehicle can only move forward along any of the indicated arrows, and never in the reverse direction. Also, when using any technology in the Hybrid/Electric pathway, with the exception of

SHEVP2, all engine and transmission technologies as well as the Electrification Path technologies shown in Figure VI-31 are prohibited. SHEVP2 is an exception because it allows engine technologies previously held by the vehicle to be inherited into the parallel hybrid system.

Figure VI-31 – NPRM (Left) and Final Rule (Right) Hybrid/Electric Pathways

b) Electrification Analysis Fleet Assignments

Since the 2012 rulemaking, manufacturers have implemented a number of powertrain electrification technologies, including 48V mild hybrid, strong HEV, PHEV, and BEV powertrains.^{1052 1053} For the NPRM analysis, the agencies identified the specific electrification technologies in each vehicle model in the MY 2016 analysis fleet, and used those technology levels as the starting point for the regulatory analysis. The agencies assigned electrification technology levels based on manufacturer-submitted CAFE compliance information, vehicle

technical specifications released publicly by manufacturers, agency-sponsored vehicle benchmarking studies, technical publications, and manufacturer CBI.¹⁰⁵⁴ For the final rule analysis, the agencies used a similar process and data sources to identify the electrification technologies in the MY 2017 analysis fleet.¹⁰⁵⁵

The agencies received comments regarding the application of electrification technologies in the MY 2016 analysis fleet. Commenters, such as the California Air Resources Board, stated the agencies mischaracterized some hybrid technologies, such as power-split and P2 hybrid architectures.¹⁰⁵⁶ Specifically CARB

was concerned about the “misclassification of the 2016 Chevrolet Malibu Hybrid as having a P2 hybrid,” noting the Malibu shared many of its drivetrain components with the 2016 Chevy Volt, a vehicle classified as a power-split HEV.

BorgWarner stated that the “modeling should be inclusive of all approaches of PHEV and HEV and not be limited only to Atkinson Cycle engines,” suggesting that it was appropriate for the NPRM analysis to include turbocharged engines in combination with PHEV and HEV technologies.¹⁰⁵⁷

The agencies agree with the underlying issue identified by both CARB and BorgWarner’s comments. In

¹⁰⁵¹ Note that the NPRM Hybrid/Electric Path (left side of Figure I-3) refers to a portion of the path containing plug-in hybrids and electric vehicles as the “Advanced Hybrid/Electric Path.” For this discussion, we will simply refer to the entire collection of these technologies, including the “Advanced” technologies, as the “Hybrid/Electric Path.”

¹⁰⁵⁴ NPRM Market Data central analysis input file.

¹⁰⁵⁵ FRM Market Data central analysis input file.

¹⁰⁵⁶ Comments from CARB, Attachment 2, NHTSA Docket No. NHTSA–2018–0067–11873, at 136.

¹⁰⁵⁷ Comments from BorgWarner, Attachment 1, Appendix, NHTSA Docket No. NHTSA–2018–0067–11895, at 10.

both cases a limitation of modeling classification, and not a lack of academic understanding of HEV systems, is the crux of the issue. In the specific case of the 2016 Chevy Malibu, the electrical architecture is a power split, however, the vehicle uses a non-Atkinson, basic direct injection engine. These characteristics put the Malibu HEV in an overlap with the powertrain models used to represent HEV systems in the agencies' analysis. If the system had been classified as a PS HEV system in the analysis fleet, the engine would have incorrectly been modeled as an Atkinson engine, resulting in overestimation of the baseline system's level of efficiency and technology applied. The overestimation of the baseline fleet model would have limited the potential for the baseline system to improve over the timeframe of the analysis. With the system classified as the P2 HEV, the engine can be accurately modeled while still accounting for the benefits of an HEV system. This allowed the platform the full potential for technology and efficiency improvement in the analysis.

The agencies considered the issues identified in comments and reviewed the MY 2017 analysis fleet information to determine what changes could improve the final rule analysis. The agencies determined that expanding the number of electrification technologies would address the CARB and BorgWarner comments, as well as the comments from others that are discussed in Section VI.C.3.a)(1) Electrification Technologies. The agencies increased the number of unique electrification technologies from twelve in the NPRM to eighteen for the final rule analysis. The expanded list enabled greater precision in the assignment of technologies to the MY 2017 analysis fleet, and enabled the agencies to characterize the electrification technologies found in the fleet accurately and realistically. The expanded list also provided more granularity for the application of technologies for the rulemaking analysis. Table VI–85 shows the full list of electrification technologies for the final rule analysis.

This collection of technologies represents the best available information the agencies have, at the time of this action, regarding both currently available electrification technologies

and electrification technologies that could be feasible for application to the U.S. fleet during the rulemaking timeframe. The agencies believe this effort has yielded the most accurate analysis fleet utilized for rulemakings to date.

As discussed in the previous section and shown in Figure VI–29, Figure VI–30, and Figure VI–31, electrification may be added to vehicles as shown on the decision tree pathways. Further application of electrification technologies to vehicle platforms was dependent on electrification technology already present on vehicles in the MY 2017 analysis fleet. Electrification may also be predicated on whether a vehicle has a dedicated platform that accommodates battery electric capability or whether a platform is designed (“package protected”)¹⁰⁵⁸ to enable the addition of some form(s) of hybridization. The agencies' assessment of each existing platform's capability to adopt electrification technologies is identified in the CAFE model market data input file.¹⁰⁵⁹

c) Electrification Adoption Features

In the NPRM and final rule analysis, electrification adoption features were applied in multiple ways. First, when an electrification technology is selected, a path logic is applied that dictates what other technologies are either superseded or mutually exclusive to the applied technology. For a detailed discussion of path logic for the final rule analysis, including technology supersession logic and technology mutual exclusivity logic, please see CAFE model documentation section. Second, application of the more advanced electrification technologies, such as the strong hybrids, plug-in hybrids, and full BEVs, result in major changes to the whole powertrain. The changes to the powertrain include substitution of transmission and engine technologies, and accordingly these technologies can only be applied at a vehicle redesign, as shown in Table VI–85 below. Finally, some of electrification technologies are restricted from application to certain vehicle classifications. These

restrictions will be discussed under the specific technology sections.

The fully-electric technologies, BEV technology and FCV technology, qualify as alternative fuel technologies. As a result, these technologies are not considered during portions of the agencies' analysis. Specifically, the exclusion of dedicated alternative fuel technology from NHTSA's analysis of potential fuel economy standards is a result of statutory obligations prescribed under EPCA/EISA.¹⁰⁶⁰ However, NHTSA performed two fuel economy analyses, a standard-setting analysis that constrained the use of the technologies, and an unconstrained analysis that did not exclude the technologies, which provides an estimation of real-world environmental impacts used as inputs for the Environmental Impact Statement (EIS). The unconstrained analysis included the alternative fuel technologies, and used the adoption features for BEVs and FCVs discussed below. Further, for purposes of analyzing EPA's tailpipe CO₂ emissions rulemaking pursuant to the Clean Air Act, consideration of these technologies is likewise unconstrained. For a detailed discussion of the analysis versions and statutory obligations please refer to Section VI.A Analytical Approach as Applied to Regulatory Alternatives, Overview of Methods and Section VI.A.4 Compliance Simulation.

The exclusion of the BEV and FCV technology from the standard-setting analysis resulted in a comment from ICCT. ICCT stated, “the agencies prevented their fleet compliance model from allowing battery electric vehicles from being applied in their analysis of the Augural standards.”¹⁰⁶¹ The agencies believe this reflects a misunderstanding of NHTSA's statutory obligation under EPCA/EISA and how the agencies ran the analysis. NHTSA did consider alternative fueled vehicles in the unconstrained analysis—but as discussed further in Section VIII, is prohibited from considering the availability of such technologies when setting maximum feasible standards.

BILLING CODE 4910-59-C**(1) Micro and Mild Hybrid**

For the NPRM and final rule analysis, the only adoption features for the SS12V and BISG technologies were functions of path logic. The SS12V and BISG technologies were allowed for

consideration in any existing vehicle configuration that did not already have a more advanced electrification technology applied. Per Table VI-85 above, the BISG technology was considered more advanced than the SS12V technology.

Mesler Engineering commented that 48V batteries used in conjunction with 12 volt systems (what are referred to in the analysis as BISG systems) are one example of a “bolt-on” technology that can be added to a vehicle during a product refresh without causing

production problems or significantly increasing costs.¹⁰⁶² Meszler Engineering stated that 48V systems do not require reengineering of the engine and can be added at any time during a model's lifespan, as shown by key suppliers that are expanding production capacity to meet customer demand for the technology.¹⁰⁶³ Meszler Engineering also pointed to examples of vehicles that utilize 48V systems, including high-volume non-luxury vehicles like the Ram pickup truck, Jeep Wrangler, and Ford F-150.¹⁰⁶⁴

The agencies disagree with Meszler Engineering's assessment of 48V technology as a "bolt-on" technology. Although BISG systems represent a first step in vehicle electrification, and the number of components involved is fewer than most other types of hybrid systems, a BISG system still requires engineering and packaging of motors, cooling systems, additional wiring harnesses from the 48V battery pack to the motors, control systems, and other components incorporated into the front engine compartment. Further, the addition of a BISG system requires recalibration and validation of numerous engine performance parameters, including emissions controls, balancing torque supply to the transmission between the BISG system and engine, and noise-vibration-harshness controls. In addition, the examples Meszler Engineering provided support the agencies' designation of SS12V and BISG systems as redesign technologies; the BISG system in the MY 2019 Ram pickup and in the MY 2018 Jeep Wrangler were introduced during a product redesign and not during a mid-cycle product refresh.¹⁰⁶⁵ ¹⁰⁶⁶ Although Ford has

indicated that the F-150 will include hybrid variants,¹⁰⁶⁷ the agencies do not have information about specific plans for a 48V system on the F-150. In consideration of this information, the agencies maintained the redesign schedule for mild hybrids for the final rule analysis.

(2) Strong Hybrids—SHEVP2, SHEVPS, P2HCR0, P2HCR1, P2HCR2

NPRM adoption features applied to strong hybrid technologies included path logic, powertrain substitution, and vehicle class restrictions. For the NPRM analysis technologies on the Hybrid/Electric path (SHEVP2 and SHEVPS) were defined as stand-alone and mutually exclusive. When the modeling system applies one of those technologies, the other one is immediately disabled from future application. Once a strong hybrid technology is applied it also supersedes lower technologies on the electrification path, allowing future application of technology to consider only more advanced forms of electrification.

In the NPRM when the SHEVP2 technology or the SHEVPS technology were applied, the transmission technology was superseded. Regardless of the transmission technology present when the technology was applied, the transmission technology was replaced by either the AT6 or DCT6. The specific transmission technology selected was based on choosing the best cost versus effectiveness.

During the NPRM analysis when the SHEVP2 technology was selected the engine technology for the platform was maintained. However, the engine technology was locked at the current level and could not be changed. For the SHEVPS technology the existing engine was replaced with an Atkinson cycle engine (Eng26).

The SHEVP2 was also constrained from application to particular vehicle technology classes or vehicles with specific performance characteristics in the NPRM. Application of the power-

split architecture was restricted from high performance vehicles and vehicles with a high towing capability requirements.¹⁰⁶⁸ These constraints prevented application to the pick-up and performance pick-up class of vehicles. The constraints also prevented application to any platform with a base horsepower rating greater than 400 HP. Additional platforms determined to be purpose built as performance platforms were also restricted from receiving SHEVPS technology.

Comments from ICCT criticized the manner in which SHEVP2 technology was applied to a platform. ICCT stated "the benefits of level-2 transmission efficiency and TURBO2 over TURBO1 are removed when P2 strong hybrid systems (SHEVP2) are selected on the electrification pathway."¹⁰⁶⁹

Additional comments regarding the adoption features of the SHEVP2 technology were received from Meszler Engineering and ICCT. Meszler argued that the locking of engine technologies when a manufacturer selects the SHEVP2 technology may preclude the selection of a more cost-effective engine technology.¹⁰⁷⁰ This concern was echoed by ICCT, who also felt the engine technology lock-in artificially increased cost for effectiveness on the overall SHEVP2 technology packages.¹⁰⁷¹ Both commenters specifically wanted an option for a high compression ratio engine technology to be considered in place of any advanced engine technology carried into the SHEVP2 technology pathway.

The agencies agreed with the need for maintaining the benefits of a higher transmission technology, and for the final rule analysis a AT8L2 transmission technology replaced the AT6 or DCT6 transmissions for all hybrid-electric technologies. The AT8L2 was selected as the optimal transmission technology point for HEV systems. The transmission technology point was selected based on observed diminishing returns for applying advanced transmission technologies to advanced engine/powertrains.¹⁰⁷²

¹⁰⁷² 2015 NAS Report—The National Academy of Science, in their 2015 report, noted that "as engines

The agencies also reconsidered engine options for SHEVP2 technology, and other strong hybrid-electric technologies. The agencies agreed with Meszler and ICCT's observation and instituted new P2 engine technology options, as discussed above. For the final rule analysis, when a platform considered the SHEVP2 option, the platform also compared maintaining the current engine technology, or selecting an HCR technology. If the SHEVP2 system chooses to apply a HCR engine, the system diverts to the new electrification sub-path of technologies that includes the P2HCR0, P2HCR1, and P2HCR2.

The P2HCR path introduced in the final rule analysis had similar constraints as the SHEVPS. Performance vehicles and vehicles with a high towing requirement were restricted from selection of the P2HCR technology. Restrictions that were applied used the same criteria described for the SHEVPS.

(3) Plug-In Hybrids—PHEV20/30, PHEV50, PHEV20T, PHEV50T, PHEV20H, PHEV50H

The plug-in hybrid options in the NPRM included PHEV30 and PHEV50 technologies. The plug-in technologies superseded the micro, mild, and strong hybrid electrification technologies and could only be replaced by full electric technologies. The path logic also allowed a PHEV30 to progress to a PHEV50.

In the NPRM, when a platform progressed to the plug-in hybrid technologies the powertrain was automatically modified. The engine technology was replaced by a high compression ratio engine (Eng26) and the transmission was replaced by the AT6 or DCT6 technology.

PHEV30 and PHEV50 were also constrained from application to vehicles with the potential for high towing demands.¹⁰⁷³ This constraint was applied by restricting access to the pickup truck vehicle technology class. Additional specific vehicle platforms were restricted based on engineering judgment.

Comments were received regarding the options for PHEV battery-electric technology. The comments are presented and discussed in Section VI.C.3.e) Electrification Technologies

incorporate new technologies to improve fuel consumption, the benefits of increasing transmission ratios or switching to a CVT diminish."

¹⁰⁷³ Power split or Parallel-selecting the Right Hybrid Architecture: SAE 2017-01-1154. = Kapadia, J., Kok, D., Jennings, M., Kuang, M. et al., "Powersplit or Parallel—Selecting the Right Hybrid Architecture," SAE Int. J. Alt. Power. 6(1):68–76, 2017, <https://doi.org/10.4271/2017-0-1154>.

above, and resulted in the creation of additional technology options for plug-in hybrids, as well as a modification of available ranges. Comments were also received regarding the engine and transmission options used in the electrification technologies, these comments are also presented and discussed above in Section VI.C.3.e) Electrification Technologies.

For the final rule analysis, the plug-in hybrid options included PHEV20, PHEV50, PHEV20T, PHEV50T, PHEV20H, and PHEV50H. As with the NPRM, the plug-in technologies superseded the micro, mild, and strong hybrid technologies. For the final rule analysis, plug-in hybrid technologies were also mutually exclusive, and the PHEV20 technologies can progress to the PHEV50 technologies.

When a platform applied plug-in hybrid technologies in the final rule analysis, the engine and transmission technologies are superseded. For all plug-in technologies, an AT8L2 transmission is used. For the PHEV20/50 and PHEV20/50H, the engine is replaced by an Atkinson cycle based engine (Eng26). For the PHEV20/50T, the engine is replaced by the TURBO1 technology engine (Eng12).

The PHEV20/30 and PHEV20/50H path also had similar constraints as the SHEVPS in the final rule analysis. Performance vehicles and vehicles with a high towing requirement were restricted from selection of the PHEV20/30 and PHEV20/50H technologies.

Restrictions that were applied used the same criteria described for the SHEVPS.

(4) Battery Electric Vehicles

For the NPRM analysis, the BEV200 technology was applied as an end-of-path technology. The BEV200 technology was the only battery electric vehicle option. For the final rule analysis, the BEV300 was added as a technology option beyond the BEV200, as discussed in Section VI.C.3.a)(1)(f) Battery Electric Vehicles. BEV200 and BEV300 technology was applied in place of all engine and transmission technologies, and was an end of path technology.

For the final rule analysis, both the BEV 200 and BEV300 had phase-in cap limitations applied based on an analysis of the market availability and cost of batteries.¹⁰⁷⁴ The BEV200 was limited to a greater extent than the BEV300, accounting for expected limits in market

demand for the shorter-range BEV.¹⁰⁷⁵ The phase-in capacity numbers were determined based on the results of the analysis of the National Energy Model System (NEMS) discussed in Section VI.D.1.b)(1)(b) Macroeconomic assumptions used to analyze economic consequences of the final rule.

(5) Fuel Cell Vehicle

For the NPRM analysis, FCV technology was also applied as an end of path technology. The FCV technology was also applied as end of path technology in the final rule analysis.

For the final rule analysis, a phase-in cap was assigned to FCV technology. The phase-in cap was assigned based on existing market share as well as an analysis of expected infrastructure availability during the time frame of regulation.¹⁰⁷⁶ ¹⁰⁹²

d) Electrification Effectiveness Modeling and Resulting Effectiveness Values

For this analysis, the agencies considered a range of electrification technologies which, when modeled, resulted in varying levels of effectiveness at reducing fuel consumption. Each technology consists of many different complex sub-systems with unique component efficiencies and operational modes. As discussed further below, the systems that contribute to the effectiveness of an electrified powertrain in the analysis include the vehicle's battery, electric motors, power electronics, and accessory load. Procedures for modeling each of these sub-systems are discussed below, and also in Section VI.B.3 Technology Effectiveness Values and in the FRM Argonne Model Documentation.

The modeled electrification technologies included micro hybrids, mild hybrids, strong hybrids, plug-in hybrids, and full electric vehicles. This section discusses how Autonomie was used to model these technologies' effectiveness. The models for the micro hybrids included a SS12V system model; mild hybrid models included BISG system models and CISC system models; strong hybrid models included SHEVP2 system models and SHEVPS system models; and finally, electric vehicle models included BEV system models and FCV system models.

(1) Electric Motors, Power Electronics and Accessory Load

Each electrified powertrain type possesses a unique effectiveness for reducing fuel consumption. Autonomie determines the effectiveness of each electrified powertrain type by modeling the basic components, or building blocks, found in each powertrain, and then combining the components modularly to determine the overall efficiency of the entire powertrain. The basic building blocks that comprise an electrified powertrain in the analysis included the battery, electric motors, power electronics, and accessory loads. Autonomie identified which components comprise each electrified powertrain type, and how these components are interlinked within each unique electrified powertrain architecture. This creates a model for

each electrified powertrain architecture that simulates how efficiently energy is transferred through each system. For example, Autonomie determines a BEV's overall efficiency by considering the efficiencies of the battery, the electric traction drive system (the electric machine and power electronics) and mechanical power transmission devices. Or, for a SHEVP2, Autonomie combines a very similar set of components to model the electric portion of the hybrid powertrain, and then also includes the combustion engine and related power transmission components.

For the NPRM and this final rule analysis, Autonomie employed a set of electric motor efficiency maps, which originated from two Oak Ridge National Laboratory (ORNL) studies: one for a traction motor and an inverter, the other for a motor/generator and

inverter.^{1077 1078} Autonomie also used test data validations from technical publications to determine the efficiency of certain electric motors. The electric motor efficiency maps are visual measurements of percent efficiency of power as a function of torque and motor RPM, and were based on representative production vehicles, especially for base and maximum speeds as well as maximum torque curve. The maps were used to determine the efficiency characteristics of the motors, but were scaled such that their peak efficiency value corresponded to the latest state of the art technologies for different electrified powertrains. The maps also included some of the losses due to power transfer through the electric machine.¹⁰⁷⁹ Table VI–86 details the electric machine efficiency map sources for the different powertrain configurations used for the NPRM.

Table VI-86 – NPRM Electric Machine Efficiency Map Sources for Different Powertrain Configurations

| Powertrain Type | Source of Efficiency Map for Motor1 (Traction Motor) + Inverter⁶ | Source of Efficiency Map for Motor2 (Motor/Generator) + Inverter |
|-----------------------------|--|---|
| SS12V, BISG | Camry EM1 data from ORNL | |
| CISG, SHEVP2 | Sonata HEV data from ORNL | |
| SHEVPS, PHEV20 | Camry EM1 data from ORNL | Camry EM2 Data from ORNL |
| PHEV50 | Camry EM1 data from ORNL | Sonata HEV Data from ORNL |
| BEV and FCV ¹⁰⁸⁰ | Nissan Leaf data from ORNL | |

For the final rule, the agencies used the same efficiency maps as the NPRM, except for BEVs. The agencies updated the BEV electric motor efficiency for the final rule analysis using data from a

more recent technical publication.¹⁰⁸¹ The agencies also scaled the maps to have peak efficiencies ranging from 96–98 percent depending on the powertrain type.¹⁰⁸² Table VI–87 below shows

powertrain types and the source of data used for the final rule.

Battery performance data (e.g., internal resistance, open circuit voltage) were measured using individual cell testing on a bench using standard test procedures, and BatPaC was used to design battery packs of different capacities and cell counts. The battery utilization (e.g. SOC range) were developed based on numerous vehicle test data.¹⁰⁸³ In addition, as discussed further below, for the NPRM analysis, the agencies resized the battery pack only with the addition of incremental mass reduction technology levels. For this final rule, the agencies updated the modeling to consider battery resizing with the application of all road load reduction technologies. Accordingly, a more appropriately-sized battery pack could result in lower vehicle mass, resulting in potentially improved effectiveness.

Development of Performance Simulation for a HEV with CVT and Validation with Dynamometer Test Data. Presented at the 28th International Electric Vehicle Symposium (EVS28). Kintex, Korea.

Beyond the powertrain components, Autonomie also considered on-board accessory devices that consume energy and affect overall vehicle effectiveness. Some electrical power is consumed by electrical accessories such as headlights, radiator fans, wiper motors, engine control units (ECU), transmission control unit (TCU), cooling systems, and safety systems, in addition to driving the motor and the wheels. In real-world driving, the electrical accessory load on the powertrain varies depending on the how features are used and the condition the vehicle is operating in, such as for night driving or hot weather driving. However, for regulatory test cycles related to fuel economy, the electrical load is repeatable because the fuel economy and CO₂ regulations control for these factors, as discussed in Section VI.B.3 Technology Effectiveness Values.¹⁰⁸⁴ Accessory loads during test cycles do vary by powertrain type and vehicle technology class, since distinctly different powertrain components and vehicle masses will consume different amounts of energy.

The baseline fleet consists of hundreds of different vehicle types that vary in the amount of accessory electrical power that they consume. For

¹⁰⁸⁴ NHTSA Benchmarking, "Laboratory Testing of a 2017 Ford F-150 3.5 V6 EcoBoost with a 10-speed transmission." DOT HS 812 520.

example, vehicles with different motor and battery sizes will require different capacities of electric cooling pumps and fans to manage component temperatures. Autonomie has built-in models that can simulate these varying sub-system electrical loads. However, for the NPRM and this final rule analysis, the agencies used a fixed (by vehicle technology class and powertrain type), constant power draw to represent the effect of these accessory loads on the powertrain. The agencies intended and expected that fixed accessory load values would, on average, have similar impacts on effectiveness as found on actual manufacturers' systems. This process was in line with the past analyses, such as in the Draft TAR and the EPA Proposed Determination.¹⁰⁸⁵ ¹⁰⁸⁶ For assumptions regarding accessory load modeling for the rulemaking timeframe, the agencies relied on research and development data from DOE's Vehicle Technologies Office and Argonne Advanced Mobility Technology Laboratory, as well as input from automotive manufacturers.¹⁰⁸⁷ ¹⁰⁸⁸ ¹⁰⁸⁹

¹⁰⁹³ Alliance of Automobile Manufacturers Comments on Draft TAR at p. 30. September 26, 2016.

¹⁰⁹⁴ EPA Proposed Determination TSD (November 2016), at p.2-270.

CARB commented on NPRM non-battery component efficiency assumptions in two respects; first by claiming that the agencies relied on outdated data for electric machines and inverter efficiencies across all electrification applications,¹⁰⁹⁵ and second by claiming that the agencies did not project any efficiency gains in those components over time.¹⁰⁹⁶ CARB stated that the three vehicles benchmarked in the ORNL studies (MY 2007 Toyota Camry Hybrid, a MY 2011 Hyundai Sonata Hybrid, and MY 2012 Nissan Leaf) were inappropriate for the agencies to use to assess the costs and efficiencies for the same components in MY 2020–2030 vehicles, given the rapid development in the past ten years in automotive electrification. CARB cited the MY 2016 Chevrolet Volt and Bolt, and the MY 2016 Toyota Prius, as examples of vehicles that had undergone electric machine efficiency improvements from one generation to the next; those vehicles generally employed efficiency improvements including reduced electric motor volume and mass, reduced power inverter volume, increased electric motor peak power density, and reduced mechanical losses through friction reduction, among other improvements.

In support of their comments that the agencies did not project any efficiency gains in non-battery components over time, CARB faulted the agencies for not including data from the October 2015 ORNL progress report for electric drive technologies, stating that benchmarking data for a MY 2014 Honda Accord Hybrid inverter and traction motor components could have been used to compare against and update the data from the MY 2007 Toyota Camry Hybrid and MY 2011 Hyundai Sonata Hybrid efficiency maps benchmarked in the older ORNL report. CARB stated that the lack of consideration of this newer data was evidence that the agencies' data selection was biased to support weakening fuel economy standards.

CARB also cited 2017 research from Argonne's Autonomie group as a source of updated data that showed efficiency gains over time for electrification technologies not considered in the agencies' analysis, including increases in high voltage system peak efficiency, increases in high voltage specific power, and decreases in costs.¹⁰⁹⁷ CARB stated

that had the agencies included newer data in the analysis, including from the same data sources from which prior data came, the analysis would have not supported the agencies' proposal.

The agencies agree that there have been improvements in non-battery component efficiency over the past few years, however CARB's characterization of the process used to employ the ORNL benchmarking data in the analysis was incorrect. Autonomie used high-level electric machine characteristics such as base and max motor speed from production vehicles along with generic efficiency map curves for each technology type, with peak efficiencies matching the current state of the art technologies discussed in ORNL reports. Although the source data for the electric machines were from older production vehicles, the peak electric motor and controller efficiencies were updated to reflect the latest available data. Specifically, the NPRM analysis modeled a 92 percent peak efficiency for motors and controllers.¹⁰⁹⁸

That said, the agencies also agreed that the analysis could use updated peak electric and controller efficiencies, and updated those for the final rule. For the final rule analysis, the agencies used 96 percent efficiency for HEVs and PHEVs, and 98 percent peak efficiency for BEVs and FCEVs.¹⁰⁹⁹ The agencies believe the final rule efficiencies are appropriate for the rulemaking timeframe.

In addition, as discussed above, other changes for the final rule analysis include updating the electric motor sizing as a function of electric power to account for lower electric machine mass, updating the BEV electric machine map to use a newer efficiency map from the Chevy Bolt, updating baseline and reference vehicle mass assumptions to reflect latest machine weight technology development, and updating the electrical accessory loads for vehicle modeling to reflect data from vehicle benchmarking. Changes and updates to the Autonomie analysis are discussed throughout this electrification section and in the FRM Argonne Model Documentation. In addition, for this final rule analysis, the agencies used the latest Argonne BatPaC model to determine the battery pack mass and manufacturing costs for electric vehicle batteries. Updates to non-battery component efficiency were small in comparison to the impact of using

updated battery modeling for the final rule analysis. Further discussion on battery modeling can be found in Section VI.C.3.e)(1) Battery Pack Modeling.

(2) Modeling and Simulating Vehicles With Electrified Powertrains in Autonomie

Data from Argonne's AMTL was used to develop the electrified powertrain models in Autonomie. The modeled electrification components were sized based on performance neutrality needs, as discussed further below, and the control algorithms were based on Argonne-collected data.¹¹⁰⁰ Detailed discussion about the development of the HEV drivetrains can be found in the Autonomie modeling documentation.¹¹⁰¹ The modeled powertrains are not intended to represent any specific manufacturer's architecture, but are intended to act as surrogates predicting representative levels of effectiveness for each electrification technology.

The agencies also broadly discussed in Section VI.B.3 Technology Effectiveness Values that certain technologies' effectiveness for reducing fuel consumption requires optimization through the appropriate sizing of the powertrain. This analysis iteratively minimizes the size of the powertrain components to maximize efficiency while at the same time enabling the vehicle to meet multiple performance criteria. The Autonomie simulations use a series of resizing algorithms which contain "loops," such as an "Acceleration Performance Loop (0–60 mph)," which automatically adjust the size of certain powertrain components until a criterion, for example 0–60 acceleration time, converges to a target value. As the algorithms examine different performance or operational criteria that must be met, no single criterion is allowed to degrade; once a resizing algorithm completes, all criteria will be met, and some may be exceeded as a necessary consequence of meeting others.

Autonomie applies different powertrain sizing algorithms depending on the type of vehicle considered because different types of vehicles not only contain different powertrain components to be optimized, but they must also operate in different driving modes. While the conventional powertrain sizing algorithm must consider only the power of the engine, the more complex algorithm for

electrified powertrains must simultaneously consider multiple factors, which could include the engine power, electric machine power, battery power and battery capacity. Also, while the resizing algorithm for all vehicles must satisfy the same performance criteria, the algorithm for some electric powertrains must also allow those electrified vehicles to operate in certain driving cycles without assistance of the combustion engine, and ensure the electric motor/generator and battery can handle the vehicle's regenerative braking power, all-electric mode operation and intended range of travel.

To establish the effectiveness of the technology packages, Autonomie simulated the vehicles performing compliance test cycles, as discussed in Section VI.B.3 Technology Effectiveness Values.^{1102 1103 1104} For vehicles with conventional powertrains and micro hybrids, Autonomie simulated the vehicles using the 2-cycle test procedures and guidelines.¹¹⁰⁵ For mild HEVs, strong HEVs, and FCVs, Autonomie simulated the 2-cycle test, with the addition of repeating the drive cycles until the final state of charge was approximately the same as the initial state of charge, a process described in SAE J1711. For PHEVs and BEVs, Autonomie simulated vehicles performing the test cycles per guidance provided in SAE J1711.¹¹⁰⁶ For BEVs, Autonomie simulated vehicles performing the test cycles per guidance provided in SAE J1634.¹¹⁰⁷

A survey of comments about the modeled effectiveness of electrification technologies showed most comments could be sorted in three major categories. The first, and largest category of comments, were concerned with effectiveness values used for the technologies. Specifically, commenters were concerned the values for the modeled effectiveness of the technologies were too low, particularly when compared to past analysis efforts. The second major category of comments

were concerned with the size of the electrification components selected in the Autonomie tool, and used to simulate the system performance. Commenters were concerned because oversized components can lead to the system violating performance neutrality constraints and artificially increasing the cost of the technology. The third major category of comments were concerned not enough variety of technologies were represented in the electrification technology models. Specifically, commenters wanted additional engine technologies allowed to couple with electrification technologies.

Each of the comments from the first category will be referenced and addressed under the specific technology sections, below. However, broadly, two factors have led to the comments raised by stakeholders. First, as discussed throughout this document, the agencies avoided using performance values in the analysis that can be traced to specific implementation of a technology type. Thus, when comparing simulated performance to any specific real world vehicle, there will be a deviation. The modeled inputs are meant to represent the typical range of values for a technology—reasonable and realistic values—but are not likely to result in performance outputs that would equal any specific existing vehicle. Second, the modeling approach implemented in the NPRM and final rule analysis succeeds in isolating the effects of individual technologies to a higher degree than previous analysis. Due to the greater use of parametric modeling of full vehicle systems, the specific effects of technologies could be isolated to a higher degree from the amplifying or muting effects of other technologies. This isolation of effect often results in lower predicted effectiveness values for individual technologies than has been observed in previous analysis, where the isolation of effect was not as precise, and often attributed efficiency gains from a combination of technological changes to a single technology.

For the second major group of comments, the agencies mostly agreed with the stakeholder observations. The issues identified were investigated by the agencies and resulted in changes to the sizing algorithms used by the agencies for the final rule analysis. The agencies further investigated the constraints of performance neutrality and ensured those constraints were followed for sizing of electrification components. Further discussion of the changes made, as well as specific answers to comments under each technology section, can be found in the

following technology subsections and in Performance Neutrality, Section VI.B.3.a)(6).

The third major group of comments from stakeholders were concerned with allowing more engine technologies to be incorporated in electrification systems. The agencies agreed with these comments and increased the number of technology combinations available. The new combinations are discussed in Section VI.C.3.a)(1) Electrification Technologies, as well as under each technology section below.

(a) Micro and Mild Hybrid Vehicles

The micro and mild hybrid systems modeled in Autonomie represented SS12V and BISG technology (and CISG technology for the NPRM). SS12V and BISG were modeled using a similar approach because both systems have low peak power, low energy storage, and allow stop/start engine idle reduction. The effectiveness improvement from both technologies is attributable to the amount of fuel saved during engine idling period on the 2-cycle test. However, only the BISG system model allowed limited assist to propel the vehicle and limited regenerative braking. For further discussion of these system models, see the FRM Argonne Model Documentation.¹¹⁰⁸

Powertrain resizing was not employed for micro or mild hybrid system application, in either the NPRM or this final rule analysis. These systems have little to no impact on the vehicle performance metrics that would be adjusted by powertrain resizing, and in turn there would be limited or no benefit in attempting to resize upon application of these systems. For example, the micro hybrid SS12V system allows the engine to be turned off when the vehicle is fully stopped to reduce idle-stop fuel consumption, but the combustion engine size must be retained to maintain performance metrics such as acceleration. The main focus of mild hybrid vehicles is to provide idle-stop and capture some regenerative braking energy, and although they also can provide some assistance to the engine during the initial propelling of the vehicle, this is done to improve efficiency and does not significantly improve the acceleration performance of the vehicle. With BISG mild hybrids, the electric machine is linked to the engine through a belt, and thus the potential power assistance is usually limited. In the NPRM, the BISG system used an 806 Wh capacity battery

pack and a 10 kW motor/generator. For the final rule analysis, the 10 kW motor/generator was paired with a 403 Wh battery pack to align with BISG systems emerging in the marketplace.

ICCT commented that the agencies unjustifiably reduced the CO₂ and fuel consumption benefits of SS12V from the Draft TAR, including a reduction in the overall effectiveness benefit when the SS12V system was applied in combination with other technologies.¹¹⁰⁹ ICCT stated that the agencies should know the precise effectiveness improvement for SS12V technology based on EPA compliance data, and the agencies should report a full listing of all the baseline 2016 vehicle models with stop-start technology, with their test-cycle, and off-cycle improvement in g/mile and percent effectiveness. ICCT claimed that the agencies either intentionally ignored the full compliance benefits of SS12V technology or “ignored the knowledge and expertise of the EPA engineering and compliance staff,” and argued that not reporting the requested data would be “hiding relevant data the agencies have readily available to more rigorously assess existing stop-start technologies and their impact for the rulemaking.” ICCT also stated that the agencies did not appropriately include the full regulatory benefit (*i.e.*, inclusion of the additional off-cycle “credit” under EPA’s program or fuel consumption improvement value under NHTSA’s program) of SS12V technologies due to their off-cycle improvements.¹¹²⁶

HDS made a similar observation, noting that the SS12V benefit from the NRPM was similar to the 2012 TSD projection, but lower than the benefit quoted by stakeholders in the Draft TAR.¹¹¹⁰ HDS cited the difference in fuel economy between two vehicles that were produced with and without a SS12V option (the 2015 Ford Fusion 1.5L TGI and the 2015 Mazda 3 i-ELOOP) which suggested effectiveness values for SS12V of about 3.3 percent for both vehicles. HDS also cited a Bosch presentation that claimed newer SS12V systems could provide effectiveness of up to 6 percent. HDS argued that this actual data and supplier data supported a benefit of at least 3.3 percent, which they stated was double the benefit in the NRPM analysis.

The agencies disagree with ICCT and HDS’ comments regarding the

effectiveness of the SS12V technology modeled in the NPRM analysis. The implementation of the full vehicle simulation approach used in the NPRM, and carried forward to the final rule analysis, clearly defines the contribution of individual technologies and separates those contributions from other technologies. The modeling approach also shows when technologies have amplifying or muting interactions. In some cases, this may appear as a reduction in performance compared to previous analysis. The agencies modeled the SS12V system in conjunction with all the IC engine and transmission combinations. The results of this parametric modeling accounted for each engine and transmission combination’s unique fuel consumption rate at idle.¹¹¹¹ The range of effectiveness for the technology in the NPRM analysis is a result of these differences. This range of values will result in some modeled effectiveness values being close to real-world measured values, and some modeled values that will depart from measured values, depending on the level of similarity between the modeled hardware configuration and the real-world hardware configuration. This modeling approach comports with the National Academy of Science 2015 recommendation to use full vehicle modeling supported by application of lumped improvements at the sub-model level.¹¹¹² The approach allows the isolation of technology effects in the analysis supporting an accurate assessment.

For both the NPRM and final rule analysis, the agencies assigned SS12V technology to vehicles in the analysis fleet using compliance data, and used compliance data to assign a vehicle’s baseline fuel economy value. The market data file indicated the presence of SS12V on a vehicle, and accordingly, the vehicles reported to include SS12V technology in the analysis fleet were modeled with the technology. For more discussion on how technologies were assigned to the vehicle platforms in the analysis fleet, please see Section VI.B.1 Analysis Fleet. The agencies accounted for the contribution of the SS12V technology in the analysis fleet by using

the reported compliance fuel economy values as the baseline fuel economy values for vehicles that included the technology. The analysis fleet fuel economy values were the reported final compliance values for the given vehicle platform and should include the benefits from all technologies on the vehicle platform.¹¹¹³ The agencies also captured the off-cycle credits provided to a manufacturer for the existence of the technology in the manufacturer’s fleet. For the NPRM and final rule analysis, the manufacturers’ fleets are modeled with baseline year compliance-reported off-cycle credits. Further, for the final rule analysis, the agencies increased the application of off-cycle credits in the analysis, as discussed in Section VI.B.2.a) Off-cycle and A/C Efficiency Adjustments to CAFE and Average CO₂ Levels.

Commenters similarly disagreed with the BISG effectiveness presented in the NPRM analysis, suggesting the resulting effectiveness improvement should be at a range of 4 percent to 6 percent.¹¹¹⁴ Such commenters claimed that it was unclear why effectiveness values were so much lower than previous effectiveness estimates. More specifically, comments centered on (1) arguing that the agencies’ modeling of BISG and CISC systems in Autonomie likely underestimated the resulting effectiveness values; (2) suggesting that the values in prior documents like the Draft TAR and the 2015 NAS report were more accurate; and (3) comparing modeled effectiveness values to claimed values achieved by actual on-road vehicles and mild hybrid systems.

CARB claimed that the agencies failed to disclose the necessary details to conclude why mild hybrid systems were projected to have lower efficiency values than past estimates. CARB also concluded the lack of engine downsizing when adding a BISG/CISC system and the lack of adjusting transmission drive ratios and shift logic were reasons why BISG/CISC effectiveness was underpredicted.¹¹¹⁵ CARB claimed not resizing the engines resulted in a “less than optimized system that does not take full advantage

Washington, DC—The National Academies Press. <https://www.nap.edu/catalog/21744/cost-effectiveness-and-deployment-of-fuel-economy-technologies-for-light-duty-vehicles>, at 292.

of the mild hybrid system.”¹¹¹⁶ CARB argued that the agencies’ assumption that manufacturers “would not optimize the engine and transmission when installing a CISG is not realistic and results in improper pairing of advanced gasoline engines and transmissions in the modeling and leads to underestimation of the efficiency benefits.” As mentioned above, CARB stated that manufacturers “often are required to make a[n] engine casting change to accommodate the system,” and when doing so, “no manufacturer would fail to pair the system with an optimally sized engine and configured transmission to take full advantage of the system’s capabilities.”¹¹¹⁷

CARB also inquired into whether the Argonne modeling “took full advantage” of the system, using Daimler’s EQ Boost system, that provides temporary boosts for acceleration and enables engine shut-off during coasting events, as an example.¹¹¹⁸ Similarly, CARB noted that CISG systems’ ability to provide low end torque makes it an “ideal technology to pair with an engine technology that may have poor low end torque but improved efficiency under other conditions; examples could include an HCR engine sized with minimal low end torque to maximize efficiency improvements in other operating conditions or a turbocharged downsized engine equipped with a larger turbine to reduce backpressure but provide improved efficiency over a larger portion of the engine map.”¹¹¹⁹ CARB stated that manufacturers are using such systems to boost engine torque at higher operating speeds so they can keep the engine operating in a more efficient region.

Commenters also cited data from suppliers that produce 48V BISG systems, including data from TULA that showed a 11 percent fuel economy benefit from a 48V system,¹¹²⁰ data from a Delphi 48V system prototype installed on a Honda Civic that showed a 10 percent reduction in CO₂ emissions levels,¹¹²¹ and data from Continental showing a 13 percent fuel savings improvement from its BISG system.¹¹²²

ICCT also cited its supplier and technology report on hybrids that estimated the benefit of mild hybrid technology at 12.5 percent, which it characterized as “remarkably similar” to that achieved by the 2019 RAM pickup truck.¹¹²³ HDS noted that even if the effectiveness values from TULA are regarded as optimistic because they are the developers of the technology, EPA’s previous modeling results of 8–9 percent effectiveness “appear reasonable in light of what is observed from certification data.”¹¹²⁴ ICCT ultimately recommended the agencies revise the effectiveness value for mild hybrid systems to include a CO₂ effectiveness value of 12.5 percent.¹¹²⁵

Commenters also stated that the effectiveness estimates for CISG systems were significantly understated,¹¹²⁶ with UCS characterizing CISG systems as showing “virtually no benefit whatsoever for CISG over BISG, and in many cases actually show[ing] an increase in fuel consumption.”¹¹²⁷ UCS stated this was a dramatic departure from previous Autonomie results, and with “no explanation whatsoever” given for the decrease in technology effectiveness.

The agencies agree with commenters that the NPRM analysis of mild hybrid technologies could be more representative of production vehicles and vehicles likely to be produced during the rulemaking time period. The agencies further conclude that the NPRM analysis overestimated the costs of such technologies. Thus, for the final rule analysis, the agencies only considered one 48V BISG system in the mild hybrid technology category. The 48V mild hybrid BISG system used the same 10 kW electric motor as the one used in the NPRM analysis, and the 48V BISG battery pack was also reduced in size to 403 W-hr from 806 W-hr to reflect more accurately the size of battery packs available in the market. In addition, the Autonomie model increased the usable battery capacity, increasing the duration of electric motor use by the vehicle before starting the

engine. The specifications and assumptions for the 48V BISG system are further discussed in the FRM Argonne Model Documentation and FRM Argonne Assumptions Summary.^{1128 1129} The discontinued use of the CISG technology is discussed in Section VI.C.3.a)(1)(c) Electrification Technologies, Mild Hybrids.

The agencies disagree with comments stating incremental effectiveness estimated by Autonomie modeling was incorrect because the effectiveness values deviated from past effectiveness values estimated in the agencies’ rulemakings or from real-world values measured on specific vehicles. As discussed in previous sections, the implementation of the full vehicle simulation approach used in the NPRM analysis and carried forward to the final rule analysis clearly defines the contribution of individual technologies through the application of parametric modeling. This approach clearly separated the contributions of each technology. The modeling approach also showed the amplifying or muting interactions between technologies. In some cases, this may appear as reduced performance in comparison to previous analysis. The agencies also strongly disagree that they should use the performance values for any specific vehicle as representative of all mild hybrid systems.

CARB also commented that the agencies’ decision to use a fixed final drive ratio and fixed shift logic based on the selected transmission did not allow for efficiency improvements when mated with electrified powertrains, with specific regards to mild hybrid BISG and CISG systems.¹¹³⁰ CARB stated that based on the information disclosed in the NPRM, “it appears that Argonne did not utilize the system in these manners nor did they allow for changes in gear ratios, final drive ratio, or transmission shift logic to optimize for efficiency improvements when mated with different electrified powertrains.”¹¹³¹ Roush Industries similarly stated that the analysis under-predicted the potential improvements of employing a BISG system because the engine could operate at a lower RPM with the help of the torque assist of the electric motor/generator, with a change to the final

drive ratio and transmission shift logic, but the analysis did not do so.¹¹³²

The agencies disagree with CARB and Roush Industries' claims about the gear ratio and shift logic used for the NPRM. As discussed in Section VI.C.2.d) Transmission Effectiveness Modeling and Resulting Effectiveness Values, manufacturers commonly maintain the same gear hardware across vehicle platforms and applications, relying on controls and shift strategy to achieve optimization. Autonomie maintained gear hardware but customized the shifting strategy for each unique vehicle system modeled¹¹³³ to reflect real-world manufacturing strategies more accurately.

CARB also commented that the performance modeled by the Autonomie tool in the NPRM analysis failed to remain neutral for over 80 percent of the modeled systems with mild hybrids. CARB felt the over-performance was "indicating some portion of the system capability was improperly modeled to improve performance rather than reduce CO₂ emissions."¹¹³⁴

The agencies agree with CARB's observations about the performance of mild hybrid combinations. The mild hybrid configuration exhibited higher performance in comparison to non-mild hybrid configurations in the NPRM analysis. For the final rule analysis, the agencies updated sizing and control of the mild hybrid systems to minimize performance changes and maintain neutrality. As discussed earlier in this chapter, updates include using smaller battery systems, updated algorithms, and updated component weights. For further discussion of performance neutrality for the final rule, see the Performance Neutrality Section VI.B.3.a)(6).

Finally, ICCT commented that the agencies should include off-cycle and "game-changing" pickup truck credits in the effectiveness estimates for hybrid pickup trucks, as "[i]t is the responsibility of the agencies to include all applicable credits with their technology packages calculations and their projections, including any additional credits that will automatically accrue."¹¹³⁵

While the agencies included many compliance flexibilities in the modeling for the final rule analysis, hybrid pickup truck credits were not modeled. The referenced pickup truck credit is set to

expire for all pickup trucks after MY 2021, so in analyzing this comment the agencies considered what technologies manufacturers could apply to pickup trucks through that model year to meet the requirements specified in the regulation. To receive credit in a model year, manufacturers must produce a quantity of improved full size pickup trucks—improvement characterized by including either hybrid technology or improved emissions performance—such that the proportion of production of such vehicles, when compared to the manufacturer's total production of full size pickup trucks, is not less than an amount specified in that model year. The agencies determined that, based on manufacturers' MY 2017 pickup truck offerings characterized in the analysis fleet and with the technology considered in this rule, no pickup truck manufacturer could meet the criteria set by EPA to qualify for the mild credit before the credit is set to expire. For the strong HEV credit, the agencies considered that forcing the application of strong HEV pickups to meet the minimum threshold of 10 percent of the fleet in order to earn the incentive credits would significantly increase the cost for compliance and be less cost-effective than other technology pathways. As the analysis seeks the most cost-effective pathway for compliance, the agencies disagree the analysis should force the application of strong HEV technology to at least 10 percent of full size pickup trucks. However, the agencies did allow and simulated maximum off-cycle and A/C off-cycle FCIVs for all manufacturers in the CAFE model for both the CAFE and CO₂ programs during the rulemaking time frame. So, while the agencies did not model pickup truck credits specifically, the final rule analysis allowed manufacturers to reach the maximum off-cycle credit cap during the rulemaking timeframe.

(b) Strong Hybrid Vehicles

The power-split hybrid (SHEVPS) model in Autonomie included a power-split device, two electric machines and an engine, and allowed various interactions between these components. The SHEVP2 model in Autonomie is based on the pre-transmission (P2) configuration where the electric motor is placed between the engine and transmission for direct flow of power to

the wheels. The vehicle can be propelled either by the combustion engine, electric motor, or both simultaneously, but the speed/efficiency region of operation for SHEVP2s under any engine/motor combination is ultimately dictated by the transmission gearing and speed. Detailed discussion of SHEVPS and SHEVP2 modeling and validation are provided in the Argonne Model Documentations.¹¹³⁶ Autonomie full vehicle models representing strong hybrids were based on vehicle test data from vehicle benchmarking.

As discussed previously in this section, power-split hybrids utilize a combustion engine, two electric machines and a planetary gear set along with a battery pack to propel the vehicle. The smaller motor/generator (EM1) is used to control the engine speed and uses the engine to either charge the battery or to supply additional electric power to the second "drive" motor. The more powerful drive motor/generator (EM2) is permanently connected to the vehicle's final drive and always turns with the wheels. The SHEVPS resizing algorithm makes an initial estimate of the size of the engine, battery, and electric motors. The initial estimates for the combustion engine and EM2 sizes are based on the peak power required for acceleration performance and the continuous power required for gradeability performance. The initial estimates for the battery and EM1 powers are based the maximum regenerative braking power. With these initial size estimates, the algorithm computes the vehicle mass, and simulations are run to determine if 0–60 and 50–80 mph acceleration performance is acceptable. If acceleration is not satisfactory (too fast or too slow), the algorithm iteratively adjusts the sizes of the engine, motors, and battery, and runs simulations until a minimum powertrain size is found that meets all requirements. With each iteration, the engine, battery, and motor characteristics were also updated for gradeability performance and regeneration, if necessary. Figure VI–32 below shows the general steps of the SHEVPS sizing algorithm. Detailed descriptions are available in section 8.3 of the FRM Argonne Model Documentation.

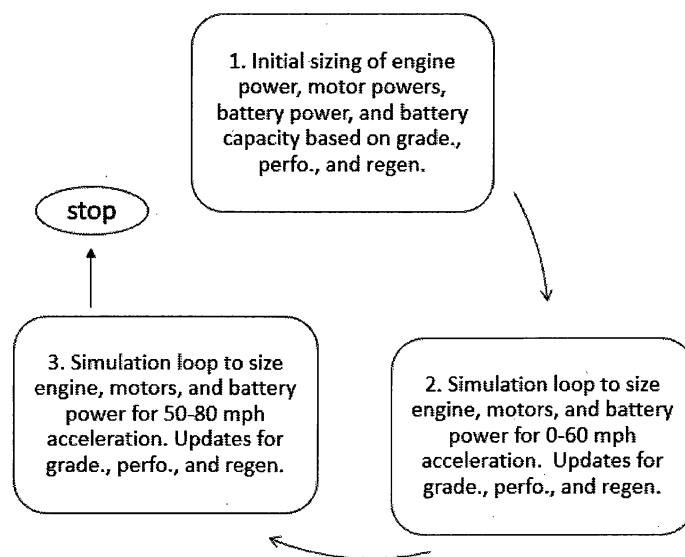

Figure VI-32 – Simplified SHEVPS Sizing Algorithm in Autonomie

A parallel hybrid (SHEVP2) uses a combustion engine and a multi-speed transmission-integrated electric motor (EM1), as discussed previously in this section. As is done with SHEVPS, the SHEVP2 resizing algorithm creates a starting point by making an initial estimate of the size of the engine, battery, and electric motor based on performance criteria or an estimated regenerative braking power, in turn calculating the associated vehicle mass. The algorithm then uses a simulation loop to find a more precise value of regenerative braking power generated in the UDDS “city driving” cycle, and adjusts the electric motor size and vehicle mass accordingly. Next, the algorithm uses simulation loops to optimize the engine, motor, and battery sizes in relation to acceleration performance criteria. In the event that the acceleration criteria requires downsizing the powertrain, the electric motor size is not reduced as this would not be suitable for the handling of regenerative braking power. If the acceleration criteria cause the electric motor to increase in size, the algorithm then returns to the regenerative braking loop and subsequently all other loops until all components are optimized. Figure VI-33 below shows a simplified sizing algorithm for SHEVP2s.

BILLING CODE 4910-59-C

In the NPRM, the acceleration optimization loops in the SHEVP2 algorithm did not resize the powertrain if the resulting acceleration time was less than the target. This strategy was intended to avoid reducing the engine

size compared to the conventional vehicle, mimicking an observed marketplace trend in which parallel hybrid models tend to retain similar engine sizes as the non-hybrid models bearing the same nameplate. However, in some cases this resulted in overly aggressive SHEVP2 acceleration times; to further maintain performance neutrality, the final rule sizing algorithm for standard (non-performance) SHEVP2 vehicle powertrains was changed to allow engine downsizing such that acceleration performance could converge toward the target value. This algorithm update is also detailed in Section VI.B.3.a)(6), Performance Engine Neutrality.

CARB, ICCT, Meszler and ACEEE commented that some combinations of advanced engines mated with strong hybrids were illogical and inefficient.^{1137 1138 1139 1140} The commenters specifically discussed combinations of SHEVP2 with TURBO2 and CEGR1 technologies that stated the incremental effectiveness resulted in near zero to negative value, but also clarified that not all combinations showed inappropriate effectiveness.

¹¹³⁹ International Council on Clean Transportation, Attachment 3, Docket No. NHTSA-2018-0067-11741, at I-25.

¹¹⁴⁰ Comments from Meszler Engineering Services, Attachment 2, NPRM Docket No. NHTSA-2018-0067-11723, at 14.

CARB further expanded that “[t]hese are not likely combinations utilized by manufacturers as they unnecessarily add both gasoline technology and hybrid technology that negates many of the benefits of the advanced gasoline technology. This error in the Agencies’ modeling leads to inflated technology costs on vehicles that are converted into P2HEVs.”¹¹⁴¹

The agencies now conclude that the NPRM included certain engine and strong hybrid pairings that resulted in incremental effectiveness that exceeded a reasonable level of performance neutrality. The agencies also agree that Autonomie should model strong hybrid technology combinations with other engine technologies. In response to these comments, for the final rule analysis the agencies updated the CAFE model to allow the use of HCR engine technologies with strong hybrids, as discussed in Section VI.C.1.c)(4) Engine Maps, HEV Atkinson Cycle Engines, and improved full vehicle modeling of turbocharged engine combinations. These changes were discussed in Section VI.B.3.a)(1) Full-Vehicle Modeling, Simulation Inputs and Data Assumptions and Section VI.C.2.d)(1)(a) Shifting Controller.

In addition, the agencies limited adoption of advanced engine technologies with strong hybrids in cases where the electrification technology would have little effectiveness benefit beyond the benefit of the advanced engine system, but

¹¹⁴¹ California Air Resources Board, Attachment 2, Docket No. NHTSA-2018-0067-11873, at 186.

would substantially increase costs. Specifically, the agencies did not model strong hybrid technologies with VCR engines (eng26a) and eBoost engines (eng23c). The agencies believe that manufacturers would not consider these combinations because the combination of electrification and advanced engine technologies are not as cost-effective as other technologies.

c) Plug-In Hybrid Vehicles

The effectiveness of the PHEV systems in the analysis was dependent on both the vehicle's battery pack size and range, in addition to the other fuel economy-improving technologies on the vehicle (*e.g.*, aerodynamic and mass reduction technologies). For the NPRM analysis, the electrification components were sized to achieve the specified all-electric range (AER) on the combined cycle (UDDS + HWFET) on the basis of adjusted energy values. As mentioned above, the PHEV would provide propulsion energy for a limited range in addition to start-stop or idle-stop. The NPRM analysis classified PHEVs into two levels: (1) PHEV30 indicating a vehicle with an AER of 30 miles; and (2) PHEV50 indicating a vehicle with AER of 50 miles.

The resizing algorithm for plug-in hybrid (PHEV) vehicles, similarly as for SHEVs, considered the power needed for acceleration performance and all-electric mode operation (compared to regenerative braking for SHEVs); the PHEV resizing algorithms used those metrics for an initial estimation of engine, motor(s) and battery powers, and battery capacity. The initial mass of the vehicle was then computed, including weight for a larger battery

pack and charging components.¹¹⁴² However, since PHEVs offer expanded electric driving capacity, their resizing algorithm must also yield a powertrain with the ability to achieve certain driving cycles and range in electric mode, in which the engine remains off all or the majority of the operation. The analysis sized the PHEV electric motors and battery powers to be capable of completing either the City Cycle (UDDS) or US06 (aggressive, high speed) driving cycle in electric mode, and the battery energy storage capacity to achieve the specified all-electric range on the 2-cycle tests on the basis of adjusted energy values.^{1143 1144}

The final rule analysis classified PHEVs into four technology levels, as discussed previously: (1) PHEV20 indicating a vehicle with an AER of 20 miles and powertrain system based on SHEVPS hybrid architecture; (2) PHEV50 indicating a vehicle with an AER of 50 miles and powertrain system based on SHEVPS hybrid architecture; (3) PHEV20T indicating a vehicle with an AER of 20 miles and powertrain system based on SHEVP2 hybrid architecture; and (4) PHEV50T indicating a vehicle with AER of 50 miles and powertrain system based on SHEVP2 hybrid architecture.¹¹⁴⁵ The

¹¹⁴² FRM ANL Model Documentation, at 8.3 Vehicle Powertrain Sizing Algorithms.

¹¹⁴³ Battery sizing and definition of combined 2-cycle tests all-electric range is discussed in detail in ANL Autonomie Model Documentation Chapter 6 Test Procedure and Energy Consumption Calculation.

¹¹⁴⁴ ANL has incorporated SAE J1711 standard into Autonomie Modeling. J1711: Society of Automotive Engineers Recommend Practice for Measuring Exhaust Emissions and Fuel Economy of Hybrid-Electric Vehicles, Including Plug-In Hybrid Vehicles.

¹¹⁴⁵ As discussed previously, the NPRM analysis included PHEV30 instead of PHEV20. However, the related resizing algorithm is applicable to either.

PHEV20, PHEV20T, PHEV50, and PHEV50T resizing algorithms were functionally equal, and differed only in the type of electric mode driving cycle simulated in each one (UDDS for PHEV20/20T, or US06 for PHEV50/50T). These algorithms simulated the driving cycles in an iterative loop to determine the size of the electric motors and the battery required to complete the cycles. In the case of PHEV20 and PHEV20T, the power of the electric motors and battery must be sized to propel the vehicle through the UDDS cycle in “charge-depleting (CD) mode;” in this mode, the electric machine alone propels the vehicle except during high power demands, at which point the engine may turn on and provide propulsion assistance. The PHEV50 and PHEV50T motor(s) and battery must be sized to power the vehicle through the US06 cycle in “electric vehicle (EV) mode,” where the engine is off at all times. Then, all PHEV algorithms adjusted the battery capacity, or vehicle range, by ensuring the battery energy content was sufficient to complete a simulated UDDS+HWFET combined driving cycle, based on EPA-adjusted energy consumption. Finally, the engine, electric motor(s), and battery powers were then sized accordingly to meet 0–60 and 50–80 mph acceleration targets. All loops were repeated until the acceleration targets were met without needing to resize the electric motors, at which point the resizing algorithm finished. Figure VI–34 below shows the general steps of the PHEV sizing algorithm. Detailed steps can be seen in section 8.3 of the FRM Argonne Model Documentation.

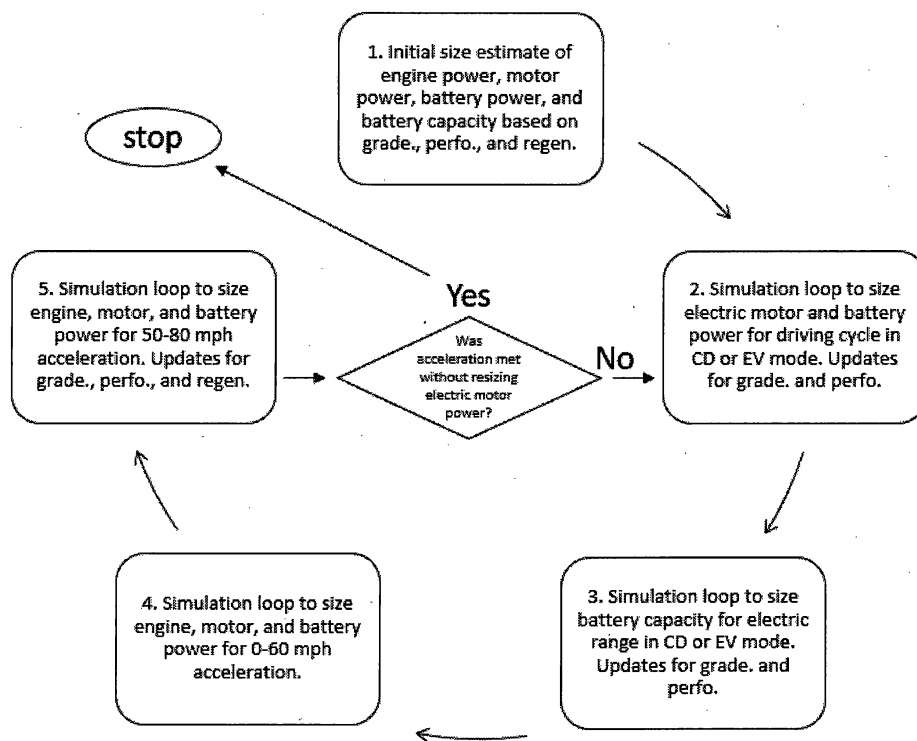

Figure VI-34 – Simplified PHEV Sizing Algorithm in Autonomie

Meszler, CARB, and BorgWarner provided comments on the effectiveness of the PHEV models. The commenters were concerned with underperformance of the technology, sizing of the components, and the variety of PHEV technologies available.

Meszler commented that PHEVs in the 2016 analysis fleet were inappropriately constrained in their future fuel economy potential by the ratio of baseline electric-only fuel economy to baseline engine-on fuel economy; and those vehicles should be allowed to improve that ratio over time, identically to vehicles that adopt PHEV technology during the analysis period.¹¹⁴⁶

The agencies must use the SAE J1711 method for determining the fuel economy for the PHEV systems. The use of SAE J1711 and the underlying dual fuel vehicle fuel economy calculations are defined by statute.¹¹⁴⁷ However, it is important to note that PHEVs are not excluded from applying greater range technologies within the PHEV technology paths; that is, a PHEV with a lower AER can progress to become a PHEV with a longer AER.

CARB commented that several aspects of the agencies' PHEV modeling contributed to increased PHEV costs. CARB stated that the electric motors were oversized, that all-electric vehicle efficiencies were low, and that the lack of battery resizing for road load reductions other than mass reduction resulted in battery energy capacities much higher than production vehicles.¹¹⁴⁸ CARB stated the modeled battery capacity to achieve a given range (kWh/mi) was larger than what exists on several representative production vehicles.

The agencies agreed with CARB's comments that electric motors and batteries may be oversized. As a result, the agencies reviewed the sizing algorithms and methods used in the NPRM analysis and updated the model for the final rule analysis. The updates resulted in smaller motor sizes and battery pack sizes for electrified powertrains, as discussed above. In addition, the review also resulted in a change to the range categories used for the PHEVs in the final rule analysis; the final rule analysis classified PHEVs into

two levels: (1) PHEV20 indicating a vehicle with an AER of 20 miles; and (2) PHEV50 indicating a vehicle with AER of 50 miles. For more discussion on the change in classifications see Section VI.C.3.a)(1)(e) Electrification Technologies, Plug-in Hybrids.

BorgWarner commented that "PHEVs and HEVs are complex systems and should be modeled in detail," and further provided, "[t]herefore, modeling should be inclusive of all approaches of PHEV and HEV and not be limited only to Atkinson Cycle engines."¹¹⁴⁹ In response, the agencies created additional powertrain options for PHEV technologies for the final rule analysis. The additional PHEV technologies included a plug-in HEV using a turbocharged engine. The additional PHEV paths used in the final rule analysis are described in Section VI.C.3.a)(1)(e) Electrification Technologies, Plug-in Hybrids.

d) Battery Electric Vehicles

Battery electric vehicles (BEVs) are vehicles with all-electric drive and with vehicle systems powered by energy-optimized batteries charged primarily from grid electricity. The effectiveness

¹¹⁴⁶ Meszler Engineering Services, Attachment 2, NPRM Docket No. NHTSA-2018-0067-11723 at 32.

¹¹⁴⁷ 49 U.S.C. 32901(b)(1).

¹¹⁴⁸ California Air Resources Board, Attachment 2, Docket No. NHTSA-2018-0067-11873, at 149. Specific comments related to costs are discussed in Section VI.C.3.e) Overview of Electrification Costs, below.

¹¹⁴⁹ BorgWarner, BorgWarner NPRM public comments 10-26-2018 Final, Docket No. NHTSA-2018-0067-11895, at 10.

of BEV powertrains is dependent on the efficiency of the components that transfer power from the battery to the driven wheels. These components include the battery, electric machine, power electronics, and mechanical gearing. For the analysis, electric machine efficiency was based on efficiency maps derived from actual electrified vehicles, and was scaled such that the peak efficiency value corresponded to the latest state-of-the-art technologies. The range of the battery electric vehicles depends on the vehicle's class and the battery pack size. For the NPRM analysis, manufacturers could apply BEV technology with an AER of 200 miles. As discussed previously, the final rule analysis added a BEV 300 to reflect vehicles in the

market for the MY 2017 analysis fleet. For further detailed discussion of how BEV sub-models are simulated in Autonomie see the FRM Argonne model documentation.¹¹⁵⁰

The resizing algorithm for BEVs is functionally the same as the PHEV algorithm; the difference is that BEVs do not use a combustion engine, and thus this component was not included in the BEV algorithm. To begin, initial estimates of motor and battery powers were calculated based on the criteria of acceleration performance, gradeability performance, and vehicle range. Then, the algorithm successively ran four simulation loops to fine tune the powertrain size to ensure that all performance and operational criteria were maintained. First, the BEV motor

and battery were sized to power the vehicle through the US06 cycle. Next, the battery capacity was adjusted to ensure the energy content is sufficient to complete a simulated UDDS+HWFET combined driving cycle, based on EPA adjustment factors to represent sticker values, and meet the vehicle range requirement. Finally, the electric motor and battery powers were sized accordingly to meet 0–60 and 50–80 mph acceleration targets. If either acceleration simulation loop resulted in a change to the electric motor size, the algorithm repeated all simulation loops. Once the acceleration targets were met without any resizing of the electric motors, the algorithm finished. Figure VI–35 below shows a simplified sizing algorithm for BEVs.

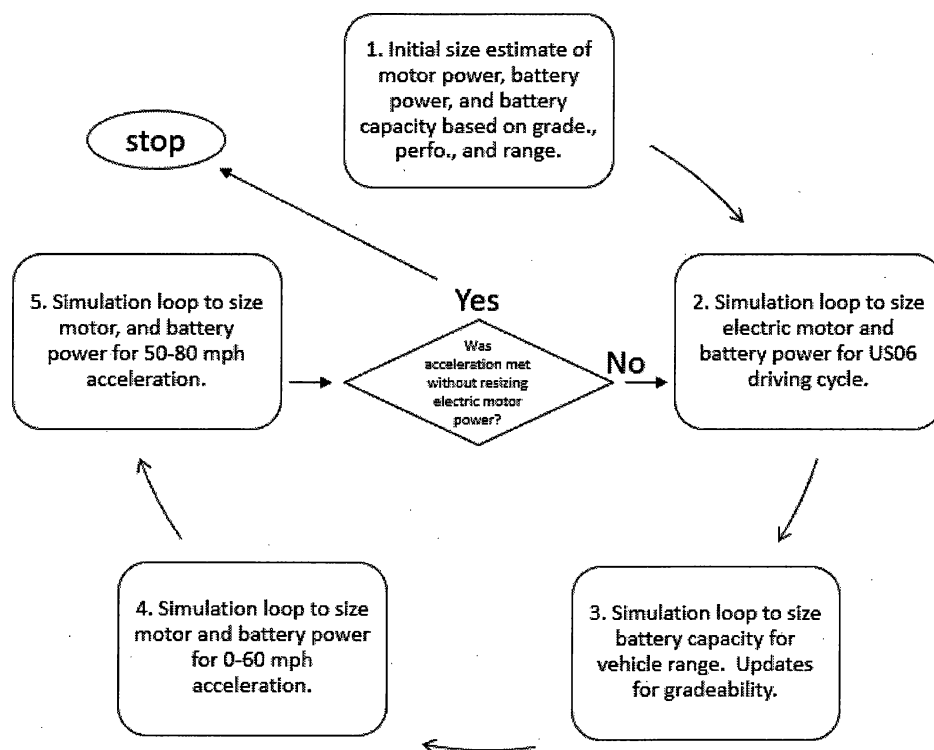

Figure VI-35 – Simplified BEV Sizing Algorithm in Autonomie

Meszler Engineering Services, commenting on behalf of NRDC, argued that the fuel economy for a vehicle adopting BEV technology was inappropriately dependent on the petroleum-based fuel economy of the transforming vehicle.¹¹⁵¹ Meszler reiterated that the fuel economy of the internal combustion engine that BEV

technology replaces does not have any impact on the efficiency of the resulting BEV, and the electric machine “should not care” whether it replaces a high or low efficiency engine, and should be modeled accordingly.

The agencies agree with Meszler that BEV effectiveness should be independent of the vehicle powertrain it will replace in production. This is, in

fact, how the vehicle model and simulation was performed in Autonomie. Autonomie models the capabilities of each unique full vehicle system independently, including BEVs. As BEV technology is adopted by vehicles, the CAFE model uses the Autonomie databases to determine the added incremental efficiency that will

¹¹⁵⁰ FRM ANL Model Documentation, at 4.6, 4.7, 4.13, 4.14, and 5.8.

¹¹⁵¹ Meszler Engineering Services, Attachment 2, NPRM Docket No. NHTSA–2018–0067–11723 at 33.

bring a specific vehicle up to the appropriate level. Since the CAFE model considers a variety of vehicle types with differing powertrain types, vehicle technology classes, performance criteria, and physical properties (curb weight, etc.), each with a different overall effectiveness, the observed efficiency increment needed to achieve BEV effectiveness will vary with each case. While these increments may differ, the final effectiveness of a BEV is independent of the powertrain it replaced. The effectiveness used in the CAFE model represents the difference between the performance of the full vehicle models—the full vehicle model representing the baseline vehicle and the full vehicle model representing the end-state with all additional fuel economy improving technology applied, as discussed in Section VI.B.3 Technology Effectiveness Values.

ICCT alleged that the agencies did not assess BEV efficiency improvements from road load reductions (*i.e.*, from mass reduction, tire rolling resistance, or aerodynamic improvements) to reduce the battery and power electronic component sizing costs.¹¹⁵² CARB similarly commented that battery packs were improperly sized, resulting in underestimation of electrified vehicle effectiveness. CARB stated that the NPRM constraints on battery sizing caused electrified vehicles to end up with oversized, less cost-effective battery packs. CARB further stated that battery designs are more scalable than engines and could thus be adjusted by manufacturers even at incremental technology steps.¹¹⁵³

For reference, battery resizing in the NPRM was constrained in the same manner as other powertrain components, such as the combustion engine. Resizing would typically be associated with a major vehicle or engine redesign, which in turn would justify the high costs of changing the powertrain. In the NPRM, the battery pack and other powertrain components were not resized for other improvements in incremental technologies such as AERO and ROLL. The agencies agree that battery packs, due to their modularity, should be capable of being resized at relatively lower cost and complexity, and thus should not be

subject to the same resizing restrictions applied to other powertrain components such as conventional combustion engines. In consideration of CARB and ICCT's comments on battery pack resizing, for the final rule, the agencies allowed SHEV, PHEV, and BEV battery packs to be resized at all incremental technology steps, including for road load reduction technology improvements (aerodynamics, rolling resistance reduction, and low levels of mass reduction). This avoided the additional cost and range associated with oversized battery packs on BEVs and other electrified vehicles.

CARB commented that the NPRM analysis oversized battery packs that targeted 200-mile label range, resulting in exaggerated battery pack costs. CARB also stated that some MY 2016–2018 BEVs exist that have a higher efficiency than simulated for BEV200s in Autonomie. They further argued that although these vehicles were assigned BEV200s, their actual range was greater than 200 miles.¹¹⁵⁴

We agree with CARB that the NPRM modeled and simulated battery packs were oversized and that the AERs for BEVs did not match the current and expected future vehicle AERs. In response to these comments, for the final rule analysis, the agencies removed certain constraints from the Autonomie battery sizing algorithm, allowing batteries to be sized as function of all road load reduction technologies. As discussed earlier, this additional battery sizing is feasible due to the modularity of battery pack construction. This update allowed the battery pack cost and mass to better reflect the actual required energy capacity and power, and improved the efficiency of modeled BEVs. The agencies also updated the modeling of electric machines used in BEVs to reflect improvements in efficiency. Furthermore, the agencies added the BEV300 (with an AER of 300 miles) to the final rule analysis, providing a better representation of production BEVs with more than 200 miles of range. For more discussion on BEV300 and electrification efficiency improvements, see Sections VI.C.3.a)(1) Electrification technologies and VI.C.3.d)(1) Electric Motors, Power Electronics and Accessory Load.

e) Fuel Cell Vehicles

The fuel-cell system in the analysis was modeled to represent hydrogen consumption as a function of the produced power, assuming normal-temperature operating conditions with a peak system efficiency of 60 percent, including the balance of plant.¹¹⁵⁵ The system's specific power is 650 W/kg. The hydrogen storage technology selected was a high-pressure tank with a specific weight of 0.04 kg H₂/kg, sized to provide a 320-mile range on the 2-cycle tests on the basis of adjusted energy values.

The sizing algorithm for FCVs was similar to PHEVs and BEVs, but adapted to size the specific components of a FCV powertrain: the electric motor, fuel-cell, hydrogen (H₂) fuel tank, and battery pack. The electric motor drives the wheels needed to propel the vehicle. During very low power operation, the battery pack alone powers the motor/wheels, depleting the battery charge. At moderate driving loads, the fuel-cell provides electrical power (generated by consuming stored H₂) to the motor and also to charge the battery. Under heavy loads, both the fuel cell and battery deliver electric power to the motor. To begin, initial estimates of motor, fuel cell, and battery powers are calculated based on criteria for acceleration performance, gradeability performance, and vehicle range. Then, the algorithm successively runs four simulation loops to finetune powertrain size, ensuring that all performance and operational criteria are maintained. First, the FCV motor and battery are sized to power the vehicle through the US06 cycle. Next, the on-board mass of H₂ fuel, as well as the fuel tank mass are adjusted to ensure the vehicle can complete a simulated 2-cycle test and meet the range requirement. Finally, the electric motor and fuel cell powers are sized accordingly to meet 0–60 and 50–80 mph acceleration targets. If either acceleration simulation loop results in a change to the electric motor size, the algorithm repeats all simulation loops. Once the acceleration targets can be met without any resizing of the electric motor, the algorithm completes. Figure VI–36 below shows a simplified sizing algorithm for FCVs.

¹¹⁵² International Council on Clean Transportation, Attachment 3, Docket No. NHTSA–2018–0067–11741, at I–82.

¹¹⁵³ California Air Resources Board, Attachment 2, Docket No. NHTSA–2018–0067–11873, at 145.

¹¹⁵⁵ Power needed for supporting components and auxiliary systems. The balance of plant in a fuel cell system is the auxiliary equipment required to

ensure the fuel cell operates as a reliable power source. This may include fuel reformers and pumps, for example.

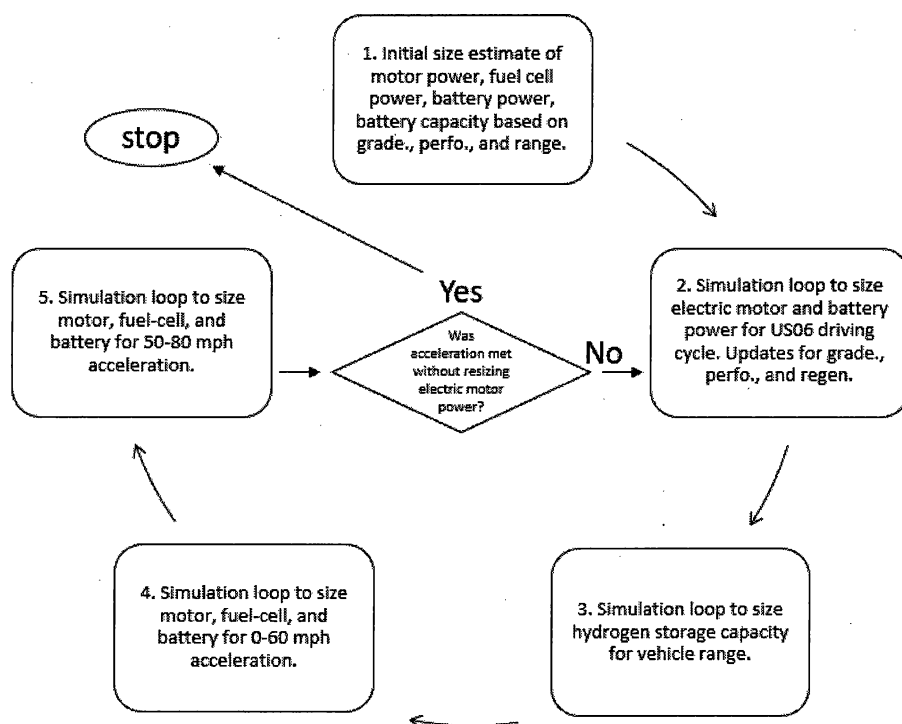

Figure VI-36 – Simplified Fuel Cell Vehicle Sizing Algorithm

The agencies did not receive comments on FCV modeling in *Autonomie*. For the final rule analysis, the agencies used the same FCV model and simulations to estimated effectiveness values.

e) Electrification Costs

The primary factors that influence the cost and effectiveness of hybrid or battery electric vehicles are the cost and efficiency of the energy storage components and electric machines. Energy storage components include battery cells, battery management systems, and thermal management systems. The electric machine components include electric motors, power electronics, controllers, and other devices that support thermal management.

Charging infrastructure is an essential component for PHEVs and BEVs, and may add to the total cost of ownership of the vehicle. However, most households are equipped with a 110-volt outlet for level 1 charging, for which no additional cost is incurred. Installing a level 2 charging outlet (220-volt) will add cost to the total ownership of the vehicle but decreases charging time. The price of level 2 residential charging equipment varies, but typically ranges from \$500 to \$2,000

before installation and state or utility incentives.¹¹⁵⁶

For this final rule analysis, the agencies used Argonne's BatPaC modeling tool to develop battery pack manufacturing costs as well as weight.¹¹⁵⁷ Battery packs were sized in terms of the vehicle's energy and power requirement and costs were estimate for each of the simulated technology combinations. The Argonne team used BatPaC to create a "lookup table" with battery pack size (energy and power) and cost as well as weight data for the full vehicle simulations to "reference," to avoid the need for conducting a full BatPaC simulation for each unique vehicle modeled in the analysis. The table included cost data for each technology key and vehicle technology classes. As discussed below, *Autonomie* runs linearly interpolate between points in the lookup tables when deriving final values from BatPaC, the differences between using BatPaC for each configuration and the interpolation using the lookup table was insignificant.

¹¹⁵⁶ U.S. Department of Energy Office of Energy Efficiency and Renewable Energy, Charging at Home, <https://www.energy.gov/eere/electricvehicles/charging-home> (last visited March 20, 2020).

¹¹⁵⁷ The agencies used BatPaC version 3.0 (released in 2015) for the NPRM and BatPaC version 3.1 (June 2018) for the final rule.

The agencies used the cost of electric machines from U.S. DRIVE's October 2017 report, "Electrical and Electronics Technical Team Roadmap." In industry, manufacturers use different types of electric machines resulting in a range of actual costs for the systems. To capture this range, the agencies considered a single type of high efficiency electric machine, representative of the range of technology available in the rulemaking timeframe, uniquely sized for each of the simulated combinations. For the final rule analysis, the cost of the electric machine was determined using a dollar-per-kilowatt metric. The agencies sized the electric machines using the method discussed in Section VI.C.3.d) Electric Effectiveness Modeling and Resulting Effectiveness Values.

The following sections discuss the method used for modeling battery and non-battery component costs, the learning curves applied to those costs, and the total costs for each type of electrification technology considered in this final rule analysis.

(l) Battery Pack Modeling

BatPaC is a software designed for policymakers and researchers interested in estimating the manufacturing cost of lithium-ion batteries for electric drive

vehicles.¹¹⁵⁸ BatPaC is used to estimate the cost of manufacturing lithium-ion batteries and examine trade-offs that result from different battery performance specifications such as power and energy capacity. BatPaC includes a library of lithium ion electrode combinations and inputs for all the parameters associated with materials and manufacturing operations in a factory.

Specifically, BatPaC models stiff-pouch, laminated prismatic format cells, placed in double-seamed, rigid modules. The model supports liquid- and air-cooling, accounting for the resultant structure, volume, cost, and heat rejection capacity. The model considers cost of capital equipment, plant area and labor for each step in the manufacturing process. The model places relevant limits on electrode coating thickness, and considers limits applicable to current and near-term manufacturing processes. The model also considers annual pack production volumes and economies of scale for high-volume production.

BatPaC calculations are based on a generic pack designs that reasonably represents the weight and manufacturing cost of batteries deployed commercially. The advantage of using this approach is the ability to model wide range of commercial design specifications for the various classes of

vehicles. This modeling approach is particularly advantageous because the data from commercially available battery packs is limited and varies widely with respect to the underlying specifications (power and energy) and constraints (mass, volume, dimensions, durability) set by the manufacturer.

BatPaC is a Microsoft Office Excel spreadsheets-based model. The data needed to design and build a battery pack, such as dimensions of the cell, estimate of materials, and manufacturing cost, are provided in the model, with the manufacturing costs for the designed battery based on a “baseline plant” designed for a battery of intermediate size and production scale so as to establish a center-point for other designs. BatPaC can be configured with alternative chemistries, charging constraints, battery configurations, production volumes, and cost factors for other battery designs by customizing these parameters in the modeling tool.

For this analysis, running individual BatPaC simulations for each full vehicle simulation requiring an electrified powertrain would have been computationally intensive and impractical, given that approximately 750,000 simulated vehicles out of the 1.2 million total simulated vehicles had an electrified powertrain. Accordingly, staff at Argonne built “lookup tables” with BatPaC to provide battery pack

manufacturing costs, battery pack weights, and battery pack cell capacities for vehicles modeled in the large-scale simulation runs.

To build the lookup tables, Argonne staff selected a range of minimum and maximum values for battery pack power (kW) and battery pack energy (kWh) for each vehicle powertrain based on a combination of market analysis and analysis of the Autonomie simulations that were run for the NPRM and final rule. The performance requirements (vehicle acceleration times, EV range, etc.) were defined from set assumptions and validated from existing vehicles.¹¹⁵⁹ The range, as well as the number of power and energy points considered to generate each lookup table, varies across powertrains. The minimum and maximum power and energy values have been selected to encompass current designs. For example, one end of the spectrum is representative of the MY 2016–2017 Tesla Model S 100D (100 kWh total battery energy, 335-mile range), while the other end of the spectrum is representative of the 2017 Mitsubishi iMiEV (16 kWh total battery energy, 62-mile range). The components were then sized in Autonomie across all vehicle classes to define the minimum and maximum values to be considered, as shown in Table VI–90.

BILLING CODE 4910–59–P

Table VI-90 - Power and Energy Ranges for the Vehicle Classes Defined with Autonomie

| Vehicle Powertrain | Battery Pack Power (kW) | | Battery Pack Energy (kWh) | |
|--------------------|-------------------------|-----------|---------------------------|-----------|
| | Min Value | Max Value | Min Value | Max Value |
| Split HEV | 23.5 | 67.1 | 1.0 | 2.8 |
| Split PHEV20 | 37.9 | 73.2 | 7.1 | 14.4 |
| EREV PHEV50 | 86.8 | 148.4 | 16.5 | 32.5 |
| BEV200 | 103.1 | 295.4 | 45.2 | 104.7 |
| BEV300 | 138.9 | 323.6 | 70.9 | 162.4 |

Figure VI–37 illustrates the inputs generated in Autonomie to create the BatPaC-based lookup tables, and the outputs characterized in the BatPaC-

based lookup tables that are used to provide estimates referenced in the agencies’ analysis. A linear interpolation was then performed in

MATLAB to determine the associated values for battery pack manufacturing cost, weight, and cell capacity.

¹¹⁵⁸ BatPaC: Battery Manufacturing Cost Estimation, Argonne National Laboratory, <https://www.anl.gov/tcp/batpac-battery-manufacturing-cost-estimation>.

¹¹⁵⁹ See Final Rule Argonne Model Documentation Section 5.9, Battery Performance and Cost Model (BatPaC).

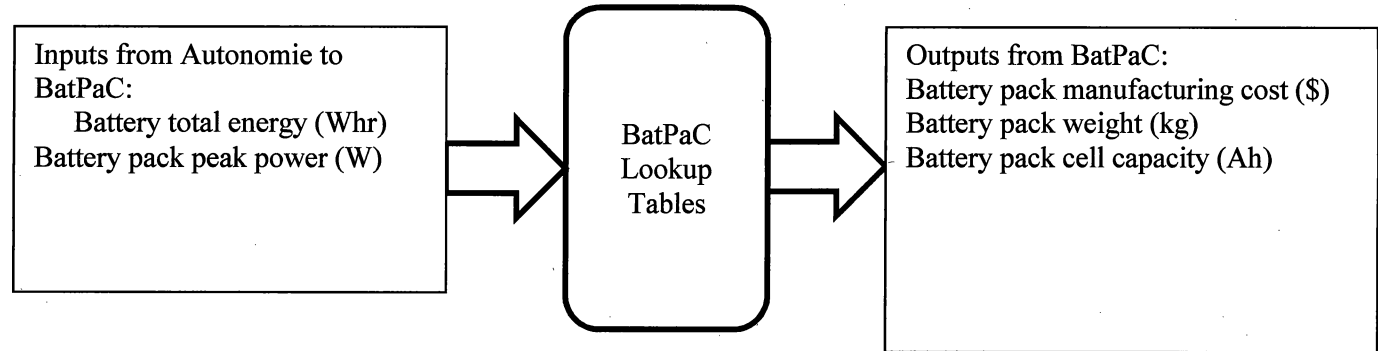

Figure VI-37 – Flowchart Showing How Autonomie Calls BatPaC Look-up Tables

Figure VI-38 shows the linear relationship between cost, power, and weight used to generate the compact passenger car BEV200 technology class lookup table presented in Figure VI-39. As seen from the figures below, the

energy values produced by BatPaC consist of a fairly linear relationship with respect to power and energy for a vehicle class. Since Autonomie runs would linearly interpolate between the points in the lookup tables when

deriving the final values from BatPaC, the differences between using BatPaC for each configuration and the interpolation using the lookup table were insignificant.

Figure VI-38 – Table Used to Generate Look-Up Table for BEV200 Compact Car Class

BILLING CODE 4910-59-C

Figure VI-39 details the estimates of \$ per kWh at the pack level generated from the lookup table for BEV200

compact cars used in the final rule analysis. As discussed further below, the specific battery costs for each simulated vehicle were presented for

the NPRM (and now for the final rule) in the docketed Argonne assumptions files and in the vehicle simulation database included in the CAFE model.

| | BEV200 | | Energy, kWh | | | |

| | | 280.0 | \$ 264 | \$ 197 | \$ 167 | \$ 149 |
| | | 320.0 | \$ 265 | \$ 198 | \$ 167 | \$ 149 |
| | | 400.0 | \$ 268 | \$ 199 | \$ 168 | \$ 150 |

Figure VI-39 - BEV200 (Compact) \$ per kWh Look-up Table for the Final Rule Analysis

During the Autonomie large-scale simulation runs, calling the BatPaC model for each individual simulation would have been computationally intensive. Using the MATLAB lookup tables reduced the time to run the approximately 750,000 simulations significantly, which in turn reduced the total simulation run time for all of the technology combinations by several days with insignificant impact on the analytical results.

(a) BatPaC Inputs and Assumptions

The Argonne documentation describing the analysis performed for the NPRM, "A Detailed Vehicle Simulation Process To Support CAFE Standards," detailed the specific assumptions that Argonne's experts used to simulate batteries and their associated costs for the full vehicle simulation modeling.¹¹⁶⁰ In addition, detail on the NPRM electrification analysis was presented in the PRIA.¹¹⁶¹ While the Argonne Summary of Main Component Assumptions Excel file correctly identified the chemistry used in the NPRM analysis as NMC333,¹¹⁶² the PRIA inadvertently described that NMC441 was used. The agencies presented selected lookup table battery cost values in the Argonne Summary of Main Component Assumptions Excel file,¹¹⁶³ as shown above, and the specific battery costs for each simulated vehicle were presented for the NPRM

and final rule in the vehicle simulation database included in the CAFE model.

Several commenters claimed that costs for electrification technologies were too high, especially regarding battery costs (note that comments on non-battery component costs are addressed separately in Section VI.C.3.e)(2) Non-battery Electrification Component Costs, below).¹¹⁶⁴ Several commenters pointed to text in interagency review documents that stated the NPRM battery modeling costs were higher than what EPA recommended,¹¹⁶⁵ and higher than what EPA had obtained from the most recent version of the BatPaC model.¹¹⁶⁶

CARB commented that the agencies incorrectly identified and assessed existing technologies, improperly oversized components and batteries for the modeled vehicle classes, and underestimated technology efficiency through improper modeling.¹¹⁶⁷ CARB also submitted supplemental comments (discussed further, below) stating that the PRIA and the underlying modeling were inconsistent regarding which exact battery chemistries were modeled for every electrified model in the fleet,

which CARB argued was crucial for understanding the battery compositions and thus their production costs.¹¹⁶⁸

ICCT stated that the agencies misrepresented the leading research on both battery and electric vehicle costs, with the result being that electric vehicles were so costly that they were modeled to remain at approximately the same penetration in 2025 with the Augural 2025 fuel economy and adopted 2025 CO₂ standards, as they were in mid-2018 (*i.e.*, between 1.5 percent and 2 percent of new vehicle sales).¹¹⁶⁹ ICCT stated that the agencies' inputs failed to reflect the latest industry data on future potential electric vehicle cost parity with combustion vehicles. ICCT commented that through a combination of incorrectly high electric vehicle prices (which, they argue, do not reflect Argonne or other leading battery research groups' work), and modeling restrictions on electric vehicles, the agencies unduly inflated technology costs of electric vehicles to comply with the standards. ICCT argued that although the agencies purported to use state-of-the-art tools like the BatPaC model for battery costs, the cost calculations erroneously pushed up electric vehicles' incremental costs above \$10,000 per vehicle. ICCT claimed that the agencies introduced errors that artificially pushed up the battery costs higher than indicated by BatPaC and other experts in the field.

NCAT noted that the PRIA described some ways in which the modeling increased battery costs, namely, that the battery pack costs were adjusted

upwards, the cost of the battery management system increased, and a cost for a battery automatic and manual disconnect unit was added.¹¹⁷⁰ Regardless, NCAT stated that the agencies analysis was not sufficiently transparent, and argued that the battery costs were significantly overestimated in the modeling supporting the NPRM. Boulder County Public Health and other Colorado municipal organizations claimed that overstated battery costs had the effect of mischaracterizing and downplaying the benefits of increased numbers of electric vehicles as part of the vehicle fleet.¹¹⁷¹ Commenters also argued that discrepancies existed between battery costs used in the rulemaking documents and battery costs found in the Argonne database, referring specifically to BISG and CISG costs (discussed further below).¹¹⁷²

In addition to comments claiming that the agencies' battery cost projections were incorrect or difficult to interpret, many commenters submitted general information about the state of battery technology and cost advances now and as projected into the future. For example, NCAT stated that battery technology has improved and battery costs have fallen dramatically, due in part to reduced material costs, manufacturing improvements, and higher manufacturing volumes.¹¹⁷³ In compliment, NCAT asserted that the demand for EVs is growing "dramatically."

ICCT stated that the agencies' analysis of electric vehicle costs and the resulting extremely low penetration levels was not in line with automakers' announcements, which included statements that they would produce far greater numbers of electric vehicles to comply with standards around the world.

ICCT summarized projections of electric vehicle battery costs for 2020–2030, and stated that the agencies did not analyze the studies and automaker announcements they cited to understand the potential for cost-effective electric drive technology.¹¹⁷⁴ ICCT stated the data they reviewed

included a variety of different technologies, production volumes, and cost elements, and although there were differences in methods for each, "they generally include in some variation of material, process, overhead, depreciation, warranty, and profit costs." ICCT summarized the results of their review, projecting that battery pack costs will decline to \$150/kWh by 2020–2023 and then to about \$120–\$135/kWh by 2025, with the exception of Tesla, which reports costs of \$150/kWh in 2018 and projected costs of \$100/kWh by 2022. ICCT stated that the results of this review were corroborated in the aforementioned EPA interagency comments on battery costs used in the proposal.

NCAT stated that the average price of a battery pack dropped from \$1,000/kWh in 2010 to \$209/kWh in 2017, demonstrating a decrease of 79 percent in seven years.¹¹⁷⁵ NCAT stated Tesla is on track to achieve \$100/kWh by the end of 2018, and Audi has been buying batteries at \$114/kWh, according to trade press reports.¹¹⁷⁶ NCAT also cited BNEF analyses showing that battery costs are projected to continue to decline substantially,¹¹⁷⁷ specifically projecting a decrease in battery cost of 77 percent between 2016 and 2030. Accordingly, NCAT stated that EVs will be less expensive to buy than conventional gasoline vehicles by 2025 in the United States.¹¹⁷⁸ Workhorse similarly echoed the assertion that EV costs will reach parity with conventional vehicle costs before 2025.¹¹⁷⁹

¹¹⁷⁵ National Coalition for Advanced Transportation, NHTSA–2018–0067–11969, citing Bloomberg New Energy Finance, "Electric Vehicle Outlook: 2018," <https://bnef.turtl.co/story/evo2018?teaser=true>.

¹¹⁷⁶ National Coalition for Advanced Transportation, NHTSA–2018–0067–11969, citing Fred Lambert, "Tesla to achieve leading \$100/kWh battery cell cost this year, says investor after Gigafactory 1 tour" (Sept. 11, 2018), <https://electrek.co/2018/09/11/tesla-100-kwh-battery-cost-investor-gigafactory-1-tour/>.

¹¹⁷⁷ National Coalition for Advanced Transportation, NHTSA–2018–0067–11969, citing Bloomberg New Energy Finance, "Electric Vehicle Outlook: 2018," <https://bnef.turtl.co/story/evo2018?teaser=true>.

¹¹⁷⁸ National Coalition for Advanced Transportation, NHTSA–2018–0067–11969, citing Jess Shankleman, "Pretty Soon Electric Cars Will Cost Less Than Gasoline" (May 26, 2017), <https://www.bloomberg.com/news/articles/2017-05-26/electric-cars-seen-cheaper-than-gasoline-models-within-a-decade>; Jess Shankleman, "The Electric Car Revolution Is Accelerating" (July 6, 2017), <https://www.bloomberg.com/news/articles/2017-07-06/the-electric-car-revolution-is-accelerating>. NCAT also noted that the up-front cost parity does not take into consideration the fuel savings and maintenance savings over the lifetime of EV use as compared to gasoline vehicle use.

¹¹⁷⁹ Workhorse Group Inc., NHTSA–2018–0067–12215.

NCAT also cited the ICCT Efficiency Technology and Cost Assessment, which concluded that, primarily because of rapid developments in battery pack technologies, EV costs will be reduced by \$4,300–\$5,300 per vehicle by 2025 compared to EPA's prior estimates in support of the MY 2017–2025 standards.¹¹⁸⁰ In that report, ICCT concluded that battery costs of \$140/kWh is a realistic estimated value by 2025, as compared with EPA estimates in the 2016 Mid-Term Evaluation (MTE) analysis of \$180–200/kWh.¹¹⁸¹

NCAT also cited improvements in manufacturing techniques, specifically by Tesla, as an example of how batteries are being manufactured in large volumes with high quality at low cost.¹¹⁸² NCAT stated that in mid-2018, Tesla was producing batteries at its Gigafactory 1 facility at an annualized rate of roughly 20 GWh, making it the highest-volume battery plant in the world.¹¹⁸³ NCAT and other commenters also cited Bloomberg's New Energy Finance research stating that the average energy density of EV batteries is improving at around 5–7 percent per year.

Finally, Workhorse commented that they have more than ten years of experience in the field of designing and assembling battery packs, and their business plans are predicated on battery costs much lower than assumed by the agencies.¹¹⁸⁴

As explained above, the agencies consulted with and relied on Argonne battery experts to develop inputs to the BatPaC model and generate the battery cost lookup tables used as references for the Autonomie full-vehicle simulations, as detailed in Argonne's documentation supporting the NPRM analysis.¹¹⁸⁵ As explained further below, the agencies also directed CARB to information about the NPRM battery cost analysis available

in the public docket in response to their FOIA request.

Commenters are correct that the EPA Draft TAR and Proposed Determination estimates for battery sizing and cost were different than the NPRM analysis. For the Draft TAR and in the Proposed Determination, a separate battery and motor sizing spreadsheet was built to determine the energy and power requirements for PHEVs and BEVs at different curb weights, and then BatPaC was used to determine specific energy (kWh/kg) and the battery pack cost estimate.¹¹⁸⁶ For this NPRM and final rule, the energy requirements for PHEVs and BEVs were determined using Autonomie simulations with the integrated BatPaC lookup table to select the appropriate battery pack size, cost, and weight. As discussed in Sections VI.B.3.a)(4) How Autonomie Sizes Powertrains for Full Vehicle Simulation and VI.B.3.a)(6) Performance Neutrality, the Autonomie full-vehicle simulation modeling assessed metrics to ensure performance requirements were met for every modeled vehicle. Appropriately accounting for vehicle metrics and individual vehicle power and weight requirements resulted in some of the differences observed between the Draft TAR and Proposed Determination estimates and the estimates presented in the NPRM and this final rule.

For the final rule, the agencies considered these public comments, market observations, literature, industry reports, and additional research. In addition, as described further below and in the Argonne documentation accompanying this final rule, Argonne consulted the A2Mac1 database for additional data points on batteries that were used to inform the final rule battery cost modeling.

As discussed above, BatPaC version 3.0 was used for the NPRM analysis because that was the most up-to-date version of BatPaC available at the time the NPRM analysis was being conducted. BatPaC version 3.1, released after the NPRM analysis was completed, was used for this final rule because that was the most up-to-date version of BatPaC available at the time the final rule analysis was being conducted.

The agencies note that BatPaC version 4.0 has been released since the analysis was completed for this final rule. Specifically, that version was released on January 14, 2020, after the rule had been submitted for interagency review. The default battery chemistry in BatPaC version 4.0 continues to be NMC622, which as discussed further in Section (i) below, reflects the reasonable

assumption this chemistry will likely continue to be used in the rulemaking timeframe based on its commercial application and market trends towards higher-nickel, lower-cobalt content chemistries.¹¹⁸⁷ As explained in this section, and further in Section (c) below, the agencies' modeled costs for battery packs aligns with current industry estimates and closely tracks future projections of battery pack costs from the Department of Energy's Vehicle Technology Office (DOE VTO) lab targets.^{1188 1189}

In addition to using BatPaC version 3.1 for this final rule, BatPaC assumptions were updated to reflect what the Argonne battery experts and the agencies believed would be representative and attainable of battery manufacturing trends in the rulemaking timeframe. Section (ii) provides additional information on BatPaC inputs and assumptions that were updated for the final rule based on public comments and the agencies own market observations and additional research. In addition, as discussed further below, for the final rule, the calculated battery pack weight and manufacturing cost was compared with the battery pack cost and weight data obtained through various benchmarking studies. The agencies believe that the Argonne methodology for producing the hundreds of thousands of battery pack cost estimates required for the full-vehicle modeling and simulation resulted in reasonable estimates of battery pack costs. The following sections provide additional context and response to comments on specific BatPaC inputs and assumptions used in the NPRM and final rule.

(i) Chemistry

The choice of chemistry for battery cells depends on the application and consideration of cost, energy density, and safety, among other factors. The PRIA described the battery pack cell chemistry used for different powertrain types modeled in the NPRM analysis.¹¹⁹⁰ For Micro HEVs, BISG HEVs, CISG HEVs, and Full HEVs, the agencies used LFP-G, rather than LMO-G, because the latter has a limited lifespan which is expected to degrade

functionality over a vehicle's lifetime, and has greater limitations on available ranges of battery charge and discharge rates. As described above, for PHEVs and BEVs, the Argonne "Summary of Main Component Performance Assumptions" file correctly stated that NMC333 was used, however the PRIA misstated that NMC441 was used.

Both UCS and CARB commented on the agencies' choice of battery chemistry, with UCS noting that this choice can have a large impact on performance and materials costs, and therefore on the modeled cost of drivetrain electrification.

First, both commenters stated that the NPRM documentation was inconsistent and unclear. UCS noted the discrepancy between the PRIA and Argonne model documentation, and also that the rulemaking documents stated the most recent version of Argonne's BatPaC model was used to estimate battery costs, but the default lithium ion chemistry in the current BatPaC model is NMC622. UCS stated the choice of NMC variant effects battery costs, as NMC622 replaces more expensive cobalt with nickel. UCS further stated it was not possible to determine the magnitude of the cost error in the PHEV and BEV battery pack costs, only that the costs were likely higher than current battery cost data supported.

CARB stated that the agencies' selected battery chemistries represented a step backward from previous analysis done for the Draft TAR. CARB claimed that the biggest lithium-ion production companies have indicated that they will use NMC811 for BEVs, and therefore NMC441 or NMC333 would not represent current technology going into BEVs or near-future BEV battery technology. CARB stated that NMC811 technology was expected to come to market in 2019, which is far sooner than anticipated, even in the agencies' prior analyses.

Commenters also noted that the chemistry chosen for mild and strong hybrids differed from what is used in current and announced HEVs. UCS stated that all non-plug-in hybrids in the proposed rule analysis used lithium iron phosphate (LFP) chemistry, but in practice, most hybrids on the road did not use this chemistry. UCS referenced the Toyota Prius and the new RAM 1500 pickup as examples of vehicles that do not use LFP chemistry. CARB similarly stated that the NPRM battery chemistry selection for PHEV and strong hybrid batteries does not represent many of the batteries that are being deployed in the market, nor have been, for several years now, but did not provide an alternative chemistry they believed to be better

¹¹⁸⁷ The agencies note that BatPaC version 4.0 provides a new option to build battery packs with NMC811.

¹¹⁹⁰ PRIA at 373.

¹¹⁸⁶ Draft TAR at 5–315.

represented in the market. CARB stated that this resulted in a “misappropriation of higher costs for electrification technologies in the Agencies’ analysis, and further highlights the Agencies’ sudden lack of knowledge about electrification, despite the far more directionally correct projections in previous analysis for the 2016 Draft TAR and EPA’s Proposed Determination.”

Similarly, UCS pointed to a discrepancy in strong hybrid battery costs between the proposed rule estimates (greater than \$1,200, even for the small car classes) and an estimate from Argonne in 2017 (\$614), to argue that the lack of detailed information made it impossible to determine if the choice of battery chemistry was responsible for the discrepancy.

The agencies carefully considered these comments. As stated above, the agencies disagree that the discrepancy in the Argonne Summary of Main Component Performance Assumptions file and the PRIA over the use of NMC333 for the NPRM analysis limited commenters’ ability to comment on battery chemistry, as both UCS and CARB communicated a belief that the agencies’ choice of battery chemistry contributed to the overstated battery costs in the NPRM. The agencies understand how the choice of chemistry impacts battery costs, and many of the commenters’ concerns intertwined the NPRM choice of battery chemistry with the NPRM battery costs. Here, the agencies respond to comments on the choice of chemistries. The agencies will also discuss costs below.

As stated earlier, although manufacturers use different battery chemistries in various HEV, PHEV, and BEV applications, the choice of chemistry for a given application depends on several factors including safety, stability, and functional requirements (high power or high energy requirements for performance) of the battery pack. In determining whether to select one battery chemistry over another, the agencies concluded that using commercially proven technologies that represented the current cost of production was more reasonable than assuming additional technologies would come to fruition during the rulemaking timeframe, and attempting to project the cost and effectiveness of such technologies. While there is ongoing research and development in battery chemistry and in other battery related technologies that have the potential to reduce costs and increase battery capacity, these

technologies have yet to be proven viable for commercial use.¹¹⁹¹

In addition, as discussed throughout this document, the agencies considered technologies that manufacturers could use to comply with standards in the rulemaking timeframe that reasonably represented the state of technology across the industry. While the battery chemistries used in commercial vehicles are largely confidential business information, proprietary teardown reports are one source of information used to learn more about the chemistries actually employed in the market. For both the NPRM and final rule, the agencies consulted Argonne’s battery experts to determine the chemistries that should be modeled in the BatPaC analysis. Argonne consulted A2Mac1 battery pack teardown reports, which confirmed that indeed, manufacturers use a range of chemistries across the electrified vehicle types. Selecting battery chemistries that can reasonably represent the range employed in the market ensured that the analysis better captured the average of costs across the industry.

For example, in addition to the reasons listed in the NPRM, LFP has been proven in commercial use, as identified in literature and battery teardown reports.¹¹⁹² This presented a basis for using LFP, as the chemistry was reasonably representative of chemistries used in mild and strong hybrids at the time of the analysis. The agencies also considered that LFP’s lower cost compared to other potential HEV battery chemistries (contrary to commenters’ statements) made it more attractive for vehicles with tight cost constraints, even with the associated lower energy density.

Similarly, although EPA selected NMC622 as the modeled battery chemistry for the Draft TAR, manufacturers were also using other NMC chemistries in hybrid and BEV applications in that timeframe depending on the required application. The chemistry selected for the NPRM, NMC333, was selected based on proprietary teardown reports that demonstrated the chemistry’s

commercial use: a survey of twelve MY 2013 to MY 2018 HEVs, PHEV, and BEVs showed that NMC333 was used in eleven of those vehicles, and NMC622 was only used in one.¹¹⁹³

Accordingly, the agencies believe that assuming LFP–G as the modeled cell chemistry for HEVs and NMC333 as the modeled PHEV and BEV chemistry for the NPRM analysis of battery costs was not unreasonable, based on their demonstrated commercial use in a range of electric vehicle applications. However, employing BatPaC version 3.1 for the final rule analysis also presented the opportunity to update the modeled battery chemistry used to assess battery costs.

The agencies similarly consulted Argonne battery experts on battery chemistry and trends to inform the final rule analysis. Argonne staff used the A2Mac1 database to determine real-world battery chemistry and configurations in different electric vehicle applications. As shown in the Argonne Full Vehicle Modeling documentation for the final rule, the A2Mac1 battery pack teardown analysis provided an array of data points on battery chemistries for different electric vehicle applications, among other relevant battery pack data, that informed the final rule battery analysis.¹¹⁹⁴

In determining which of these chemistries would best represent the range of chemistries demonstrated in the market, the agencies considered several issues. Due to the increasing manufacturing volume of battery packs with NMC, it is expected that NMC battery cells will continue to be used in battery packs across different electric vehicle applications in the future. The agencies considered concerns about NMC formulations with varying cobalt content, and issues including the current and future cost of cobalt.¹¹⁹⁵

¹¹⁹³ A Detailed Vehicle Simulation Process To Support CAFE and CO₂ Standards for the MY 2021–2025 Final Rule Analysis, Section 5.9 Battery Performance and Cost Model (BatPaC), referencing A2Mac1 Automotive Benchmarking, <https://a2mac1.com>.

¹¹⁹⁵ See, e.g., MIT Energy Initiative. 2019. Insights into Future Mobility, at 78. Cambridge, MA: MIT Energy Initiative (“... significant uncertainty remains about the steady-state price of cobalt in the future as demand and supply continues to increase [internal citation omitted]. Under our base case scenario, global demand for cobalt in 2030 from new EV sales (even if all EVs use batteries with the high nickel content of NMC811) would reach approximately 80% of the world’s total cobalt output in 2016. Considering that only 15% of the worldwide demand for cobalt in 2017 was used in EV batteries (Jackson 2019), an increase in demand of this magnitude might result in higher prices for cobalt. Thus, automakers may need to move to different battery chemistries that are less reliant on cobalt to avoid raw materials shortages and price volatility.”).

Available at <https://www.science-direct.com/science/article/pii/S2095809918312177>. Some examples include lithium-sulfur battery cell chemistry and solid-state electrolyte battery cells.

¹¹⁹² Details of cell chemistry and battery cooling system are described in Nelson, Paul A., Gallagher, Kevin G., Bloom, Ira D., and Dees, Dennis W. *Modeling the Performance and Cost of Lithium-Ion Batteries for Electric-Drive Vehicles—SECOND EDITION* (2012), available at <https://publications.anl.gov/anlpubs/2015/05/75574.pdf>.

and the cobalt supply chain.¹¹⁹⁶ These concerns, among others, have led to the market shift towards cathode active materials with a higher fraction of nickel and less cobalt.¹¹⁹⁷ Manufacturers have demonstrated the use of NMC622, which contains more nickel and less cobalt than NMC333, in different electric vehicle applications. In

addition, as CARB noted and has been reported in the news for some time, the expected next step in battery chemistries using even less cobalt is NMC811. However, the shift to higher-nickel-content chemistries is not without challenges; increasing nickel content results in lower thermal stability, leading to safety concerns.¹¹⁹⁸

For the final rule analysis, based on these considerations, the agencies in consult with Argonne determined that it was reasonable to model HEV, PHEV, and BEV batteries using NMC622 as the cathode active material, as shown in Table VI-91 below.

Table VI-91 – Battery Chemistry Applications in the NPRM and Final Rule

| Battery Chemistry Application | | |
|-------------------------------|--------------------|--------------------|
| | BatPaC version 3.0 | BatPaC version 3.1 |
| | NPRM | Final Rule |
| Micro HEV | LFP | LFP |
| Mild HEV | LFP | LFP |
| HEV | LFP | NMC622 |
| PHEV | NMC333 | NMC622 |
| BEV | NMC333 | NMC622 |

The agencies recognize that there will be advancements in battery chemistries during the rulemaking timeframe. As discussed further in Section (3), below, the analysis accounts for the potential that battery costs will decrease, but in a technology-agnostic manner. The agencies used BatPaC to model battery costs for the analysis by modeling battery prices in a specific year—in this case, MY 2020—and then used learning curves to reduce the cost of batteries over time. The learning curves act as a proxy for potential future improvements in battery chemistry and other battery-related advancements that would reduce costs. Using the learning curves in this way makes it unnecessary to make inherently uncertain projections of potential future improvements in battery chemistry over time.

BatPaC version 4.0, which contains NMC811 as a chemistry option, was released after the analysis for this rule was completed. However, the cost estimates generated in BatPaC version 3.1 using NMC622, with discussed learning curves applied resulted in

estimated \$/kWh battery pack costs, during the rule making time frame within a reasonable range of other estimated projections that considered NMC811 as the predominant battery chemistry. As discussed further in Section (3), a significant shift in battery chemistry alone is only one factor required to significantly lower battery costs; other developments like increases in battery pack production quantities and cell yield (plant efficiencies) would be required to reach the commonly-cited \$100/kWh target.

The agencies recognize that the specific chemistries manufacturers may choose for future model years may or may not be the same as the chemistries selected by the agencies for the analysis. However, this approach mirrors the approach taken to modeling technology effectiveness and cost used across the analysis; the modeled technology effectiveness and cost represents a level of performance representative of the typical range of performance across industry. If the agencies modeled pre-production battery chemistries unlikely

to be widely adopted by the industry for several years, the analysis would likely under-predict the actual cost and effectiveness of electrification technology application. Accordingly, the agencies determined that using LFP-G as the modeled chemistry of choice for mild hybrids and NMC622 as the modeled chemistry of choice for strong HEVs, PHEVs, and BEVs was reasonable.

The agencies also refined other inputs and assumptions used for modeling battery costs in BatPaC, based on a review of public comments and subsequent review of market research, technical publications, and other information.

Argonne continuously studies the battery pack designs of existing electrified vehicles in the market, using, among other information, detailed battery pack teardown analysis reports spanning a range of electrified vehicle types and vehicle classes produced over a range of MYs. For the final rule, Argonne utilized detailed battery pack teardown analysis reports for 10 MY

The teardown analysis reports were used to evaluate different battery pack design criteria, including battery pack power, battery pack energy, battery pack configuration, total number of cells per module, number of modules per pack, battery pack mass, energy density (cell/pack), cell voltage, battery pack voltage, cathode chemistry, cell capacity, and pack capacity. The metrics data collected from teardown analysis were used to estimate the battery pack manufacturing cost and mass (energy density – Wh/kg) in BatPaC for these exemplar vehicles from the A2Mac1 database. The data collected was also used to validate the battery pack design assumptions in BatPaC for the final rule. The four metrics that BatPaC provides are: Battery pack manufacturing cost, battery pack weight (energy density – Wh/kg), battery pack capacity (Ah) and nominal battery pack voltage. Since the A2mac1 teardown reports do not avail the manufacturing costs of these battery packs, the analyses and comparisons were limited to the scope of the other three criteria.

For the NPRM, Argonne used the U.S. Department of Energy VTO targets for battery energy density (Wh/kg) for high energy and power density – (W/kg) for high powered batteries.¹²⁰⁰ As a result of the analysis discussed above Argonne updated the method of estimating battery pack weight for each battery pack design in the final rule analysis.

The analysis revealed greater influences on battery pack design by usable energy density characteristics then was initially assumed for the NPRM. For the final rule analysis BatPaC was used for battery pack weight estimates along with manufacturing cost estimates.

As discussed further in Section VI.C.3.e)(1)(c) Battery Pack Costs, the number of cells per pack influenced total battery pack costs for the final rule. As result of the analysis discussed above Argonne updated the number of cells in each battery. For the final rule analysis battery cell counts increased or decreased for some battery pack designs, while battery counts for some designs remained the same. Argonne's process for evaluating different design criteria for electrified vehicles is detailed further in the Argonne model documentation.¹²⁰¹

The agencies also updated other BatPaC inputs and assumptions based on additional market information or research. For the NPRM, the agencies modeled battery packs in BatPaC using the default values associated with the baseline manufacturing plant, including an annual production rate of 100,000 batteries.¹²⁰²

The estimate for battery pack costs incorporates an assumption of the battery pack production volume. Both BatPaC version 3.0, used in the NPRM, and BatPaC version 3.1, used in the final rule, include a default value assumption

of 100,000 battery pack units manufactured per year per manufacturing plant as well as the plant efficiency (cell yield) of 95 percent. For the final rule, the agencies adjusted the production volume assumption used in BatPaC version 3.1 to 25,000 battery pack units, based on the analysis presented below.

As described in the BatPaC model documentation, the BatPaC models the differences in pack designs and how they affect the costs of one or more steps in the battery production process and the physical plant layout.¹²⁰³ For example, increasing the power of the battery packs without increasing the number of cells, or cell capacity, results in the model increasing the area of the cells and decreasing the electrode coating thickness. This results in an increased cost of the coating equipment, the floor area occupied by the equipment, and the direct labor for the process.¹²⁰⁴ The agencies are aware that each manufacturer (not brand) has a unique battery pack design that differs from other manufacturers. Accordingly, it is likely that each manufacturer's BEV models had distinct characteristics, such as unique battery packaging space, energy requirements, thermal control systems, and safety systems, which cause battery pack designs to vary between each manufacturer.

Thus, the agencies determined that even though one battery manufacturer

¹²⁰⁵ *Id.*

might manufacture batteries for multiple vehicle manufacturers, the default BatPaC assumption of 100,000 battery pack units manufactured per plant likely did not account for all of the cost differences in pack designs between manufacturers. Therefore, the agencies assumed the production volume of each battery pack type was reasonably represented by the BEV production volume for each manufacturer. The agencies also assumed that battery pack manufacturing plants operated at reasonable capacity during that timeframe, which would produce the lowest cost assumption.

The agencies analyzed BEV sales for MYs 2016–2019, referencing data collected by the Department of Energy.¹²⁰⁶ Table VI–93 shows that individual manufacturer U.S. BEV sales are substantially below 100,000 units per year except for Tesla, beginning in MY 2018 Tesla is a vertically integrated battery and BEV manufacturer, which is not the model the remainder of the industry has implemented, or intends to, based on the agencies current understanding. More specifically, Tesla sold more BEVs than all manufacturers combined in MYs 2016, 2018, and 2019. 2017 was the only year in which all other manufacturers *combined* sold

more BEVs than Tesla. Ultimately, in selecting a battery pack volume estimates for an industry-wide assessment, the agencies sought to accurately account for both the representative production volumes and representative practices applicable to the industry. As such, the agencies evaluated the average per manufacturer volumes, less the outlying and vertically integrated volumes of Tesla (shown in Table VI–94). As depicted in Table VI–93 and Table VI–94, the data show that the average annual sales of BEVs for individual manufacturers, excluding Tesla, is just 5% of the default battery pack production volume in BatPaC.

Table VI-93 – BEV Sales in the U.S. from 2016 to 2019

| U.S. BEV Sales by Model in Order of Market Introduction | | | | | | |
|---|------|--------|---------|---------|---------|---------|
| Vehicle | Type | 2016 | 2017 | 2018 | 2019 | Total |
| Nissan Leaf | EV | 14,006 | 11,230 | 14,715 | 12,365 | 52,316 |
| Smart ED | EV | 657 | 544 | 1,219 | 680 | 3,100 |
| Mitsubishi I EV | EV | 94 | 6 | - | - | 100 |
| Ford Focus EV | EV | 901 | 1,817 | 560 | - | 3,278 |
| Tesla Model S | EV | 30,200 | 26,500 | 25,745 | 15,090 | 97,535 |
| Chevy Spark | EV | 3,035 | 23 | 7 | - | 3,065 |

Table VI-94 - Individual Manufacturer Average Annual BEV Sales in the U.S.**from 2016 to 2019**

| Vehicle | Number of Manufacturers | Type | 2016 | 2017 | 2018 | 2019 |
|-----------------------------------|-------------------------|------|--------|--------|---------|---------|
| All Manufacturers ¹²⁰⁷ | 11 | EV | 7885 | 9499 | 21,711 | 21,992 |
| Total (all Tesla Models) | 1 | EV | 49,800 | 49,970 | 191,627 | 189,355 |
| Total (all Non-Tesla Models) | 10 | EV | 3693 | 5452 | 4719 | 5255 |

In consideration of this data, when estimating the production volume in the final rule analysis, the agencies selected a value of 25,000 units per year per manufacturer as a reasonable estimate for the average industry for MY 2020, which is the base model year for estimated battery pack costs using BatPaC version 3.1. As discussed in Section VI.C.3.e)(3) Electrification Learning Curves, other model year battery pack costs are estimated using cost learning. Using the default production volume of 100,000 units per year per manufacturer, the agencies would have underestimated the actual cost of battery pack production for MY 2020, as the model assumes that production costs decrease as production volumes increase. By selecting the value of 25,000 units per year per manufacturing plant, the battery cost estimate from the BatPaC model better aligned with the cost estimate published in industry-recognized reports such as the UBS MY 2016 Chevy teardown report.^{1208 1209 1210}

The agencies performed a sensitivity study for production volume using BatPaC version 3.1. The cost of the battery pack dropped by 15 percent on average when the production volume was changed from 25,000 to 100,000 units per year. The sensitivity analysis showed that manufacturing plant volume has a significant impact on battery pack costs and therefore it is important to use realistic production

volume estimates for the battery pack cost analysis.

Manufacturing plant efficiency is another parameter important to estimate battery pack costs. BatPaC version 3.1 defines manufacturing plant efficiency in terms of cell yield, or the number of cells that are usable out of the total number of cells that the plant produced.¹²¹¹ Since battery pack technology and battery pack manufacturing processes are proprietary, the data on plant efficiencies are not widely reported. While BatPaC uses a default cell yield (plant efficiency) value of 95 percent, Argonne battery experts have used an 85 percent cell yield value to represent the current production yield for internal DOE studies.¹²¹² By selecting an 85 percent cell yield value for the final rule analysis, the agencies aligned the cell yield value assumption with internal DOE studies.

In addition, as discussed in detail above, the final rule analysis was performed using BatPaC version 3.1, with NMC622 assumed as the battery chemistry for HEVs, PHEVs, and BEVs. Separate from the inputs and assumptions discussed here, the Argonne battery experts made a number of changes to BatPaC version 3.1, and these are extensively documented in the BatPaC manual,¹²¹³ as well as in

Argonne model documentation for final rule.

(b) Comments on Information Availability

In addition to comments that the agencies' battery pack costs were too high, the agencies received comments that the analysis for battery pack costs was unclear and not well documented. ICCT stated that the agencies largely obscured the BEV cost sources and calculations, which made it "nearly impossible for even very interested researchers to understand how all the BatPaC costs translate into BEV costs that can be compared with other full-BEV costs in the literature."¹²¹⁴ ICCT stated that to enable meaningful public comments, the sources and cost calculations must be made explicit and the agencies must provide an additional public comment opportunity.¹²¹⁵

CARB claimed that it could not comment meaningfully on the battery modeling for the NPRM analysis without extensive additional information.¹²¹⁶ As such, CARB submitted a letter to the agencies' NPRM docket posing, under FOIA, a number of questions pertaining to battery assumptions used for the modeling. This requested information concerned what version of BatPaC was used in the NPRM analysis, inputs incorporated into the BatPaC model; and information about how battery costs were generated for the analysis.

Specifically, CARB's initial comments alleged that the agencies had not disclosed the exact version of BatPaC used, and had simply claimed to use the "most up-to-date" version of BatPaC,

¹²⁰⁷ Note, for the assessment, Nissan and Mitsubishi are considered a single manufacturer.

¹²⁰⁸ Proposed Determination TSD at 2-127.

¹²⁰⁹ Based on the battery cell to battery pack ratio of 1.3 to 1.5, the 2015–2019 cell-level figure of \$145 per kWh used in the MY 2016 Chevy Bolt would translate to approximately \$190 to \$220 per kWh on a pack level.

¹²¹⁵ *Id.*

¹²¹⁶ California Air Resources Board, NHTSA–2018–0067–11873.

and further that the agencies had not disclosed “the BatPaC modeling files that were used, clear statements about what version of the model was used, or thorough descriptions of the inputs to those modeling runs.” CARB claimed that without that information, “there is no way to know what assumptions were made for raw material pricing, battery cell yields, pack electrical connection topology, battery production volume assumptions, or if any additional parameters were modeled, like rapid charging capability.” CARB argued that these pieces were critical to understanding whether the BatPaC model was estimating proper battery pack cost values.

In a subsequent docketed comment submitted as an administrative appeal to NHTSA’s FOIA response, CARB reasserted that, in fact, the “most recent version” of BatPaC had not been used, because the FOIA response stated clearly that version 3.0 had been used and Argonne had updated to version 3.1 in October 2017, which was the last version released before the NPRM was published. CARB further argued that NHTSA was “choosing to withhold information about battery pack configurations,” and that the agencies had not posted the BatPaC model version and files used for the NPRM to the agencies’ dockets, inhibiting meaningful comment.

The majority of information sought by CARB’s comment was already published in supporting documents and materials posted to the agencies’ dockets and online websites for the NPRM. Nevertheless, in an effort to answer CARB’s specific questions, NHTSA also processed the initial comment as a FOIA request and provided a written response directly to CARB within the comment period. This response both pointed CARB to the locations where the sought material could be located among the published NPRM materials, and expressly answered several of CARB’s questions for clarification, such as identifying the specific version of BatPaC utilized in the NPRM analysis. For example, although the Argonne model documentation describing the battery modeling for the NPRM was included in the docket, the agencies’ response directed CARB to the precise location in the docket where it could be found.

The agencies believe that the NPRM docket contained enough information for stakeholders to comment meaningfully. This is apparent from the voluminous comments the agencies received regarding the NPRM’s electrification analysis—including from CARB. For example, as discussed above,

CARB submitted extensive comments on each element of the battery cost modeling that CARB claimed the agencies did not adequately explain. As discussed above, CARB stated that the agencies’ selected battery chemistries represented a step backward from previous analysis done for the Draft TAR. CARB noted that regardless of whether NMC441 or NMC333 was chosen for PHEVs and BEVs in the NPRM analysis, the biggest lithium-ion production companies have indicated that they will use NMC811 for BEVs, and therefore neither NMC441 nor NMC333 would represent current technology going into BEVs or near-future BEV battery technology. CARB stated that NMC811 technology is expected to come to market in 2019, which, the agencies note, is far sooner than anticipated, even in the agencies’ prior analyses. CARB was accordingly able to communicate its opinion that NMC881 should have been used to model battery chemistries for the NPRM analysis, and that NMC441 or NMC333 should not be used.

As these comments demonstrate, in addition to the extensive comments listed above, the expansive information, data, and documentation concerning the Argonne BatPaC modeling analysis for the NPRM sufficiently enabled commenters to submit voluminous technical analysis regarding the electrification analysis. Moreover, while the docketed and published NPRM materials themselves afforded sufficient notice on these topics, the agencies even undertook the additional step of directly responding to CARB in writing in an attempt to address specific questions raised by CARB. This written correspondence both directed CARB to specific locations on the rulemaking dockets and agencies’ websites where information CARB was seeking could be accessed, and even directly answered several of CARB’s questions through narrative responses. Both CARB and other commenters submitted subsequent comments, which referenced the material described in this written response. Accordingly, the agencies consider the information provided with the NPRM sufficient to enable meaningful comment, which is underscored by the voluminous technical comments received on the electrification issues.

For this final rule, the BatPaC model version 3.1 (June 2018) model documentation has been included in the docket for this rulemaking.¹²¹⁷

¹²¹⁷ Nelson, Paul A., Ahmed, Shabbir, Gallagher, Kevin G., and Dees, Dennis W. Modeling the Performance and Cost of Lithium-Ion Batteries for

Furthermore, Argonne’s detailed documentation describing the modeling process used to support this final rule provides information and specific assumptions that Argonne’s experts used to simulate batteries and their associated costs for the full vehicle simulation modeling.¹²¹⁸ These resources, in addition to the detailed description of the battery cost modeling process provided here and in the FRIA provide interested stakeholders the necessary tools to understand the battery cost modeling analysis.

c) Final Rule Battery Pack Costs

As discussed above, based on comments and additional research, the agencies updated the battery cost analysis for the final rule by relying on BatPaC version 3.1.¹²¹⁹ In addition, as outlined above and explained in more detail in the Argonne Model Documentation for this final rule, several inputs and assumptions were updated based on public comments, market research, and additional literature review. The agencies computed the average battery pack cost across all road load combinations for electrification technologies that could be reasonably compared between the NPRM and final rule.¹²²⁰

Table VI–95 to Table VI–99 show the differences between battery pack costs presented in the NPRM and final rule.¹²²¹ The tables show absolute cost differences between battery packs, which can vary for battery packs with different energy and power combinations. For example, as shown in Table VI–96, the cost difference between the NPRM and final rule for a Mild HEV battery pack with a 1kWh energy and 10kW power rating is – 28 percent. Similarly, the cost difference in an HEV battery pack with a 1kWh battery energy and 40kW power rating is 5 percent. In summary, the percentage increase or decrease in the table represents the

Electric-Drive Vehicles, Third Edition (ANL/CSE–19/2), available at <https://publications.anl.gov/anlpubs/2019/03/150624.pdf>.

¹²¹⁸ A Detailed Vehicle Simulation Process To Support CAFE and CO2 Standards for the MY 2021–2026 Final Rule Analysis.

¹²¹⁹ Modeling the Performance and Cost of Lithium-Ion Batteries for Electric-Drive Vehicles, Third Edition (ANL/CSE–19/2) provides a complete list of changes and assumptions incorporated in BatPaC version 3.1.

¹²²⁰ Costs data is from the CAFE Model core file Battery_Costs.csv.

¹²²¹ The absolute cost differences shown here is by comparing the cost of battery pack with similar number of cells in the NPRM to the final rule cost lookup tables for compact and medium car. The cost differences between the NPRM and the final rule cost lookup tables for small SUV, medium SUV and Pickup trucks will be different from the table shown here.

absolute cost differences between the battery packs used in NPRM and in final rule.

Figure VI–40 to Figure VI–42 shows the average battery pack costs across all road load combinations for each applicable vehicle technology class for SHEVPS, PHEV50, and BEV200s between the NPRM and final rule.¹²²² Since the battery pack size varies for different road load combinations, the

battery pack cost across different road load combinations varies as well. For example, there are 105 combinations of different mass reduction, aerodynamic improvements and rolling resistance improvements. The battery pack size for an initial road load condition that includes MR0, AERO0 and ROLL0 is larger, and therefore, the cost of the battery pack is higher as well. The battery pack size is smaller for the

highest level of road load reduction such as in MR6, AERO20 and ROLL20, and the cost of battery pack is less as well.

Table VI–95 shows the cost difference in Micro HEV battery packs. The cost reduction is from the reduced number of cells in the battery pack.

BILLING CODE 4910–59–P

Table VI-95 – Percentage Cost Differences for Micro HEV Battery Packs

| Micro HEV | | | Energy, kWh | | | | |
|-------------|-----------|-----|-------------|------|------|------|------|
| BatPac Cost | Power, kW | 0.5 | 0.6 | 0.8 | 1.0 | 1.2 | 1.4 |

Table VI–97 shows the percentage cost differences for HEV battery packs. Even as the battery chemistry changed

to NMC622, the cost increase is from the different battery pack production

volume and plant efficiency assumptions used in the final rule.

¹²²² The agencies did not simulate SHEVPS and BEV200 powertrain architectures on pickup trucks

in the NPRM, so those are not included in the comparison.

¹²²³ In the NPRM, additional hardware component costs were included as part of the battery pack cost.

Table VI-97 – Percentage Cost Differences for SHEVPS Battery Packs

| HEV | | | Energy, kWh | | | | | |
|-------------|-----------|------|-------------|-----|-----|-----|-----|-----|
| BatPac Cost | Power, kW | | 0.9 | 1.0 | 1.2 | 1.4 | 1.6 | 1.8 |
| | | | | | | | | |
| | | 10.0 | | | | | | |
| | | 20.0 | | 14% | 13% | 13% | 14% | 14% |
| | | 30.0 | | 11% | 10% | 9% | 8% | 9% |
| | | 40.0 | | 10% | 8% | 7% | 6% | 5% |

Figure VI-40 shows the difference in battery pack costs for SHEVPS applications between the NPRM and final rule. Power-split hybrids could not

be used in pickup trucks due to their unique power and towing requirements, so those technology classes are not shown. In general, the cost of the battery

pack in the final rule analysis increased due to the updated battery pack production volume and plant efficiency assumptions.

Figure VI-40 – Comparing SHEVPS Average Battery Costs (Costs do not include RPE or Learning Curve Adjustment)

Table VI-98 shows the percentage cost differences between the NPRM and final rule for PHEV50 battery packs. The

cost increase in the PHEV50 battery pack shown here is mainly due to the increase in number of cells per pack as

well as the other updated BatPaC assumptions.

Table VI-98 – Percentage Cost Differences for PHEV50 Battery Packs

| PHEV50 | | | Energy, kWh | | | | | |
|-------------|-----------|--|-------------|------|------|------|------|------|
| BatPac Cost | Power, kW | | 10.0 | 20.0 | 30.0 | 40.0 | 50.0 | 60.0 |
| | | | 26% | 17% | 11% | 6% | 3% | 1% |
| | | | 26% | 17% | 11% | 6% | 3% | 1% |
| | | | 20% | 17% | 11% | 7% | 3% | 1% |
| | | | 14% | 17% | 11% | 7% | 3% | 1% |
| | | | 8% | 15% | 11% | 7% | 3% | 1% |

Table VI-94 shows the difference in average PHEV50 battery pack costs between the NPRM and final rule for all technology combinations.

**Figure VI-41 - Comparing PHEV50 Average Battery Costs (Costs do not include RPE or Learning Curve Adjustment)**

Table VI-99 shows the percentage cost differences for BEV battery packs. In the example shown in Table VI-99, the agencies compared the cost lookup

table from the NPRM with 300 cells to the cost lookup table in the final rule analysis with 320 cells. The cost increase in the higher energy packs is

due to the different battery pack production volume and plant efficiency value assumptions, along with the different battery chemistry assumption.

Table VI-99 – Percentage cost differences in BEV200

| BEV200 | | | Energy, kWh | | |
|-------------|-----------|-------|-------------|------|------|
| BatPac Cost | Power, kW | | 50.0 | 70.0 | 90.0 |
| | | 60.0 | 2% | 2% | 2% |
| | | 80.0 | 3% | 3% | 3% |
| | | 100.0 | 3% | 3% | 3% |
| | | 120.0 | 3% | 3% | 3% |
| | | 140.0 | 3% | 3% | 3% |
| | | 160.0 | 3% | 3% | 3% |

BILLING CODE 4910–59–C

Figure VI–42 shows the average cost of BEV200 battery packs across all technology combinations for technology classes that could be compared between the NPRM and final rule. As shown, for the final rule analysis, the average cost of a BEV200 battery pack is lower than the average cost of the NPRM BEV200 battery pack. For the final rule analysis, the agencies updated the motor efficiency map for BEVs (as explained in Section VI.C.3.d) Electrification Technology Effectiveness) and updated the glider share of the vehicles from 50

percent of the curb weight to 71 percent of the vehicle curb weight (as explained in Section VI.C.4 Mass Reduction). In addition, the updated motor weight resulted in further reduced vehicle weights. This combination of improved vehicle assumptions resulted in reduced energy and power requirements in BEVs.

The agencies also observed that even as the number of cells in the battery pack increased from 300 to 320, and changes in production volume and plant efficiency values resulted in marginal cost increases for higher energy packs,

the overall battery capacity requirement went down due to overall reduction in power and energy demand from electric vehicles.¹²²⁴ A reduction in battery capacity leads to reduced cell size in a pack with number of cells and voltage. A reduction in cell size leads to cost reductions at the cell level and at the pack level. In general, a higher capacity battery pack is more expensive than a lower capacity battery pack due to the increase in cell size for a given number of cells and voltage.^{1225 1226}

BILLING CODE 4910–59–P

¹²²⁴ As explained above, the energy density values in the NPRM were kept constant. For the final rule analysis, the power density varied to meet different power and energy requirements, as was observed through market research.

¹²²⁵ Nelson, Paul A., Ahmed, Shabbir, Gallagher, Kevin G., and Dees, Dennis W. Modeling the

Performance and Cost of Lithium-Ion Batteries for Electric-Drive Vehicles, Third Edition (ANL/CSE–19/2), at 15 (battery design worksheet). Available at <https://publications.anl.gov/anlpubs/2019/03/150624.pdf>.

¹²²⁶ The amount of electrode materials and electrode area of the cells are determining cost

factors in the battery. Higher capacity battery packs require additional manufacturing steps to increase the energy density of the pack.

Figure VI-42 – Comparing BEV200 Average Battery Costs

(Costs do not include RPE or Learning Curve Adjustment)

The graphs demonstrate the range of cost changes observed, with the other electrification technologies falling somewhere in between the extremes. In summary, the agencies observed that the BEV200 technology showed a cost reduction in battery packs across all vehicle platforms with the largest reductions occurring for the largest battery packs. In contrast the PHEV50 technology showed a cost increase in battery packs across all vehicle platforms with the smallest increase for the largest battery packs and the largest increase for the smallest battery packs.

It is worth noting the cost decreases seen across the technologies are generally larger than the cost increases.

For the final rule, when possible, the calculated battery pack weight and manufacturing cost was also compared with the battery pack cost and weight data obtained through various benchmarking studies. For example, UBS reported a battery pack manufacturing cost of \$12,500 from its 2017 Chevrolet Bolt teardown analysis.¹²²⁷ Using a production volume of 25,000 packs per year per plant and similar battery pack design, BatPaC

estimated a manufacturing cost of \$10,680.¹²²⁸ These comparisons were used to verify the different assumptions used in BatPaC and helps represent the battery packs for electrified vehicles used in representative market volume. Table VI-100 shows a comparison of specifications estimates for 60 kWh and 160 kW battery packs from the 2016 DOE VTO report¹²²⁹ and BatPaC version 3.1 (June 2018), and the Chevrolet Bolt. The comparison shows modeled and actual battery packs are in close agreement.

| NHTSA/EPA from BatPaC version 3.1 (2018) | \$178 | \$141 | \$112 | \$77 |

As shown in the table above, there are a range of cost estimates for battery packs. Each individual cost estimate is derived based on certain set of assumptions to arrive at a rate of cost reduction. Among all the different cost estimates, Bloomberg New Energy Finance (BNEF) has the most aggressive year-over-year cost reductions, based on the historical learning rate of 18% and their battery demand forecast.¹²⁴⁰ Similar to other sources of cost estimates BNEF assumes improved battery chemistry and battery density increasing greater than 200Wh/kg by 2030. In order for the battery manufacturer to achieve economies of scale, BNEF assumes a global battery manufacturing facility capable of producing battery packs for both stationary energy storage and vehicle applications.

A recent report from the Massachusetts Institute of Technology (MIT), the MIT Energy Initiative's Insights into Future Mobility, has the most conservative estimate among all the cost sources listed the Table VI-101. The authors use a more rigorous two-stage method of estimating composite battery learning curves independently for (a) battery material synthesis and minerals costs, and (b) battery pack production processes. The learning rates are defined as the cost reduction that results from cumulative volume doubling, and produce separate cost

learning rates for the two stages of 3.5 percent and 16.5 percent, respectively. The study argues that there are greater opportunities for cost learning in the production stage than the chemical synthesis stage, which is more mature. These cost estimates produce global EV fleet penetration rates that may not be as aggressive as other estimates, reaching only 33 percent by 2050. This study also assumes NMC811 will be available by 2030.

The cost estimates from other sources referenced above also include assumptions about higher levels of battery pack production and higher density battery cells. Most cost estimates assume improved battery chemistry, such as NMC811. As discussed above, the agencies determined that modeling assuming NMC622 was reasonable, based on current production vehicles, the relative uncertainty surrounding large-scale NMC811 deployment in the rulemaking timeframe, and the ability to account for lower battery pack costs over time with cost learning. The agencies also believe that, based on the market analysis and from the teardown analysis, improvements in battery chemistry may be slow to be applied in a widespread manner, and therefore the economies of scale required to achieve considerable cost reductions solely from improvements in chemistry may remain effusive during the rulemaking timeframe.

For these reasons, the agencies believe that the BatPaC-generated battery cost estimates using the updated inputs and assumptions are reasonable.

2) Non-Battery Electrification Component Costs

Battery components are the biggest driver of the cost of electrification, however, non-battery electrification components also add to the total cost required to electrify a vehicle. In this analysis, the agencies accounted for the following non-battery component costs: Electric motor(s), inverter, and other power electronics including a bi-directional DC/DC converter, a voltage step down DC/DC converter, and an on-board charger. Collectively, these components (except for the on-board charger) are referred to as the electric traction drive systems (ETDS), or the electric machine. Non-plug-in hybrid electric vehicles include all of the listed components except for an on-board charger; PHEVs include all of the listed components; and BEVs include all of the listed components except, in some cases, a second motor.

For the NPRM, the agencies accounted for battery pack costs and ETDS costs independently.¹²⁴¹ The Alliance commented broadly in support of separating electrification hardware costs and battery costs, and stated that it was a positive change to the modeling.¹²⁴² The Alliance correctly noted that the separation allowed for separate learning rates and cost differentiation between the two distinct pieces of electrification technologies.

¹²⁴⁰ Logan Goldie-Scot, A Behind the Scenes Take on Lithium-ion Battery Prices, Bloomberg New Energy Finance (March 5, 2019), <https://about.bnef.com/blog/behind-scenes-take-lithium-ion-battery-prices/>.

¹²⁴¹ PRIA at 362.

¹²⁴² Alliance of Automobile Manufacturers, NHTSA-2018-0067-12073, at 140.

As stated in the PRIA,¹²⁴³ the agencies derived the cost values for the EDTS using Argonne National Laboratory's "Assessment of Vehicle Sizing, Energy Consumption, and Cost through Large-Scale Simulation of Advanced Vehicle Technologies" report.¹²⁴⁴ Generally, the agencies referred to this report in the PRIA as the DOE VTO report, as it was a report that reviewed results of the DOE VTO. Some commenters seemed confused by this alternative reference—even questioning why the agencies didn't rely on recent Argonne National Laboratory reports.¹²⁴⁵ To clarify, this report was written by Argonne National Laboratory, and to avoid further confusion it is referred to using the full title throughout this rule.

CARB expressed concerns with non-battery component effectiveness values, arguing that the agencies inappropriately relied on outdated data for electric machines and inverter efficiencies across all electrification applications, and further claiming that the agencies did not project any efficiency gains in those components over time.¹²⁴⁶ Broadly, as these comments on effectiveness related to the NPRM non-battery component cost estimates, CARB claimed that the agencies failed to consider new data, including the 2015 ORNL Annual Progress Report for the Power Electronics and Electric Motors Program, and two Argonne studies, which rendered the analysis unrepresentative of actual technology costs.

CARB also commented that the agencies did not provide any substantive discussion or documentation of how non-battery component costs were developed for the NPRM analysis. CARB claimed that dissonance existed between the PRIA description of voltage systems and associated costs needed for different performance classes, the Autonomie files, and the technologies input file, and that this served as an example of

how the agencies failed to include information regarding how costs and cost differences were derived, or any component changes from previous analyses.

CARB also commented that the lack of disclosure of non-battery cost development information was an issue for other electrification technologies. CARB cited the increase in parallel (P2) and power-split (PS) hybrid systems costs relative to costs used in past agency analyses, noting that there was no discussion on what changed from the past analyses. CARB referenced a 2010 FEV teardown (Light Duty Technology Cost Analysis, Power-Split and P2 HEV Case Studies, EPA-420-R-11-015) study that the agencies had previously relied on for component costs, noting that not only did the agencies ignore that study in the NPRM, but that ICCT had commented 2010 FEV report overstated strong hybrid costs at the time of the study, making it likely that costs are likely to be lower now and even more so in the future. CARB claimed that the agencies provided no justification or rationale for the increases in strong hybrid modeled costs for the proposal, and that there was no meaningful way to comment on the exact components or cost changes that the agencies relied upon. Similarly, CARB cited EPA's 2016 Proposed Determination and associated public comments from Ford and Tesla on the Draft TAR for the proposition that non-battery costs, which were lower in the Draft TAR than the NPRM, were conservative and not overly optimistic.

Finally, in addition to the ORNL and Autonomie group studies that CARB referenced as examples of sources that provided updated data on non-battery component effectiveness and costs, CARB claimed that newer data existed from a UBS Global Research report that examined the component costs of a MY 2016 Chevrolet Bolt, and the agencies did not discuss why the newer data was not used in the NPRM analysis. CARB stated the significant upward adjustment in non-battery costs from previous analyses was not supported by industry input, analysis conducted by other outside sources, or by the agencies' previous analyses.

As explained above, for the NPRM the agencies relied on Argonne's "Assessment of Vehicle Sizing, Energy Consumption, and Cost through Large-Scale Simulation of Advanced Vehicle Technologies" for EDTS costs. In turn, the Assessment of Vehicle Sizing, Energy Consumption, and Cost through Large-Scale Simulation of Advanced Vehicle Technologies report referenced electric machine data provided by

OEMs, suppliers, and Oak Ridge National Laboratory.¹²⁴⁷ Regarding CARB's assertion that the agencies did not refer to the UBS Global Research report on the MY 2016 Chevy Bolt teardown for the NPRM, the agencies agree. The UBS Global Research report was not available at the time the CAFE model inputs were finalized for the NPRM analysis. That study, among others, was considered for the final rule.

For the final rule analysis, the agencies carefully considered comments and the referenced studies, as well as other studies. The agencies determined the cost and component efficiency estimates from U.S. DRIVE's October 2017 report, Electrical and Electronics Technical Team (EETT) Roadmap,¹²⁴⁸ provided reasonable estimates to use in the final rule. The EETT Roadmap report reflected considerable work by the DOE VTO collaboratively with U.S. DRIVE, a government-industry partnership. The EETT Roadmap report estimated the 2017 manufacturing cost of a commercial on-road 100kW ETDS consisting of a single electric traction motor and inverter. The reported costs were approximately \$1,800, with the cost of the electric motor accounting for \$800, and approximately \$1,000 for the inverter, equaling \$18/kW for the ETDS.

The agencies also referenced the UBS MY 2016 Chevy Bolt teardown report to compare the cost of the ETDS.¹²⁴⁹ To compare the costs, the agencies applied the \$18/kW metric for ETDS as determined by EETT Roadmap report to the 150kW ETDS used in the MY 2016 Chevy Bolt (\$18kW × 150kW = \$2700). As shown in Table VI-102, the cost estimate from the above computation aligned with UBS MY 2016 Chevy Bolt teardown cost estimate. As a result, the agencies determined that it was appropriate to use \$18/kW to estimate the cost of the ETDS for all hybrid and electric vehicle architectures for the final rule.

The EETT Roadmap report did not explicitly estimate the cost of other electrical equipment present in PHEVs and BEVs, such as on-board chargers, DC to DC converters, and charging cables, but recommended cost targets for the years 2020 and 2025. As a consequence, the agencies relied on the

UBS MY 2016 Chevy Bolt teardown report to estimate the cost of on-board chargers, DC to DC converters, and charging cables. Table VI-102 shows the

cost estimate for the ETDS from the EETT Roadmap report and from the UBS MY 2016 Chevy Bolt teardown report, and the cost estimate for other

electrical equipment from the same UBS report.

BILLING CODE 4910-59-P

Table VI-102 – Cost Estimates from the EETT Roadmap Report and UBS MY 2016 Chevy Bolt Teardown

| | EETT Roadmap Report | UBS MY 2016 Chevy Bolt Teardown |
|---------------------|----------------------------|--|
| ETDS | \$18/kW | \$17.76/kW |
| On-Board Charger | - | \$85/kW |
| DC to DC Converter | - | \$90/kW |
| High Voltage Cables | - | \$450 |

Table VI-103 – Final Rule Non-Battery Electrification Component Costs Assumptions (2017\$)

| Electric Propulsion Systems | Cost metric | Application assumption |
|---|--------------------|---------------------------------------|
| Traction Motor + Inverter + Bi-Directional Converter | \$18/kW | Calculated for Peak motor power |
| Generator Motor + Inverter + Bi-Directional Converter | \$18/kW | Calculated for Continuous motor power |
| On-board charger for BEV | \$85/kW | Calculated for 7kW required for BEV |
| On-board charger for PHEV | \$85/kW | Calculated for 2kW required for PHEV |
| DC/DC Converter | \$90/kW | For all electric and hybrid vehicles |
| High voltage cables, charging cord & connectors | \$450 | For all electric and hybrid vehicles |

While the EETT Roadmap report estimated the cost of the ETDS at the system level, the report did not itemize the cost of individual components in electric motor and inverter in 2017. However, the EETT Roadmap report provided target cost estimates for the motor and inverter system for the year 2025. As shown in Table VI-104, the

EETT Roadmap report estimated a cost reduction of 73 percent for the inverter and 59 percent for the motor relative to 2017. Using the percentage cost reductions from 2025 to the on-road status as defined in the EETT Roadmap report, the agencies developed an estimated motor and inverter component cost for 2017. The resulting

cost estimate for 2017 using the scaling factor matches the \$18/kW for motor and inverter (\$10/kW for Inverter + \$8/kW for motor). Since the motor and inverter component costs are developed based on a \$/kW basis, the agencies applied the same \$/kW metric for all hybrid and electric vehicle applications for the final rule analysis.

BILLING CODE 4910-59-C

In addition, the EETT Roadmap report provided notably newer data than the 2010 FEV teardown study referenced by commenters. Based on these considerations, the agencies determined that the EETT Roadmap report provided

reasonable costs to estimate the cost of EDTS components in the rulemaking timeframe.

(3) Electrification Learning Curves

The total incremental costs of electrification powertrain technologies are comprised of the DMC as modified by the learning curves for each individual powertrain component, which include batteries, non-battery

components, and IC engines and transmissions (for hybrids and PHEVs). The PRIA showed the learning curves for battery and non-battery electrification technologies,¹²⁵⁵ and listed the sources used to develop those curves, including the 2015 NAS report,

¹²⁵⁴ U.S. DRIVE, Electrical and Electronics Technical Team Roadmap, at 23 (Oct. 2017), available at <https://www.energy.gov/sites/prod/files/2017/11/f39/EETT%20Roadmap%2010-27-17.pdf>.

¹²⁵⁵ PRIA at 380.

Wright-based learning curves,¹²⁵⁶ and Argonne's 2016 Assessment of Vehicle Sizing, Energy Consumption, and Cost through Large-Scale Simulation of Advanced Vehicle Technologies.¹²⁵⁷ Learning rates for batteries were also derived using Argonne's BatPaC model.

For the NPRM, to develop the learning curves for non-battery components, the agencies consulted Argonne's 2016 Assessment of Vehicle Sizing, Energy Consumption, and Cost through Large-Scale Simulation of Advanced Vehicle Technologies report. The report provided estimated cost projections from the 2010 lab year to the 2045 lab year for individual vehicle components.^{1258 1259} The agencies considered the component costs used in electrified vehicles, and determined the learning curve by evaluating the year over year cost change for those components.

The agencies used BatPaC version 3.0 to develop the NPRM learning curves for batteries. As discussed above, BatPaC calculations are based on generic pack design for a given set of inputs that could reasonably represent potential current and future designs. Because BatPaC does not simulate battery costs as a function of time, the agencies modified the battery volume inputs for MY 2015, MY 2020, MY 2025 to show costs in each of those MYs. Like the non-battery component analysis, a learning curve was developed from the year over year cost change, and this rate was used to develop the learning curves used in the NPRM.

CARB stated that publicly available data supported lower costs in the near term than what the applied learning

curve rates would do to the battery costs developed by the agencies, and the agencies failed to consider new information or data to adjust battery costs.¹²⁶⁰ CARB stated that considering the substantial volume of publicly available information and public input to the agencies' previous analysis, projected battery costs should have been adjusted even further downward for the NPRM. CARB stated that instead, the agencies moved costs upward without sufficient justification, and in contrast, the analysis for the Proposed Determination and 2016 Draft TAR provided far more justification for those modeled battery costs.

As discussed in Section VI.B.4.d) Cost Learning, above, ICCT commented broadly on the change in approach to learning curves since the Draft TAR, stating that this change in approach led to lower decreases in costs over time in the NPRM than the Draft TAR analysis. ICCT compared EPA's Draft TAR learning curves and NPRM learning curves for batteries in MYs 2016–2025, concluding that there was a 29% reduction in learning for batteries from EPA's Draft TAR analysis to the NPRM analysis.

The agencies considered an array of both present and future cost estimates from various public and private sector organizations to validate the rate at which battery pack costs declined over time. These estimates, in addition to estimates submitted by commenters as discussed in BatPaC Inputs and Assumptions and Final Rule Battery Pack Costs are shown in Table VI–101. In addition, the agencies had to consider how to project learning rates out through 2050, as discussed in Section VI.B.4.d) Cost Learning and Section VI.C.3.e)(3) Electrification Learning Curves.

The agencies also assessed and reviewed literature evaluating more recent battery technology development.^{1261 1262} The NPRM

analysis used a three percent learning rate per year from MY 2033 to MY 2050. Learning rate forecasts from MY 2033 to MY 2050 for this final rule analysis were scaled down in steps from the previous analysis based on literature, market research, and Wright's learning curve assumptions.

It is difficult to predict which battery chemistry and production processes will be prevalent for electrified vehicles in MY 2030, let alone for MY 2050. The agencies reviewed potential battery chemistries that could come into readiness for adoption at different timeframes, such as MY 2030s to MY 2039, and MY 2040 to MY 2050.¹²⁶³ It is possible that costs based on other lithium-ion based chemistries will learn at the same rate as lithium-ion NMC development. However, the same learning effect in battery production may not be additive across different chemistries, especially in learning effects related to battery production. Accordingly, the learning rates applied between MY 2030 to MY 2039 considered development and increased volume for the same or similar battery chemistries as an NMC battery platform.¹²⁶⁴ Learning curves beyond MY 2040 were flattened further to ensure that the cost of batteries did not lower beyond the projected price of the raw materials. Further, new chemistries introduced in later years may learn at different rates than the curve identified for NMC-based chemistries. The battery pack cost learning rate that resulted from this exercise produced the schedule that appears in Table VI–96, which shows this final rule analysis battery pack cost reduction as function of time. By MY 2040, the pack cost has reduced by 54 percent. Accordingly, the estimated battery pack cost between MY 2040 and MY 2050 as shown in Figure VI–43 below shows flatter curve.

Figure VI-43 – Battery Pack Cost Learning in Final Rule

The reference cost is defined for MY 2020 vehicles, and vehicles produced in subsequent years (as well as earlier years) use a per kWh cost that is a percentage of the 2020 cost. As the figure shows, the cost reduction is rapid through MY 2030, after which cost reductions slow considerably. As discussed above, the cost projections assumed different battery chemistries and different rates of cost learning.

The agencies expect there will be incremental improvements in battery chemistry, energy density, plant efficiency, and production volume over the timeframe modeled in the analysis. While each of these factors may have an impact on the rate at which battery costs decline over time, the agencies determined that using the same cost learning projection method from the NPRM to project learning rates out through 2050 provided a reasonable method for accounting for something that is inherently uncertain. Accordingly, the learning curve used in the NPRM and in the final rule represent a composite learning curve irrespective of the type of battery chemistry, the production volume necessary to achieve economies of scale, or energy density of the battery pack. For the final rule, the agencies have performed sensitivity analyses varying the battery pack learning rate, and these analyses are presented in FRIA Chapter VII.E Sensitivity cases.

(4) Electrified Powertrain Costs

For the NPRM analysis and carried forward for the final rule analysis, the total electrified powertrain costs were developed by summing individual component costs. The costs associated with the IC engine, transmissions, electric machines, and battery packs were combined to create a full-system cost, per Section VI.C.3.e)(2) Non-battery Electrification Component Costs, Section VI.C.3.e)(1) Battery Pack Modeling, Section VI.C.1.g) Engine Costs, and VI.C.2.e) Transmissions Costs. This approach assured all technologies appropriately contributed to the total system cost.

The Alliance commented in support of the agencies' accounting separately for the subsystems' costs and benefits for CISC, BISG, P2 hybrid, power split hybrid (PS), and PHEV technologies.¹²⁶⁵ The Alliance noted that these distinctions are important to capture the differences between various technologies, which can have separate packaging requirements, efficiency potentials, and vehicle applications. Ford echoed the Alliance comments on the modeling of electric vehicles in the NPRM, stating they supported the use of separate cost and benefits modeling for P2 and power split strong hybrid technologies.¹²⁶⁶ Additionally, Ford commented that the modeling "better

reflects market realities by recognizing that manufacturers cannot simply pass on the entire incremental costs of hybrid, plug-in hybrid, and battery electric vehicles to the customers."

Comments from other stakeholders generally stated that the NPRM powertrain sizing approach resulted in costs for complete powertrains that were too high compared to other studies or market observations. In addition, as discussed in Section VI.C.1.g) Engine Costs, CARB also commented that the costs associated with IC engines were not excluded from the final costs of BEV vehicles.¹²⁶⁷ CARB continued, stating that "the final costs of BEV vehicles are higher due to the inclusion of the base absolute costs, to which the assigned BEV incremental cost would be added." The agencies agreed with CARB that inclusion of IC engine costs in the BEV cost was an error in the analysis.

In response to this comment, the agencies developed absolute costs for baseline engines for the CAFE Model so the absolute costs for IC engines could be removed from BEVs. In the final rule analysis, when a vehicle adopted BEV technology, the costs associated with IC powertrain systems were removed. As the vehicle walks through the technology tree, becoming a battery electric vehicle, the motor and inverter (ETDS) costs replaced the internal IC engine costs. Since the cost of the ETDS accounted for significant portion of the

¹²⁶⁵ Alliance of Automobile Manufacturers, NHTSA-2018-0067-12073, at 140.

¹²⁶⁷ NHTSA-2018-0067-11873 at p.122.

total cost of electrification, it was important to accurately characterize the motor size (motor rating). To do this, the agencies used the MY 2017 market data file to compute the average engine power for each technology class.

For SHEVPS and SHEVP2 vehicles, as explained further in Section VI.C.3.e(4)(c) Strong Hybrid Costs, the agencies computed the average rating for traction and generator motors across all road load combinations using Autonomie simulation runs. Since motor sizing varies based on road load levels, the average motor sizes acted as a mid-range representation for motor ratings across all road load combinations. The full range of motor sizes are driven by road load limits; the motor size for initial road load levels (MR0, AERO0 and ROLL0) would be larger compared to the motor size for highest level of road load reduction (MR6, AERO20 and ROLL20). After calculating the average motor size, the agencies applied the \$18/kW metric (derived from the EETT Roadmap report) for both traction motors and generator motors. As discussed earlier, the agencies also used the cost of the CVTL2 as proxy to represent the cost of the eCVT used in power-split hybrid vehicle systems, and used the cost of the AT8L2 as proxy for the cost of the

planetary gear set used in the P2 parallel hybrid system. The total cost of electrification for power-split hybrid vehicles includes the cost of the eCVT transmission, and the total cost of electrification for the P2 parallel hybrid vehicles includes the cost of the planetary gear set transmission.

CARB also submitted supplemental comments attempting a cost walk for electrified powertrain technologies, stating that inconsistencies in the model files and PRIA and lack of documentation about how the costs were derived “[left] the public without the ability to understand why the costs are what they are and what should be applied.”¹²⁶⁸ Accordingly, a cost walk for a vehicle adopting an electrified powertrain is shown below. Additional comments on electrified powertrain costs are discussed in each individual technology section below, along with a discussion of changes made for the final rule in response to these comments.

For the final rule analysis, the agencies have updated several electrification inputs and assumptions in response to these comments, as discussed in the previous sections. An example of how the costs are applied to a simulated vehicle platform’s technology cost is discussed here, to assist CARB and other stakeholders in assessing electrification technology

costs for the final rule analysis. The example shows the costs for a vehicle with conventional engine and transmission technology as it adds electrification technology.

The application of the electrification costs to an existing platform follows the same basic process for each technology on the electrification path. All technology costs used are for the model year of the electrification technology application. The first step is the process is the removal of the costs associated with the conventional drivetrain technologies. The next step is the application of the costs associated with the electrification technology. The costs include the cost of the engine, if applicable, transmission, non-battery components, and the battery pack. After the electrification costs are applied, other technology costs, such as aerodynamic or rolling resistance technologies are applied.

The specific example is the Toyota Rav4 LE AWD/XLE AWD simulated platform. The platform data were used from the reference run CAFE model standard setting vehicle_report.csv result file, augural standards results. The change in technology for the simulated platform was between MY 2023 and MY 2024. Table VI–107 shows the costing change between the MYs.

Table VI-107 – Cost Difference Between MY 2023 and MY 2024 Toyota Rav4 LE AWD/XLE AWD Simulated Platform

| MY | Tech Key | Tech Cost (2018\$) |
|------|---|--------------------|
| 2023 | HCR1; AT8; IACC; CONV; SAX; ROLL20; AERO15; MR0 | 1,596.51 |
| 2024 | IACC; PHEV20; LDB; SAX; ROLL20; AERO20; MR1 | 10,122.64 |
| | Cost Difference | 8,526.13 |

Table VI–108 shows the costs, and where to find them, for the drivetrain components subtracted from the MY 2023 version of the platform. The costs for current engine and transmission

were subtracted. To properly cost the engine it is important to note the engine was designated as a 4C1B engine, or, 4 cylinder 1 bank engine type. For more information about engine geometry

designation in the technology input file please see Section VI.A.7 Structure of Model Inputs and Outputs.

¹²⁶⁸ California Air Resources Board, NHTSA–2018–0067–12428, at 25.

Table VI-108 – Costs Removed During Electrification Cost Integration for Rav 4 example

| Technology | Designation | Data location | MY 2024 value (2018\$) |
|--------------|-------------|---|------------------------|
| Engine | HCR1 / 4C1B | Technologies Input file ('4C1B' Tab, 'HCR1' Row) | 5,835.32 |
| Transmission | AT8 | Technologies Input file ('SmallSUV' Tab, 'AT8' Row) | 2,195.21 |

The costs for the new electrification technology were then applied. For the specific example the simulated vehicle platform is being converted to a PHEV20 powertrain. For all the technologies in

the electrification path two major component groups were always added, the battery pack and the non-battery components. Hybrid electric technologies will also include the cost

for an engine. Table VI-109 shows the costing data for the non-battery pack electrification technology components, and where the cost data can be found.

Table VI-109 – Costs added for the Non-Battery Pack Electrification Technology**Components for Rav4 example**

| Technology | Application Note | Data location | MY 2024 value (2018\$) |
|------------------|--|--|------------------------|
| Engine | Per application features the PHEV20 technology has a specific engine applied | Technologies Input file ('4C1B Tab', 'PHEV20' row) | 5804.24 |
| PHEV20 Equipment | The non-battery components of the system | Technologies Input file ('SmallSUV' Tab, 'PHEV20' row) | 6049.74 |

The battery pack is cost is determined by multiplying the baseline battery pack cost by the learn curve factor. Table VI-

110 shows the calculation of the battery pack costs. The baseline battery costs are determined per discussions in

Section VI.C.3.e)(1) Battery Pack Modeling.
BILLING CODE 4910-59-P

Table VI-110 – Battery Pack Cost for Rav 4 Example

| | Application Note | Data Location | (2018\$) |
|-----------------|-------------------------|--|----------|
| Learning Factor | Value in MY 2024 = 1.24 | Technologies Input file ('SmallSUV' Tab, 'PHEV20' row) | |
| Base Cost | \$3590 (2018\$) | Battery_Costs.csv file, a core CAFE model file. | |
| | | Resultant Battery Pack Cost | 4,451.6 |

Table VI-111 shows a summary of the total cost application for the technology transition of the Rav4 example platform. The added costs of the addition of the

LDB technology, improvement from AERO15 to AERO20, improvement from MR0 to MR1 are summarized. However, the costing data for these technologies

can be found in the Technology Input file on the 'SmallSUV' tab under each technology's respective rows.

Table VI-111 – Summary of Technology Cost Change for Rav4 Example

| MY | Technology Removed | Technology added | MY 2024 Cost (2018\$) | Technology Cost (2018\$) |
|------|--------------------|---------------------|-----------------------|--------------------------|
| 2023 | | | | 1596.51 |
| | Engine (HCR1) | | (5,835.32) | -4,238.81 |
| | Transmission (AT8) | | (2,195.21) | -6,434.02 |
| | | PHEV20 Engine | 5804.24 | -629.78 |
| | | PHEV20 Components | 6049.74 | 5,419.96 |
| | | PHEV20 Battery Pack | 4,451.60 | 9,871.56 |
| | | MR1, AERO20 and LDB | 251.08 | 10,122.64 |
| 2024 | | | 8526.13 | 10,122.64 |

The following sections discuss specific electrification component cost comments on the NPRM, responses, and any relevant assumptions for the final rule analysis.

a) Micro Hybrid Cost

As stated in PRIA, the cost of SS12V in NPRM included the cost of the battery, learning rate and retail price equivalent.¹²⁶⁹ The assumed direct manufacturing cost (DMC) was the same as was used for the Draft TAR and the Proposed Determination,¹²⁷⁰ but adjusted for learning and updated from 2013 to 2016 dollars. Cost learning made the cost of SS12V presented in the NPRM slightly lower than the Proposed Determination.

ICCT compared the agencies' NPRM cost effectiveness estimate for SS12V with EPA's Proposed and Final Determination analyses, and concluded that the latter analyses found SS12V cost nearly \$100 less than the agencies found in the NPRM, with a higher effectiveness benefit.¹²⁷¹ ICCT noted its difficulty in evaluating whether SS12V technology was actually cost-effective, since the NPRM CAFE model added the incremental cost of BISG over SS12V. ICCT stated that because SS12V is not

as cost effective as other technologies in the electrification technology pathway, such as BISG, the analysis' estimate of SS12V costs was exaggerated and resulted in an unrealistic increase in compliance costs.

While BISG is more expensive than the SS12V, BISG provides additional benefits such as smoother start-stop (reduced vibration during each start-stop event), launch assist and/or torque assist (during certain sudden acceleration while passing or load at low speed for short burst of time). Therefore, the effectiveness of SS12V should not be compared to BISG. The agencies have always considered BISG as a separate technology. Also, the effectiveness of SS12V in the Proposed Determination was determined using ALPHA modeling. A peer reviewer noted that "[a]ccording to the documentation review, ALPHA's stop/start modeling appears to be very simplistic."¹²⁷² As discussed in Section VI.B.3 Autonomie model, the Autonomie tool simulates the technology as part of the full vehicle system, accounting for interactions with other technologies, and therefore the agencies believe the full-vehicle simulations provide more realistic effectiveness estimates than the value from the Proposed Determination. For

these reasons, the agencies disagree with ICCT's assertions. For SS12V, the agencies continued to use the costs from the NPRM, which are consistent with the Draft TAR and Proposed Determination. The ETDS costs presented in the final rule do not include the cost of the battery.

b) Mild Hybrid Cost

The belt integrated starter generator (BISG) and crank integrated starter generator (CISG), sometimes referred to as mild hybrid systems, provide idle-stop capability and use a higher voltage battery with increased energy capacity over typical automotive batteries. The higher voltage allows the use of a smaller, more powerful and efficient electric motor/generator which replaces the standard alternator. For the NPRM the agencies developed the costs for the mild hybrid systems assuming the use of a 115V system. The battery, motor, and supporting components were sized and costed based on this voltage level.

Many commenters asserted that the costs presented in the NPRM analysis for BISG and CISG systems were inflated or incorrect.¹²⁷³ ICCT noted that because mild hybrid systems were

¹²⁷³ International Council on Clean Transportation, NHTSA–2018–0067–11741; Union of Concerned Scientists, NHTSA–2018–0067–12039; Fiat Chrysler Automobiles, NHTSA–2018–0067–11943; Alliance of Automobile Manufacturers, NHTSA–2018–0067–12073; California Air Resources Board, NHTSA–2018–0067–11873.

widely adopted by the fleet under the augural standards, the high cost of those systems had a significant impact on the costs of the standards.¹²⁷⁴

Meszler Engineering Services noted that the NPRM documentation presented BISG/CISG battery costs that were “not unreasonable,” and that the CAFE model database of battery costs used for NPRM analysis included estimates for those electrification technologies that were \$259 higher than those presented in the NPRM documentation.¹²⁷⁵ Meszler surmised that it initially appeared as if the model may have been applying a redundant RPE factor to BISG/CISG costs, but noted that the determination that the costs differed from those documented by a constant absolute offset made that assumption an unlikely possibility.

ICCT and UCS both noted the discrepancy between the reported battery costs in the PRIA and costs reported in the NPRM Autonomie simulation databases.¹²⁷⁶ ICCT disagreed with the agencies’ approach to modeling batteries in the NPRM analysis, stating that “[n]ot only is [the Argonne] database exceedingly difficult to access to modify battery costs (as battery costs should be a user input), but it makes it much harder to see how battery costs affect mild hybrid costs over time.”¹²⁷⁷ Claimed difficulties aside, ICCT concluded that the battery costs were outdated and grossly overstated, based on the tables in section 6.3.9.12 of the PRIA and the outputs of the low battery cost sensitivity case, which ICCT stated were more closely aligned with EPA and other research on battery costs. ICCT presented its own best estimate of NPRM BISG costs, stating that they were not able to make the PRIA and datafile costs match up.

Several commenters noted that the costs of BISG/CISG systems were higher for Small Cars/SUVs and Medium Cars than for Medium SUVs and Pickup trucks, which the Alliance and FCA described as “implausible” and “misaligned with industry understanding,” and which ICCT described as “contrary to basic engineering logic, which holds that a system which would be smaller and have lower energy and power

requirements would be less expensive, not more.”¹²⁷⁸ Both ICCT and UCS stated that regardless of alleged errors in costs between technology classes, even the lower of the values presented in the PRIA overestimated the cost of mild hybrid batteries.¹²⁷⁹

The Alliance and FCA urged the agencies to update the CAFE model to address this issue so that the cost of compliance was properly reflected in the results. To estimate the impact of the error, the Alliance and FCA modified the technology input file so that the Medium SUV and Pickup truck electrification costs were changed to be identical to the Small Car/SUV and Medium Car costs for SS12V, BISG, and CISG, and re-ran the CAFE model to show an estimated \$13 billion increase in compliance costs under the augural standards with the error corrected.¹²⁸⁰

Conversely, CARB modified the fuel consumption improvement estimates for BISG systems to match those predicted by Argonne in a recent report after calculating the smallest modified improvement from MYs 2015–2025 for five vehicle classes, resulting in efficiency improvements of 8.5–11 percent.¹²⁸¹ CARB also reduced the non-battery costs for Small Car/SUVs to match the non-battery costs for Medium SUV and Pickup trucks, which CARB stated still reflected higher costs than those previously used by EPA in the Proposed Determination. CARB did not modify the battery costs, but did comment that they were overstated by approximately 50 percent “due to the erroneous oversizing of the battery.” CARB’s modified run decreased average vehicle technology costs by a range of \$300–\$500 per year, “reflecting an approximate 25 percent drop in 2029 model year incremental technology

costs to meet the existing standards relative to the rollback standards.”

Commenters also pointed to prior agency analyses, studies, and applications of BISG systems to provide examples of what they believed BISG system costs should be, with ICCT arguing that the agencies’ cost values for BISG/CISG systems were contrary to the research and evidence.¹²⁸² HDS noted that the 2018 PRIA estimate was approximately double the estimate from the 2016 Draft TAR, that the difference in battery costs between those two analyses did not explain the difference, and that there was no discussion in the PRIA that did so.¹²⁸³

UCS stated that BISG system costs have already reached that which was predicted in EPA’s first Final Determination, published in 2017, for 2025, and would decline further because of continued volume-based learning.¹²⁸⁴ UCS also cited a 2018 Argonne report that estimated the battery component cost for a mild hybrid system to be \$159.35, and a Chevrolet Malibu eAssist teardown study that estimated total battery subsystem direct costs at \$166, and battery modules, power distribution, and covers at \$120 in direct manufacturing costs.¹²⁸⁵ UCS summarized that the aforementioned costs are less than half the costs listed in the PRIA and approximately one quarter of the “BatPaCCost” value given in the Argonne input files. UCS also cited cost estimates from the 2015 NAS report and two EPA reports, and concluded that the agencies did not sufficiently explain why the NPRM cost data differed so substantially from this other available information.

ICCT cited its own 2016 study of supplier costs with estimates for 48V mild hybrid systems, estimating the system cost at \$600–\$1,000 (with costs on the lower side for cars and the higher side for light trucks) in the 2025 timeframe.¹²⁸⁶ ICCT pointed to the RAM 1500 pickup truck as an example of a vehicle with a BISG system that “has already validated the ICCT figures in 2019.” ICCT noted that the BISG system, branded as eTorque, was first offered as a “free standing” option on the RAM 1500 truck for \$800, and that price was recently raised to \$1,450. ICCT stated that even with the higher price, applying the agencies’ RPE of 1.5 means

that the direct manufacturing cost is less than \$1,000, which is less than the \$1,616 direct manufacturing cost estimate in the NPRM for 2016 pickup trucks.¹²⁸⁷ Similarly, UCS cited the \$500 premium that General Motors charged for the technology on its

Chevrolet Silverado pickup trucks with eAssist.¹²⁸⁸

The agencies reviewed all of the comments and information provided. It appears there may have been confusion about what costs were used for the Draft TAR and NPRM. For the Draft TAR,

non-battery BISG costs, including learning and RPE, were \$1,701 compared to \$1,186 for the NPRM (both costs in 2018 dollars). Therefore, the costs for the NPRM were lower than for the Draft TAR when cost accounting is on an equivalent basis.

Table VI-112 – Absolute BISG costs, without Batteries, Includes Learning and Retail Price Equivalent for MY 2017 in 2018\$

| Draft TAR¹²⁸⁹ | NPRM¹²⁹⁰ | Final Rule¹²⁹¹ |
|-------------------------------------|----------------------------|--------------------------------------|
| \$1,701 | \$1,186 | \$847 |

The agencies also determined the cost presented by EPA in Draft TAR (see Table 5.131 in Draft TAR) was the direct manufacturing cost of the BISG system, and not the retail price equivalent. The Draft TAR cost estimate in Table VI-112 includes the RPE and costs updated from 2013 to 2018 dollars. The agencies agree with the commenters about the discrepancy in the cost of the battery pack for the BISG system presented in PRIA and in CAFE model. To avoid any confusion, Table VI-112 shows the *non-battery* costs of the BISG system.

After considering the comments and reviewing the approach used in the NPRM, the agencies agreed updating the cost of the BISG system was appropriate for the final rule analysis. Adjustments were based on using a 48V BISG system instead of the 115V system used for the

NPRM. For the final rule, the agencies considered several cost sources, including the EPA-sponsored FEV report titled: Light-Duty Vehicle Technology Cost Analysis on 2013 Chevrolet Malibu ECO with eAssist BAS Technology Study.¹²⁹² Based on the teardown study, EPA estimated the direct manufacturing cost of the BISG system (without batteries) to be \$1,045 in 2013 dollars. This included a cost adjustment for reduced voltage insulation. The agencies also considered the 2019 Dodge Ram eTorque system retail price. A cost of \$1,195 for water-cooled system and \$1,450 for air-cooled system in 2018 dollars was deduced from the retail price of eTorque assist (BISG) system. The 2015 NAS report estimated the cost range of BISG

technology at \$888 to \$1,164 in 2010 dollars in 2025.¹²⁹³ This is equivalent to a range of \$1,020 to \$1,337.27 in 2018 dollars in 2025. The agencies also reviewed confidential business information on BISG cost and mass estimates provided by manufacturers.

For the final rule analysis, the agencies used the A2Mac1 database to develop a bill of materials for BISG systems. The agencies sourced cost estimates for the motor, inverter and DC-DC converter from the 2017 EETT roadmap report.¹²⁹⁴ The agencies used BatPaC model version 3.1 to perform a standalone analysis determining the cost of a battery pack for the 48V system.¹²⁹⁵ Table VI-113 shows the cost and mass estimates for BISG components used in the final rule.

¹²⁸⁷ ICCT also stated that the eTorque system offered improved performance and driveability and contributes to higher payload and towing ratings for 2019 compared with 2018, and noted that the agencies “have completely failed to account for the consumer value of the utility benefits” from the system. The agencies’ approach to simulating performance neutrality and the consumer benefit of increased performance are discussed in Section VI.B.3.a)(6) Performance Neutrality.

Table VI-113 – Cost and Mass Estimate of BISG components (2018 dollars)

| Components | DMC | RPE |
|---|--------------|----------------|
| Motor, Inverter & cooling system (10kW) | \$184 | \$276 |
| DC to DC converter (2kW) | \$184 | \$276 |
| Battery Pack (0.43kWh) | \$405 | \$608 |
| Water Pump | \$43 | \$65 |
| Wiring harness | \$29 | \$44 |
| Connecters | \$10 | \$16 |
| Belt pulley modifications to A/C compressor | \$10 | \$15 |
| Auxillary electric oil pump to transmission | \$46 | \$69 |
| Modifications to auxillary brake pump | \$43 | \$65 |
| Brackerts for motor and battery attachment | \$15 | \$23 |
| Total | \$970 | \$1,455 |

The agencies compared the cost estimates in the 2017 EETT roadmap report and found they aligned well with cost estimates from sources cited by commenters. For reference, Table VI-113 above showed the cost estimate for BISG system (without the battery) used in Draft TAR, NPRM and in Final Rule. Furthermore, the agencies considered the Alliance and FCA analysis, provided in their respective comments, recommending the use of the same BISG system cost for both cars and trucks.¹²⁹⁷ ¹²⁹⁸ This analysis, supplemented with CBI data, demonstrated that the costs for implementing BISG systems on different vehicle classes was not appreciably different. The agencies agree with this assessment. For the final rule analysis, the cost of the BISG system is the same for cars, SUVs, and pickups.

(c) Strong Hybrid Cost

In the NPRM and this final rule analysis, the total cost for strong hybrids (SHEVP2 and SHEVPS) included the electric machine, battery pack, IC engine, and transmission. Discussed earlier in Section VI.C.3.d) Electrification Effectiveness Modeling, each strong hybrid powertrain is optimized for the given vehicle class by appropriate sizing of the electric

machine, IC engine and battery pack. Accordingly, the costs represent the optimized system. For the NPRM, the agencies referred to the “*Assessment of vehicle sizing, energy consumption, and cost through large-scale simulation of advanced engine technologies*” report to estimate the cost and effectiveness for different hybrid systems for the NPRM.¹²⁹⁹ For the final rule, as discussed in Section 2) and further below, the agencies sourced cost estimates from the October 2017 U.S. DRIVE report, “*Electrical and Electronics Technical Team Roadmap*.”¹³⁰⁰

SHEVP2 and SHEVPS have different characteristics and in turn have different costs, as reflected in both the NPRM and this final rule analysis. The cost for engines and transmissions for SHEVP2s are based on estimates discussed further in Sections VI.C.1 Engine Path and VI.C.2 Transmission Path, respectively. The cost for SHEVP2

electric machines and battery packs were dependent on their sizes, which were optimized by the Autonomie sizing algorithm. SHEVPS total powertrain costs includes the optimized battery pack, electric machine, an Atkinson engine, and the CVT.

Many commenters generally stated that the costs of hybrid technology were overestimated in comparison to prior agency estimates and other publicly available sources, and that the agencies’ documentation of hybrid system costs was unclear.

Meszler Engineering Services commented that the net costs of vehicles that apply SHEVP2 technology were in error, resulting from the way that the CAFE model applied HCR, CEGR and TURBO technology in combination with the SHEVP2 strong hybrid system.¹³⁰¹

HDS claimed that cost estimates for both SHEVP2 and SHEVPS were significantly higher than the Draft TAR estimates, differing by a factor of about 2 for SHEVP2 and by a factor of 2.5 for SHEVPS, with no justification given for the increase in costs.¹³⁰² HDS noted that the SHEVPS cost estimates were particularly surprising since the costs have been investigated extensively since that technology was introduced to the market over a decade ago. HDS stated that the 2016 TAR estimates were in line with other analyses like the NAS

estimate, and consistent with actual retail price increments observed in the market.

HDS also pointed to cost estimates based on teardown studies sponsored by EPA and the European Union,¹³⁰³ public cost data disclosed by suppliers of hybrid systems, and the retail prices of available hybrid vehicles as estimates that contradict the agencies' NPRM cost estimates. HDS compared the European Vehicle Market Phase 1 FEV cost analysis to the costs published by EPA in the TAR, concluding that the EU costs "even at [levels adjusted for the strength of the Euro] are quite similar to EPA estimates of \$2,650 to \$3,300 (depending on vehicle size) published in the TAR for the P2 hybrid, and also shows that the PS hybrid is just 7 percent more expensive than the P2 hybrid." HDS stated that battery costs have also certainly decreased since 2012 when the report was written, so current costs are estimated to be approximately \$400 less than the values cited above.

HDS also cited a methodology to estimate costs from retail price increments in the market,¹³⁰⁴ stating that a typical cost-to-retail price ratio is 1.5. Applying this methodology, the cost of the SHEVPS hybrid as used by Ford and Toyota would be in the \$2,500 to \$3,000 range, the cost of a SHEVP2 as used by Hyundai Kia would be \$2,250, and the cost of a low volume and/or luxury model system would be estimated at \$3,300 for a SHEVP2.

Similarly, ICCT stated that the agencies failed to analyze properly the dozens of hybrid vehicles in the marketplace, their costs which were lower than the agencies assumed, and their rapid improvements from automakers and suppliers competitively developing lower cost components for those vehicles.¹³⁰⁵ ICCT observed an incremental price increase in the analysis for hybrid vehicles under the augural standards of approximately \$6,600 per hybrid vehicle in 2017 and \$4,800 in 2025, and concluded that this was not a plausible result considering hybrid component costs and full-vehicle prices in the marketplace in 2016 as well as the technology improvement that continues to enter the fleet. ICCT stated that the agencies must set a maximum cost premium for full hybrids

of \$2,500 in 2017, declining linearly to \$1,400 by 2025 for mid-size cars and crossovers, with cost components likely scaling by vehicle power requirements (up for pickups, down for smaller cars), which it stated the agencies must also account for in the modeling.

ICCT stated that the agencies must disclose the basis for the "unrealistically high" hybrid system cost estimates, such that the public can clearly connect the bottom-up cost components to full vehicle costs for all vehicle models that have hybrid cost applied.¹³⁰⁶ ICCT stated that hybrid system cost estimates are "one of the most important technology cost estimations to assess the Augural standards' compliance cost, as the NPRM projects that 22 percent of vehicles will need full hybrid systems to meet the augural standards," and accordingly after disclosing those costs, the agencies must provide another opportunity for public comment. Similarly, CARB stated that it was unable to decipher the hybrid cost components, and without that information could only guess as to why the costs increased relative to costs in the Draft TAR and EPA's Proposed Determination.¹³⁰⁷ As such, CARB stated they could not make a conclusion as to whether improper battery resizing, incorrectly modeled batteries, or oversized electric motors contributed to the overestimation of costs for strong hybrid systems.

The agencies believe comparing the retail price of P2 or PS hybrid to conventional vehicles could be misleading. Even though hybrid vehicles may have higher direct manufacturing costs, manufacturers may choose not to price it higher than the conventional version of the vehicle. In other words, manufacturers may choose to subsidize the cost of hybrid technologies to gain overall credit for fleetwide compliance. Therefore, the agencies believe that comparing retail price between hybrid and conventional vehicles should be done only when other sources of information are available to corroborate the differences in retail price.

The agencies also referred to an EPA-sponsored teardown and cost estimate report as suggested by HDS. Table VI-114 shows the absolute cost of P2 and PS hybrid systems as estimated in the EPA sponsored teardown report and the absolute cost estimated in the final rule in 2018\$. As indicated above, the

absolute cost in the final rule includes the cost of transmissions for the PS and P2 hybrid systems. The EPA teardown cost estimate includes the cost of the eCVT for the PS hybrid systems only. The P2 hybrid system costs do not include the cost of engine and transmission in the table below.

Although ICCT suggested that the agencies cap the maximum cost premium for full hybrids of \$2,500 in 2017 and linearly decrease the cost to \$1,400 by 2025, ICCT did not provide any supporting material to suggest that maximum upper limit of \$2,500 for full hybrid is economically feasible, nor did they provide an example of an existing full hybrid vehicle in the marketplace with a technology increase of \$2,500 in 2017. ICCT also did not make it clear if the costs suggested would be applicable to P2 or PS hybrid architecture.

Based on the comments, the agencies reassessed SHEVP2 and SHEVPS cost estimates for the final rule. As discussed above, the agencies referred to U.S. DRIVE's October 2017 report, "Electrical and Electronics Technical Team Roadmap"¹³⁰⁸ to estimate the cost of motors and inverters. The agencies also agreed with commenters and referenced the MY 2016 Chevrolet teardown report by UBS to estimate the cost of other hybrid components such as wiring harness, cables, voltage-step-down DC to DC converters, and on-board chargers. Per Section VI.C.3.e)(2) Non-battery Electrification Component Costs, for the final rule, the cost of non-battery hybrid system components includes the cost of traction motor, motor/generators, high voltage cables and connectors, charging cord, and on-board chargers. The cost of the planetary gear set is also included in the cost of non-battery components. Per Section VI.B.4 Technology Costs, for the final rule, the cost of hybrid systems is presented as absolute cost, and not as an incremental to some previous technology (absolute cost includes the retail price equivalent). The agencies used the cost of the AT8L2 transmission as a cost proxy for the planetary gear set in P2 hybrid systems, and used the cost of CVTL2 transmission as a cost proxy for planetary gear set for PS hybrid systems. It should also be noted the costs shown here do not include the cost of engine coupled to the hybrid system.

The agencies reviewed the FEV 2010 Ford Fusion HEV teardown report, Light Duty Technology Cost Analysis, Power-

Split and P2 HEV Case Studies.¹³⁰⁹ In a Split-HEV architecture, there are two motors; one motor provides torque while the other motor act as a generator to recapture the energy during regenerative braking. The report does not capture the cost of motor-generator and the cost of the DC to DC converter. The report did not include an extensive teardown of a P2 hybrid vehicle, but rather made a cost adjustment for the PS motor and inverter to reflect additional cost. Table VI-114 shows the breakdown of cost estimates for the

electric machine in the 2010 Ford Fusion HEV.¹³¹⁰ Since the costs were developed in 2009\$, the cost estimates for the same components are presented in 2018\$. Table VI-115 shows the cost estimate for electric machines for a midsize passenger car for MY 2017 in 2018\$.¹³¹¹ The cost is estimated using the EETT Roadmap report as explained earlier. Since EPA uses indirect cost multiplier (ICM) to determine the final retail price, and ICMs vary for different technologies, the agencies compared the

direct manufacturing cost from report to the direct cost estimate in the final rule.

The direct manufacturing cost estimated in the Light Duty Technology Cost Analysis, Power-Split and P2 HEV Case Studies published for EPA is \$3,689.28 in 2018\$, and direct manufacturing cost estimated for electric machines in this final rule is \$4,355.82. As mentioned before, the cost of the motor-generator and the cost of the DC to DC converter is not captured in that report.

Table VI-114 - Absolute Cost of P2 and PS Hybrid Systems in FEV Report and Final Rule

| 2010 Ford Fusion HEV (not including battery pack) | 2009\$ DMC | 2018\$ DMC |
|--|-----------------------|-----------------------|
| Transmission System (eCVT and Motor) | \$2,216.43 | \$2576.34 |
| Electrical Power Supply System (Inverter) | \$755.96 | \$878.42 |
| Electrical Distribution and Control System (Cables) | \$201.5 | \$234.22 |
| Total of HEVPS in FEV report | \$3,173.89 | \$3,689.28 |

Table VI-115 - Direct Manufacturing Cost Estimate for a Midsize Non-performance Car for MY 2017 (2018\$)

| Cost of Electric Machine in Final Rule (not including battery pack) | MY 2017 | MY 2017 |
|--|----------------|----------------|
| Midsize Non-Performance Car (MY2017) | DMC | RPE |
| Motor + Inverter +DC Converter + Cables | \$2666.44 | \$3999.66 |
| CVT | \$1689.37 | \$2534.06 |
| Total Cost of SHEVPS in final rule | \$4355.82 | \$6533.73 |

(d) PHEV Cost

Plug-in hybrid vehicles' costs were developed similar to strong hybrids for the NPRM analysis and the final rule analysis. The plug-in-hybrid system components were optimized, per Section VI.C.3.d)(2) Modeling and Simulating Vehicles with Electrified Powertrains in Autonomie and the resultant systems were used to determine costs, per Battery Pack Modeling and Non-battery

Electrification Component Costs. Per Section VI.C.3.c) Electrification Adoption Features, the agencies used one engine technology and one transmission technology per plug-in hybrid architecture type.

For PHEVs following SHEVP2 on the hybrid/electric architecture path, per Section VI.C.3.a)(1) Electrification technologies, the total cost of the technology package was determined from summing the costs of the TURBO1 engine, the AT8L2 transmission, and the

battery and non-battery electrification technology components. For PHEVs following SHEVPS on the hybrid/electric architecture path, per Section VI.C.3.a)(1) Electrification technologies, the total cost of the technology package was determined from summing the costs of the Atkinson engine, the CVT transmission, and the battery and non-battery electrification technology components.

CARB provided observations about non-battery component costs for PHEVs,

¹³⁰⁹ Light Duty Technology Cost Analysis, Power-Split and P2 HEV Case Studies, EPA-420-R-11-015 (November 2011), available at <https://nepis.epa.gov/Exe/ZyPDF.cgi?P100EG1R.PDF?Dockey=P100EG1R.PDF>.

¹³¹⁰ Table D-4 (components considered are transmission, power distribution cables and Inverter). The cost of inverter is from Table D-11.

¹³¹¹ Average peak power for the traction motor used in this final rule is 72kW, and 37kW continuous power for the generation motor.

arguing that what the agencies asserted for the incremental costs of a PHEV over a strong hybrid vehicle are not supported in the market.¹³¹² CARB cited the Toyota Prius Prime and Hyundai Sonata as examples of vehicles that share most of their components with their non-plug-in hybrid counterparts, with components like the on-board charger and higher voltage, larger energy capacity battery pack excepted. CARB stated the agencies' lack of discussion about how non-battery component costs were developed made it "virtually impossible to understand what the drivers are for the increases in costs relative to the Agencies' previous analysis for the 2016 Draft TAR and EPA's Proposed Determination." CARB concluded that the available PHEV market offerings do not support the higher costs relative to the Draft TAR and EPA's Proposed Determination analyses, and no justification was provided for the change.

The agencies agree with CARB that the incremental costs of PHEV over strong hybrid costs were too high, and that values were not supported by the market. In response to this comment, the agencies updated the non-battery component costs as well as the battery costs to better reflect the market values. In addition, the agencies have optimized the Autonomie modeling in a way to maintain the same engine, transmission and other components from a SHEVP2 or SHEVPS moving to a PHEV20/50 or PHEV20T/50T.¹³¹³ For further discussions on PHEV modeling and updates, see Section VI.C.3.a)(1) Electrification technologies and Section VI.C.3.d) Modeling and Simulating Vehicles with Electrified Powertrains in Autonomie. The updates discussed here and applied to the final analysis resulted in values that more accurately represented PHEV technology costs.

(e) BEV Cost

For the NPRM and this final rule analysis, the total costs of BEVs included optimized battery pack and electric machine costs. Like the other electrified powertrains, Autonomie optimized both the size of the battery pack and electric machine to fulfill the performance neutrality requirements for each vehicle. Further discussion on electrification technology component sizing and optimization is provided in Section VI.C.3.d) Modeling and Simulating Vehicles with Electrified Powertrains in Autonomie. Discussion on electrification component costing is provided in Battery Pack Modeling and Non-battery Electrification Component Costs. When computing the total cost of a vehicle, the agencies remove the costs of the IC engines and transmission when a conventional or hybridized powertrain adopts BEV technologies. In Section VI.C.1 Engines Path and Section VI.C.22 Transmission, the agencies discussed the absolute costs used for engine and transmission technologies in the final rule analysis.

ICCT stated that if the agencies had considered BEV battery and other component costs correctly, cost parity would be reached with conventional combustion vehicles in the 2025–2027 timeframe.¹³¹⁴ ICCT went on to allege that if the agencies removed all constraints on electric vehicles,¹³¹⁵ they would appropriately realize that the 2025 standards are more cost-effective if electric vehicles are included.

The agencies disagree with ICCT's statement that BEVs would reach parity to IC engines by the 2025–2027 timeframe. For this final rule analysis, the agencies have updated the battery pack costs, electric machine costs, and excluded costs of IC engines and transmission when a vehicle was converted to a BEV. However, the costs

still did not reach parity within the rulemaking time frame. Furthermore, NHTSA notes that the decision to exclude BEV technology from the CAFE program standard-setting analysis is not a choice made by the agency, but a statutory requirement.¹³¹⁶

(f) FCV Cost

For the NPRM and the final rule analysis the agencies considered fuel cell vehicle technology advancements in hydrogen storage tanks, sensors and control systems, and market penetration.¹³¹⁷ The agencies are also considered the availability of hydrogen refueling stations across the country and cost of compressed hydrogen.^{1318 1319} Although the agencies did not receive any comments on the cost of fuel cell vehicles, the agencies updated the cost of hydrogen storage tanks and fuel cells based on a cost analysis from Department of Energy (DOE), Office of Energy Efficiency and Renewable Energy (EERE), Fuel Cell Technologies Office.¹³²⁰

The DOE estimates that the cost of a compressed gas storage system is around \$28/kWh (assumed rate of production of 10,000 units per year). The hydrogen fuel price ranges from \$12.85 to \$16 per kilogram, which translates to approximately \$5.60 per gallon on an equivalent energy basis.¹³²¹

Table VI–116 shows the evolution of the fuel cell vehicle costs from the Draft TAR to final rule (costs include the fuel cell, control systems, motors, inverters, hydrogen storage tanks, wiring harness, hydrogen fuel sending lines, safety systems, sensors and hardware for mounting and installation). The cost of the battery pack and battery management system is not included in the cost of the fuel cell vehicle.

Table VI-116 – Cost of Fuel Cell Technologies(2018\$)

| Draft TAR | NPRM | Final Rule |
|-------------|-------------|-------------|
| \$20,346.54 | \$17,381.97 | \$20,512.00 |

¹³¹² California Air Resources Board, NHTSA–2018–0067–11873.

¹³¹³ *I.e.*, a SHEVP2 with a turbocharged engine may adopt PHEV20T or PHEV50T technology, but a SHEVPS will only ever adopt PHEV20 or PHEV50 technology, as the SHEVPS do not use turbocharged engines.

¹³¹⁴ International Council on Clean Transportation, NHTSA–2018–0067–11741.

¹³¹⁵ As discussed above, the agencies believe that ICCT misunderstood the agencies' statutory obligations and the differences between the

standard setting modeling scenario and the "real-world" modeling scenario. The agencies did not apply additional constraints on BEVs in the NPRM analysis.

¹³¹⁶ See 49 U.S.C. 32902(h).

4. Mass Reduction

Mass reduction is a relatively cost-effective means of improving fuel economy and reducing CO₂ emissions, and vehicle manufacturers are expected to apply various mass reduction technologies to meet fuel economy and CO₂ standards. Reducing vehicle mass can be accomplished through several different techniques, such as modifying and optimizing vehicle component and system designs, part consolidation, and adopting lighter weight materials (advanced high strength steel, aluminum, magnesium, and plastics including carbon fiber reinforced plastics). The cost for mass reduction depends on the type and amount of materials used, the manufacturing and assembly processes required, and the degree to which changes to plants and new manufacturing and assembly equipment is needed. In addition, manufacturers may develop expertise and invest in certain mass reduction strategies that may affect the approaches for mass reduction they consider and the associated costs. Manufacturers may also consider vehicle attributes like noise-vibration-harshness (NVH), ride quality, handling, and various acceleration metrics when considering how to implement any mass reduction strategy. See Section VI.B.3.a)(5) Maintaining Vehicle Attributes for more details.

The automotive industry uses different metrics to measure vehicle weight. Some commonly used measurements are vehicle curb weight,¹³²² gross vehicle weight (GVW),¹³²³ gross vehicle weight rating (GVWR),¹³²⁴ gross combined weight (GCVW),¹³²⁵ and equivalent test weight (ETW),¹³²⁶ among others.

The vehicle curb weight is the most commonly used measurement when comparing vehicles. A vehicle's curb weight is the weight of the vehicle including fluids, but without a driver, passengers, and cargo.

¹³²² This is the weight of the vehicle with all fluids and components but without the drivers, passengers, and cargo.

¹³²³ This weight includes all cargo, extra added equipment, and passengers aboard.

¹³²⁴ This is the maximum total weight of the vehicle, passengers, and cargo to avoid damaging the vehicle or compromising safety.

¹³²⁵ This weight includes the vehicle and a trailer attached to the vehicle, if used.

¹³²⁶ For the EPA two-cycle regulatory test on a dynamometer, an additional weight of 300 lbs. is added to the vehicle curb weight. This additional 300 lbs. represents the weight of the driver, passenger, and luggage. Depending on the final test weight of the vehicle (vehicle curb weight plus 300 lbs.), a test weight category is identified using the table published by EPA according to 40 CFR 1066.805. This test weight category is called "Equivalent Test Weight" (ETW).

A vehicle's glider weight, which is vehicle curb weight minus the powertrain weight, is used to track the potential opportunities for weight reduction not including the powertrain. A glider's subsystems may consist of the vehicle body, chassis, interior, steering, electrical accessory, brake, and wheels systems. However, as noted in the PRIA, the definition of a glider may vary from study to study (or even simulation to simulation).

Each of the subsystems presents an opportunity for weight reduction; however, some weight reduction is dependent on the weight reduction of other subsystems. The agencies characterize mass reduction as either primary mass reduction or secondary mass reduction. Primary mass reduction involves reducing mass of components that can occur independent from the mass of other components. For example, reducing the mass of a hood (*e.g.*, replacing a steel hood with an aluminum hood) or reducing the mass of a seat are examples of primary mass reduction because each can be implemented independently. Other components and systems that may contribute to primary mass reduction include the vehicle body, chassis, and interior components.

When significant primary mass reduction occurs, other components designed based on the mass of primary components may be redesigned as well. An example of a subsystem where secondary mass reduction can be applied is the brake system. If the mass of primary components is reduced sufficiently, the resulting lighter weight vehicle could safely maintain braking performance and attributes with a lighter weight brake system. Other examples of components where secondary mass reduction can be applied are wheels and tires.

For this analysis, the agencies consider mass reduction opportunities from the glider subsystems of a vehicle first, and then consider associated opportunities to downsize the powertrain, which are accounted for separately.¹³²⁷ As explained later, in the Autonomie simulations, the glider system includes both primary and secondary systems from which a percentage of mass is reduced for different glider weight reduction levels; specifically, the glider includes the body, chassis, interior, electrical accessories, steering, brakes and wheels.

¹³²⁷ When the mass of the vehicle is reduced by an appropriate amount, the engine may be downsized to maintain performance. See Section VI.B.3.a)(5) Maintaining Vehicle Attributes and Section VI.B.3.a)(6) Performance Neutrality for more details.

The model sizes the powertrain based on the glider weight and the mass of some of the powertrain components in an iterative process. The mass of the powertrain depends on the powertrain size. Therefore, the weight of the glider impacts the weight of the powertrain.¹³²⁸ See Section VI.B.3.a)(3) Vehicle models for Autonomie and Section VI.B.3.a)(4) How Autonomie Sizes Powertrains for Full Vehicle Simulation for more details.

The agencies use glider weight to apply non-powertrain mass reduction technology, and use Autonomie simulations to determine the size of the powertrain and corresponding powertrain weight for the respective glider weight. The combination of glider weight (after mass reduction) and re-sized powertrain weight equal the vehicle curb weight. See Section VI.C.4.d)(1) glider mass and mass reduction subsection below for more detail on glider mass and glider mass reduction.

(a) Mass Reduction in the CAFE Model

Several studies have explored the amount of vehicle mass reduction that is feasible in the rulemaking timeframe and the cost for that mass reduction.^{1329 1330 1331 1332} Those studies were sponsored by the agencies, CARB, ICCT, the automotive industry, and material manufacturers, and are discussed in Section VI.C.4.e)(1), below. All of the studies showed that the maximum feasible amount of mass reduction that can be applied in the rulemaking timeframe is around 20 percent of a baseline vehicle's curb weight. The National Academies of Sciences similarly concluded, based on some of these same studies along with other information, that it is feasible to

¹³²⁸ Since powertrains are sized based on the glider weight for the analysis, glider weight reduction beyond a threshold amount during a redesign will lead to re-sizing of the powertrain. For the analysis, the glider was used as a base for the application of any type of powertrain. A conventional powertrain consists of an engine, transmission, exhaust system, fuel tank, radiator and associated components. A hybrid powertrain also includes a battery pack, electric motor(s), generator, high voltage wiring harness, high voltage connectors, inverter, battery management system(s), battery pack thermal system, and electric motor thermal system.

¹³²⁹ DOT HS 811 692: Investigation of Opportunities for Lightweight Vehicles Using Advanced Plastics and Composites.

¹³³⁰ A Review of the Safety of Reduced Weight Passenger Cars and Light Duty Trucks by Michigan Manufacturing Technology Center, October 2018.

¹³³¹ ATG Silverado Body Light weighting Study, Aluminum Technology Group, January 2017.

¹³³² 2013 NanoSteel Intensive Body-In-White, EDAG and NanoSteel Company Inc.

reduce up to 20 percent of the mass of the vehicle.¹³³³

As discussed in Section VI.C.4.e), the mass reduction studies show that the cost for mass reduction increases progressively as the amount of mass reduction increases. In other words, lower levels of mass reduction are more cost effective than higher levels of mass

reduction. As in past rulemakings, the agencies have considered multiple levels of mass reduction to provide options similar to what manufacturers could consider at vehicle redesigns.

For the NPRM, the agencies included five levels of mass reduction with a maximum of 20 percent glider mass reduction, corresponding to 10 percent

curb mass reduction, using the assumption that the glider was 50 percent of curb weight. Table VI–117 shows the glider and curb weight mass reduction levels for each level of mass reduction considered in the NPRM analysis.

Table VI-117 – NPRM Mass Reduction Technology Level and Associated Glider and Curb Mass Reduction (Passenger Cars and Light Trucks)

| MR Level | MR % (50% Glider Share) | Approximate Percentage Mass Reduction at Curb Weight Level |
|-----------------|--------------------------------|---|
| MR0 | 0% | 0.0% |
| MR1 | 5% | 2.5% |
| MR2 | 7.5% | 3.8% |
| MR3 | 10% | 5.0% |
| MR4 | 15% | 7.5% |
| MR5 | 20% | 10.0% |

The agencies received a number of comments suggesting that the amount of mass reduction allowed should be 20 percent of curb weight, as well as suggestions that the agencies should assume the glider represents 75 percent of the vehicle's curb weight. These comments are addressed in more detail in Section VI.C.4.d) below, but some understanding of how the glider share assumption affects the maximum amount of mass reduction allowed in the CAFE model is required here.

Several commenters stated that the agencies should allow further levels of mass reduction technology improvements in the CAFE model. For example, ICCT commented that the agencies must revise their treatment of mass reduction because studies have demonstrated that at least 20% mass reduction of curb weight is available for adoption across vehicle classes by 2025.¹³³⁴ ICCT stated that based on these studies, the agencies must increase the maximum available mass reduction potential levels to include up to 20% and 25% mass reduction of curb weight, as the industry “will cost-effectively deploy at least 15% vehicle curb mass reduction in the 2025 timeframe at net zero cost.” ICCT caveated that amount

of mass reduction seems less likely in smaller cars, which typically employ lower levels of mass reduction, so a constraint of 7.5 percent mass reduction as was applied in the Draft TAR would be appropriate for those vehicles.

ICCT also commented that there were numerous material improvements in development that were not considered in the rule, including but not limited to higher strength aluminum, improved joining techniques for mixed materials, third-generation steels with higher strength and enhanced ductility, a new generation of ultra-high strength steel cast components, and metal/plastic hybrid components, among other technologies mentioned in ICCT's working paper on light-weighting.

In assessing these comments, the agencies reconsidered the mass reduction studies and available reports and agreed that additional levels of mass reduction should be available for the final rule analysis. In response to comments, the agencies made two adjustments to allow higher levels of mass reduction in the analysis. First, as explained in Section VI.C.4.d)(1), below, the agencies increased the glider percentage of vehicle curb weight used for the analysis from 50 percent to 71

percent. As explained in that section, increasing the glider percentage also increases the amount of curb weight reduction for all levels of mass reduction. Second, the agencies created another level of mass reduction (MR6) in the CAFE model, which represents a significant application of carbon fiber in the vehicle to achieve nearly 30 percent reduction in glider weight (which approximately translates to 20 percent reduction in vehicle curb weight). For example, incorporating a carbon fiber tub,¹³³⁵ or a carbon fiber monocoque with aluminum sub frame in the front and back,¹³³⁶ or a carbon fiber splitter and carbon fiber wheels,¹³³⁷ allows for greater levels of mass reduction, albeit at a very high cost. These technologies are not ready for high volume production vehicles.

Table VI–118 shows the levels of mass reduction technology available for application in the final rule analysis, with the associated glider weight percentage reduction and the percentage curb weight reductions for passenger cars and light trucks. As discussed in Section VI.C.4.c) below, the agencies declined to place a constraint on the amount of mass reduction technology that smaller cars could adopt.

¹³³³ Cost, Effectiveness and Deployment of Fuel Economy Technologies for Light-Duty Vehicles, National Academy of Sciences, 2015, at 212.

¹³³⁴ NHTSA–2018–0067–11741. ICCT also alleged that the agencies intentionally disregarded the studies that presented this result; those comments

are discussed in Section VI.C.4.e) Mass Reduction Costs, below.

¹³³⁵ The BMW i3 and BMW i8, which are about 20 percent lighter than an average MY 2017 vehicle, use a carbon fiber tub.

¹³³⁶ The Alfa Romeo 4c/4c Spider, which is about 20 percent lighter than an average MY 2017 vehicle, uses this design.

¹³³⁷ The Ford Shelby GT350R which is about 20 percent lighter than an average MY 2017 vehicle, uses this design.

Table VI-118 – Final Rule Mass Reduction Technology Level and Associated Glider and Curb Mass Reduction

| MR Level | Percent Glider Weight | Percent Vehicle Curb Weight (Passenger Cars) | Percent Vehicle Curb Weight (Light Trucks) |
|-----------------|------------------------------|---|---|
| MR0 | 0% | 0.00% | 0.00% |
| MR1 | 5% | 3.55% | 3.55% |
| MR2 | 7.5% | 5.33% | 5.33% |
| MR3 | 10% | 7.10% | 7.10% |
| MR4 | 15% | 10.65% | 10.65% |
| MR5 | 20% | 14.20% | 14.20% |
| MR6 | 28% | 20.00% | 20.00% |

The agencies continue to believe the maximum feasible mass reduction levels identified in comprehensive design studies, such as those discussed in Section VI.C.4 Mass Reduction Costs are the most reliable for projecting the maximum amount of mass reduction in the rulemaking timeframe, and therefore have determined MR6 is the highest level that should be used for the final rule analysis. While the information provided by ICCT on newer materials and manufacturing and assembly methodology is interesting and relevant, this information, by itself, is insufficient to assess the amount of mass reduction that is feasible and the cost for the mass reduction. ICCT did not provide a comprehensive analysis showing a design concept that maintains vehicle attributes and performance, such as noise, vibration and harshness, stiffness, handling, compliance with NHTSA safety standards, good performance under NHTSA NCAP and IIHS rating systems, and other criteria. The various studies in Section VI.C.4.e) Mass Reduction considered those factors to varying degrees. Without that rigorous analysis, the actual amount of mass

reduction that could be enabled through the use of those materials and methods described by ICCT, and the cost of achieving that mass reduction, would be highly speculative. As explained in Section VI.C.4.e) Mass Reduction below, the agencies determined the NHTSA-sponsored design studies remain a reasonable basis for estimating a feasible amount of mass reduction and the cost for mass reduction in the rulemaking timeframe, because those studies considered a wide range of materials (including advanced materials) and design solutions.

(b) Analysis Fleet Mass Reduction Assignments

The agencies included an estimated level of mass reduction technology for each vehicle model in the MY 2016 analysis fleet for the NPRM, and have updated the estimates for the MY 2017 analysis fleet for the final rule analysis. The methodology used to provide each vehicle model an appropriate initial mass reduction technology level for further improvements was described in detail in the Draft TAR (when NHTSA first employed this methodology), in the PRIA accompanying the NPRM, and is

reproduced here, in part, to provide additional context to the agencies' responses to comments on analysis fleet mass reduction assignments. The methodology used in this final rule was unchanged from the NPRM.

For the Draft TAR, NHTSA/Volpe Center staff developed regression models to estimate curb weights based on other observable attributes. With regression outputs in hand, Volpe evaluated the distribution of vehicles in the analysis fleet. In addition, vehicle platforms were evaluated based on the sales-weighted residual of actual vehicle curb weights versus predicted vehicle curb weights. Based on the actual curb weights relative to predicted curb weights, platforms (and the subsequent vehicles) were assigned a baseline mass reduction level (MR0 through MR6). For the NPRM and final rule analysis, the agencies followed a similar procedure for the MY 2016 and MY 2017 analysis fleets.

To develop the curb weight regressions, the agencies grouped vehicles into three separate body design categories for analysis: 3-Box, 2-Box, and Pick-up.

Table VI-119 – Mass Reduction Body Styles Sets

| 3-Box | 2-Box | Pick-up |
|-------------------------------|---|----------------|
| Coupe Sedan Convertible | Hatchback Wagon Sport Utility Minivan Van | Pick-up |

For the NPRM and final rule analysis, the agencies retained the MY 2015

regressions for 3-Box and 2-Box vehicles, however the pickup category

regression was updated in response to comments on the Draft TAR. The

agencies trained a new regression with EPA MY 2014 data and added pick-up bed length as an independent variable. As a result of stepping back to MY 2014 data for the pick-up regression, the training data did not include the all-aluminum body Ford F-150 in the calculation of the baseline. The advanced F-150 in the MY 2015 pick-up regression meaningfully affected Draft TAR regression statistics because the F-150 accounted for a large portion of observations in the analysis fleet, and the F-150 included advanced weight savings technology.

The agencies leveraged many documented variables in the analysis fleet as independent variables in the regressions. Continuous independent variables included footprint (wheelbase × track width) and powertrain peak

power. Binary independent variables included strong HEV (yes or no), PHEV (yes or no), BEV or FCV (yes or no), all-wheel drive (yes or no), rear-wheel drive (yes or no), and convertible (yes or no). In addition, for PHEV and BEV/FCV vehicles, the capacity of the battery pack was included in the regression as a continuous independent variable. In some body design categories, the analysis fleet did not cover the full spectrum of independent variables. For instance, in the pickup body style regression, there were no front-wheel drive vehicles in the analysis fleet, so the regression defaulted to all-wheel drive and left an independent variable for rear-wheel drive.

Furthermore, the agencies evaluated alternative regression variables in response to comments from vehicle

manufacturers on the NHTSA/Volpe analysis in the Draft TAR.¹³³⁸ The agencies evaluated regressions including overall dimensions of vehicles, such as height, width, and length, instead of and in addition to just wheelbase and track width. The experimental regression variables only marginally changed predicted curb weight residuals as a percentage of predicted curb weight, at an industry level and for most manufacturers. The results were not significantly different, and therefore the agencies opted not to add these variables to regressions or replace independent variables presented in Draft TAR with new variables.

BILLING CODE 4910-59-C

Each of the three regressions produced outputs effective for identifying vehicles with a significant amount of mass reduction technology in the analysis fleet. Many coefficients for independent variables provided clear insight into the average weight penalty for the utility feature. In some cases, like battery size, the relatively small sub-sample size and high collinearity with other variables confounded coefficients.

By design, no independent variable directly accounted for the degree of weight savings technology applied to the vehicle. Residuals of the regression captured weight reduction efforts and noise from other sources.

The agencies received many comments on the Draft TAR encouraging the use of observed technologies in each vehicle, and in each vehicle subsystem to assign levels of mass reduction technology. As a practical matter, the agencies cannot conduct a tear down study and detailed

cost assessment for every vehicle in every model year. However, upon review of many vehicles and their subsystems, the agencies recognized a few vehicles with MR0 or MR1 assignments in NHTSA's analysis of the Draft TAR that contained some advanced weight savings technologies, yet these vehicles and their platforms still produced ordinary residuals. Engineers from industry confirmed important factors other than glider weight savings and the independent variables considered in the regressions may factor into the use of lightweight technologies. Such factors included the desire to lower the center of gravity of a vehicle, improve the vehicle weight distribution for handling, optimize noise-vibration-and-harshness, increase torsional rigidity of the platform, offset increased vehicle content, and many other factors. In addition, engineers highlighted the importance of sizing shared components for the most

demanding applications on the vehicle platform; optimum weight savings for one platform application may not be suitable for all platform applications. For future analysis, the agencies will look for practical ways to improve the assessment of mass reduction content and the forecast of incremental mass reduction costs for each vehicle.

Figure VI-44 below shows results from the pickup truck regression on predicted curb weight versus actual curb weight. Points above the solid regression line represent vehicles heavier than predicted (with lower mass reduction technology levels); points below the solid regression line represent vehicles lighter than predicted (with higher mass reduction technology levels). The dashed lines in the Figure VI-44 show the thresholds (5, 7.5, 10, 15, 20 and 28 percent of glider weight). Final rule glider weight assumption is 71 percent of vehicle curb weight.

BILLING CODE 4910-59-P

Figure VI-44 – Observed Curb Weight vs. Actual Curb Weight for the MY 2017 Analysis Fleet for 71 Percent Glider Share

BILLING CODE 4910-59-C

For points with actual curb weight below the predicted curb weight, the agencies used the residual as a percent of predicted weight to get a sense for the level of current mass reduction technology used in the vehicle. Notably, vehicles approaching -20% curb weight widely use advanced composites throughout major vehicle systems, and few examples exist in the MY 2016 fleet.¹³³⁹

¹³³⁹ This evidence suggests that achieving a 20% curb weight reduction for a production vehicle with a baseline defined with this methodology is

Generally, residuals of regressions as a percent of predicted weight appropriately stratified vehicles by mass reduction level. Most vehicles showed near zero residuals or had actual curb weights close to the predicted curb weight. Few vehicles in the analysis fleet were identified with the highest levels of mass reduction. Most vehicles with the largest negative residuals have demonstrably adopted advanced weight savings technologies at the most expensive end of the cost curve.

extremely challenging, and requires very advanced materials and disciplined design.

To validate the residuals, the agencies estimated the mass reduction technology level for several vehicle models in the analysis fleet and compared those estimates to the numerical results from the regression analysis. To estimate the mass reduction technology level for the selected vehicles, the agencies conducted an in-depth review of available information on the materials, design, and last redesign year for those vehicle models, and compared that information with the designs and materials used in the mass reduction feasibility and cost studies summarized in Section VI.C.4.e), below.

That comparison showed good agreement with the technology levels from the regression analysis.

The agencies believe the regression methodology is a technically sound methodology for estimating mass reduction levels in the analysis fleet.

As part of their comments stating the NPRM modeling reflected reality better than the Draft TAR and Proposed Determination analyses, Toyota commented broadly that the MY 2016 baseline fleet used in the NPRM encompassed powertrain and tractive energy (including mass reduction) improvements more representative of vehicles on the road today.¹³⁴⁰ Toyota noted that the 2016 baseline fleet generally contained higher levels of technology compared to the MY 2014 and MY 2015 baseline fleets, and included a comparison of its initial fleet mass reduction assignments in the Draft TAR and the NPRM. Toyota showed how moving further up the technology tree (e.g., starting with a baseline that includes higher levels of technology) for certain pathways such as mass reduction increased costs exponentially. Toyota stated that the NPRM underestimated mass reduction cost values.

While a more specific discussion of costs is located in Section VI.C.4.e), the agencies agree with Toyota's assessment that the costs for mass reduction technology increase exponentially as progressively higher levels of mass reduction are incorporated. Having an accurate assessment of baseline technology levels ensures that the subsequent application of technology and its associated costs is correctly accounted for.

C.A.R produced a report in response to the Draft TAR that generally agreed with the regression methodology of using observed vehicle attributes for estimating mass reduction levels, as opposed to comparing vehicle curb weight from a newer model year to a previous generation of the same vehicle, pointing to several of the limitations discussed above.¹³⁴¹

Both ICCT and H-D Systems commented on the methodology for identifying mass reduction technology levels in the analysis fleet, with ICCT broadly stating that by placing additional mass reduction technology in the baseline, the agencies artificially removed "the most cost-effective

lightweighting from future use, which incorrectly increases the costs of all subsequent mass-reduction in the compliance modeling."¹³⁴²

ICCT claimed that the agencies unjustifiably increased the amount of vehicle mass reduction technology present in the 2016 baseline fleet from the 2015 baseline used in the Draft TAR, stating that the 2015 Draft TAR fleet had 26 percent of vehicles sold with some level of mass reduction applied (MR1 or a higher level), whereas the 2016 NPRM fleet had 47 percent of vehicles sold with some level of mass reduction applied. In addition to faulting the agencies for not acknowledging the change and not attempting to justify it, ICCT stated that the 2016 analysis fleet mass reduction assignments were overstated, as "it appears that the agencies have applied mass reduction technology to vehicles in the model that did not have mass reduction applied in the real world." ICCT stated that the effect of this change was to "render[] unavailable mass reduction technologies for these vehicles in the model," causing the model to select less cost-effective technologies instead and driving the modeled compliance costs higher.

ICCT argued that to substantiate the changes made to the baseline fleet mass reduction assignments, the agencies must show data on how these improvements are evident in the fleet and to quantify and include their realized benefits in the analysis, including a detailed and justified explanation of all mass reduction technologies deemed already to have been applied to the MY 2016 analysis fleet. More specifically, ICCT stated that the agencies "must clearly and precisely share their estimated percent (and absolute pounds) mass reduction amount for each vehicle make and model in the baseline fleet (rather than simply showing binned categories), and their technical justification for each value," and "[t]o not do so obscures the agencies' new methods and data sources from public view, rendering their lightweighting calculations a black box."

In addition, ICCT recommended that the agencies conduct two sensitivity analyses, one assuming that every baseline make and model has not yet applied any lightweighting (setting the baseline to 0% mass reduction), and one assuming that each vehicle model has applied Draft TAR baseline mass reduction assignments, to demonstrate how much the agencies' decision to load

up more baseline technology affects the compliance scenarios.

ICCT concluded that because the changes in baseline mass reduction assignments from prior analyses to the NPRM "are opaquely buried in the agencies' datafiles and unexplained, we believe the agencies have to reissue a new regulatory analysis and allow an additional comment period for review of their methods and analysis."

To address ICCT's comment, it is important to understand the mass reduction baseline technology assignment methodology previously used by EPA in the Draft TAR and Proposed Determination.¹³⁴³ As stated in the Draft TAR, the curb weight of each vehicle model in the MY 2008 analysis fleet (used for the 2012 rulemaking to establish MYs 2017–2025 standards) was assumed to be at a baseline MR0 level. The mass reduction technology level in the MY 2014 analysis fleet was determined by comparing the curb weight of the MY 2014 vehicle to the most similar vehicle in the MY 2008 analysis fleet.¹³⁴⁴ The curb weight of the newer model year vehicle was adjusted to account for changes in the vehicle footprint and changes in mass due to added safety technology. If a vehicle did not have a previous generation vehicle, then the sales weighted average percent mass reduction over the manufacturer's name plate product line was used to represent the expectation of mass reduction technology available within the vehicle.

EPA listed some limitations to this methodology in the Draft TAR,¹³⁴⁵ and others are also addressed here. First, assuming that every vehicle started with MR0 technology did not account for the actual varying levels of mass reduction technology that existed in the MY 2008 fleet. Second, for each vehicle model, there was no accounting for the mass associated with different powertrain configurations. This was particularly problematic because the method did not account for light weight technology already available in the vehicle structure to counter the increased mass associated with more advanced powertrains, such as HEV, PHEV, and EV technologies.¹³⁴⁶ Third, there was no sales-weight accounting for the various configurations in estimating the vehicle model mass reduction technology level, meaning that if a high-sales-volume vehicle employed significant mass reduction technology, that vehicle was not credited as such in the analysis

fleet. Fourth, there was no accounting for mass increases due to the addition of future regulatory requirements like potential safety regulations. Fifth, there was no accounting for mass associated with changes in vehicle attributes and utility, such as the addition of infotainment systems and crash avoidance technologies. These limitations all individually had the effect of overestimating mass reduction technology effectiveness and undercounting mass reduction technology costs across the fleet, and accordingly their combined effect was significant. The lack of controls for these items introduced errors into the mass reduction technology level effectiveness estimates.

After considering the comments, the agencies determined the use of the regression method, based on observable attributes, is the best available methodology to provide a reasonable estimate of mass reduction technology for the analysis fleet. The agencies believe that, contrary to ICCT's assertion, the regression methodology used in the NHTSA Draft TAR, NPRM, and final rule analyses provides a more transparent method for calculating baseline mass reduction technology assignments. The methodology was fully explained in the Draft TAR and PRIA, and avoided the limitations identified by EPA by using data from the analysis fleet, and not requiring the use of or assumptions about the exact mass reduction levels of vehicles in a

prior model year fleet. In addition, the regression accounted for differences in powertrains between trim levels, including non-ICE powertrains by accounting for these factors in the regression analysis.

Also, because manufacturers generally apply mass reduction technology at a vehicle platform level (*i.e.*, using the same components across multiple vehicle models that share a common platform) to leverage economies of scale and to manage component and manufacturing complexity, conducting the regression analysis at the platform level leads to more accurate estimates for the real-world vehicle platform mass reduction levels. The platform approach also addresses the impact of potential weight variations that might exist for specific vehicle models, as all of the individual vehicle models are aggregated into the platform group, and are effectively averaged using sales weighting, which minimizes the impact of any outlier vehicle configurations.

The agencies also disagree that the changes in baseline mass reduction assignments were unexplained. The PRIA discussed reasons that baseline mass reduction assignments differed from prior analyses, including that, “[s]ince the Draft TAR, many platforms have not been redesigned, but in some cases the sales-weighted residuals for carryover platforms have moved. In the case of 2-Box and 3-Box vehicles, the analysis attributes such changes to differences in sales mix year-over-year

and other updates to reported curb weights and platform designations. In the case of platforms with pick-up trucks, the analysis updated the pick-up regression since the Draft TAR, so that may be a contributing factor.”¹³⁴⁷

To the extent that the NPRM glider weight assumption impacted the NPRM MY 2016 analysis fleet baseline mass reduction assignment values, the agencies presented a table in the PRIA showing how different glider weight assumptions impacted mass reduction technology levels for the analysis fleet.¹³⁴⁸ The following Table VI–123 recreates that table in part, with updates based on the glider weight values used for the final rule.

For example, from the regression analysis, the Ford F–150 has a predicted curb weight (residual) of 12.4 percent of the actual curb weight. If the glider weight assumption is 50 percent of the vehicle curb weight (like in NPRM), then the agencies would assign MR5 as an initial mass reduction assignment in the analysis fleet. With this high level of mass reduction technology already applied, the opportunity for further mass reduction would be limited. However, if the glider weight is assumed to be 71 percent of the vehicle curb weight, then Ford F–150 would be assigned MR4, and would have an opportunity to apply another level of mass reduction albeit at higher cost.

¹³⁴⁷ PRIA at 424.

¹³⁴⁸ PRIA at 422.

Table VI-123 – Mass Reduction Technology Levels for the MY 2017 Analysis Fleet for 50% and 71% Glider Share of Curb Weight

| CAFE Model Platform Code | Example Code | Mass Reduction Residual (%) | Mass Reduction Level for 71% Glider Weight (Final Rule) | Mass Reduction Level for 50% Glider Weight (NPRM) |
|--------------------------|--------------------|-----------------------------|---|---|
| Li8 | BMW i8 | -23.0% | MR6 | MR5 |
| Lamborghini-A | Aventador | -17.4% | MR6 | MR5 |
| Alfa | Alfa Romeo 4C | -23.2% | MR6 | MR5 |
| Li8 | BMW i3 94 R19 | -18.4% | MR5 | MR5 |
| Omega | Cadillac CT6 | -14.4% | MR4 | MR5 |
| Y-CAR/Y1XX | Chevrolet Corvette | -12.5% | MR4 | MR5 |

| RamVan | Ram ProMaster | -12.0% | MR4 | MR5 |
| Lamborghini-H | Huracan | -11.7% | MR4 | MR5 |
| Global Epsilon/E2XX | Chevrolet Malibu | -11.2% | MR4 | MR5 |
| NBC(2) | Toyota Prius C | -15.5% | MR3 | MR5 |
| SKYACTIV R | Mazda MX-5 | -14.4% | MR3 | MR5 |
| MODEL S | Tesla Model S | -11.3% | MR3 | MR5 |
| V | Nissan Versa | -10.8% | MR3 | MR5 |
| II | Honda Civic | -10.6% | MR3 | MR5 |
| Basic(K-Basic1) | Kia Soul | -10.0% | MR3 | MR5 |

The agencies also disagree that the amount of vehicle mass reduction technology present in the 2016 baseline fleet was “unjustifiably increased” from the 2015 baseline used in the Draft TAR. Table VI-124 shows the percent mass reduction technology used in Draft TAR, NPRM, and in final rule. It is clear from the table below that total percentage of MY 2016 vehicle fleet used in the

NPRM had nearly the same level of some mass reduction technology applied compared to the Draft TAR. Similar to ICCT’s observations, 28 percent of the MY 2015 vehicle fleet used in the Draft TAR had some level of mass reduction technology (MR1 to MR5) and 26 percent of MY 2016 vehicle fleet had some mass reduction technology applied. Since the agencies

assumed a reduced glider share in the NPRM, the percentage of vehicles assigned a MR4 or MR5 technology level increased compared to Draft TAR. In addition, for this final rule, the agencies observed that many of the vehicles in the MY 2017 fleet had been redesigned, which provided the opportunity to incorporate additional mass reduction technologies.

Table VI-124 – Mass Reduction Assignment

| | | Draft TAR | NPRM | Final Rule |
|-----|------------------------------------|--------------------|-------------------|-------------------|
| | Percentage glider weight reduction | 75% Percent glider | 50 percent glider | 71 percent glider |
| MR0 | 0% | 72.00% | 73.01% | 57.18% |
| MR1 | 5% | 11.93% | 7.68% | 15.62% |
| MR2 | 7.5% | 8.35% | 3.30% | 7.66% |
| MR3 | 10% | 6.91% | 5.88% | 7.79% |
| MR4 | 15% | 0.56% | 5.34% | 11.42% |
| MR5 | 20% | 0.25% | 4.80% | 0.10% |
| MR6 | 28% | 0.00% | 0.00% | 0.03% |

The agencies considered a sensitivity case that assumed no mass reduction,

rolling resistance, or aerodynamic improvements had been made to the MY

2017 fleet (i.e., setting all vehicle road levels to zero—MRO, AERO and

ROLL0), in response to ICCT's comment. While this is an unrealistic characterization of the initial fleet, the agencies conducted a sensitivity analysis to understand any affect it may have on technology penetration along other paths (e.g., engine and hybrid technology). Under the CAFE program, the sensitivity analysis shows a slight decrease in reliance on engine technologies (HCR engines, turbocharge engines, and engines utilizing cylinder deactivation) and hybridization (strong hybrids and plug-in hybrids) in the baseline (relative to the central analysis). The consequence of this shift to reliance on lower-level road load technologies is a reduction in compliance cost in the baseline of about \$300 per vehicle (in MY 2026). As a result, cost savings in the preferred alternative are reduced by about \$200 per vehicle. Under the CO₂ program, the general trend in technology shift is less dramatic (though the change in BEVs is larger) than the CAFE results. The cost change is also comparable, but slightly smaller (\$200 per vehicle in the baseline) than the CAFE program results. Cost savings under the preferred alternative are further reduced by about \$100. With the lower technology costs in all cases, the consumer payback periods decreased as well. These results are consistent with the approach taken by manufacturers who have already deployed many of the low-level road load reduction opportunities to improve fuel economy.

Second, as discussed above, EPA's Draft TAR baseline mass reduction assignments had identified limitations that the regression methodology has addressed. Moreover, as discussed above, the regression methodology was updated from the Draft TAR to characterize data better on pickup trucks. The agencies do not believe that conducting sensitivity analyses using these outdated or limited assumptions would be useful for this final rule.

More narrowly, HDS commented that while the regression coefficients between 2-box and 3-box vehicles for footprint seemed consistent, the regression coefficients for horsepower between the 2-box and 3-box vehicles seemed incorrect because both types of vehicles use similar engines.¹³⁴⁹ HDS stated that "[c]ollinearity between footprint and HP or other effects caused by having electric vehicles (with electric motor HP ratings) in the regression data is the probable cause of these inconsistent coefficients for HP, but this cannot be confirmed without access to the same database used by NHTSA."

HDS concluded that "[r]evisions to the regression could have a significant effect on the baseline assignment of vehicles, as the current assignment for vehicles like the 2016 Mazda MX5 as having the highest level of weight reduction technology (MR5) and the 2016 Chevy Malibu as having MR4 technology appear incorrect as their curb weights are comparable to other similar MY 2016 vehicles in their respective class."

While many of the vehicles share same the same powertrain for passenger cars and SUVs or for cars and pickup trucks, the utility and functionality of the vehicle in SUVs and pickup trucks (2-box) is different than passenger cars (3-box). The presence of additional structure for towing or higher capacity towing, rear cross member, higher capacity suspension, and other differences, enable SUVs and pickup trucks to have towing and heavier payload capability. For example, Ford uses the nearly similar displacement and horsepower engines in Mustang EcoBoost Coupe and in F150 2WD XL, Regular Cab, Long Box. However, the curb weight for the pickup truck is higher than the Mustang. Directionally, this supports that the 2-box weight per horsepower coefficient should be greater than the 3-box coefficient, just as it is in the for the regression. The coefficient for passenger cars and SUVs has not changed since the Draft TAR (based on MY2015 vehicle fleet). Based on the comments to Draft TAR, for the NPRM, a new set of coefficients were generated for pickups using the MY 2014 vehicle fleet. This was done so that coefficients were not skewed due to presence of the aluminum intensive Ford F150 pickup truck. Hence, the agencies believe the coefficients used in the regression analysis are directionally correct and disagree with HDS's assertion. The agencies further note that HDS did not suggest any alternate methodology or specific coefficients to use in the regression analysis.

(c) Mass Reduction Technology Adoption Features

The agencies described in the NPRM that given the degree of commonality among the vehicle models built on a single platform, manufacturers do not have complete freedom to apply unique technologies to each vehicle that shares the platform: while some technologies (e.g., low rolling resistance tires) are very nearly "bolt-on" technologies, others involve substantial changes to the structure and design of the vehicle, and therefore often necessarily affect all of the vehicle models that share that platform. In most cases, mass reduction technologies are applied to platform

level components and therefore the same design and components are used on all of the vehicle models that share the platform.

As discussed in Section Analysis Fleet, above, each vehicle in the analysis fleet is associated with a specific platform. Similar to the application of engine and transmission technologies, the CAFE model defines a platform "leader" as the vehicle variant of a given platform that has the highest level of observed mass reduction present in the analysis fleet. If there is a tie, the CAFE model begins mass reduction technology on the vehicle with the highest sales in model year 2017. If there remains a tie, the model begins by choosing the vehicle with the highest Manufacturer Suggested Retail Price (MSRP) in MY 2017. As the model applies technologies, it effectively levels up all variants on a platform to the highest level of mass reduction technology on the platform. So, if the platform leader is already at MR3 in MY 2017, and a "follower" starts at MR0 in MY 2017, the follower will get MR3 at its next redesign (unless the leader is redesigned again before that time, and further increases the mass reduction level associated with that platform, then the follower would receive the new mass reduction level).

Important for analysis fleet mass reduction assignments (discussed above), and for understanding adoption features as well, is the agencies' handling of vehicles that traditionally operated on the same platform but had a mix of old and new platforms in production when the analysis fleet was created. As described in the PRIA, the Honda Civic and Honda CR-V traditionally share the same platform. In MY 2016, Honda redesigned the Civic and updated the platform to include many mass reduction technologies. Also in MY 2016, Honda continued to build the CR-V on the previous generation platform—a platform that did not include many of the mass reduction technologies on the all new MY 2016 Civic. In MY 2017, Honda launched the new CR-V that incorporated changes to the Civic platform, and the Civic and CR-V again shared the same platform with common mass reduction technologies. The NPRM and final rule analyses treat the old and new platforms separately to assign technology levels in the baseline, and the CAFE model brings vehicles on the old platform up to the level of mass reduction technology on the new shared platform at the first available redesign year.

Furthermore, as stated in the NPRM and PRIA, unlike the analysis presented in the Draft TAR that restricted high

¹³⁴⁹ H-D Systems, NHTSA-2018-0067-11985.

levels of mass reduction for cars to show a safety neutral pathway to compliance, the NPRM analysis did not artificially restrict mass reduction to achieve a safety neutral outcome.¹³⁵⁰ The NPRM CAFE model considered MR0 through MR5 for all vehicles at redesign, and similarly for the final rule, the CAFE model considers MR0 through MR6 for all vehicles at redesign.

Ford commented in support of the removal of “previously applied modeling rules that disallowed the mass reduction technology pathway for certain vehicle classes since this restriction was not supported by an adequate technical justification.”¹³⁵¹ ICCT commented that a constraint of 7.5 percent mass reduction to smaller cars, as was applied in the Draft TAR, would be appropriate for those vehicles.

The agencies considered ICCT’s comment that mass reduction on small passenger cars should be limited to 7.5 percent, and Ford’s comment supporting the removal of “previously applied modeling rules that disallowed the mass reduction technology pathway for certain vehicle classes.” Neither CAFE standards nor this analysis mandate mass reduction, or mandate that mass reduction occur in any specific manner. The mass reduction cost subsection below shows mass reduction is a cost-effective technology for improving fuel economy and CO₂ emissions. The steel, aluminum, plastics, composite, and other material industries are developing new materials and manufacturing equipment and facilities to produce those materials. In addition, suppliers and manufacturers are optimizing designs to maintain or improve functional performance with lower mass. Manufacturers have stated that they will continue to reduce vehicle mass to meet more stringent standards, and therefore, this expectation is incorporated into the modeling analysis supporting the standards to: (1) Determine capabilities of manufacturers; and (2) predict costs and fuel consumption effects of CAFE standards. The CAFE and CO₂ rulemakings in 2012, and the Draft TAR and EPA Proposed Determination, imposed an artificial constraint that limited vehicle mass reduction in some small vehicles to achieve a desired safety-neutral outcome. For the current rulemaking, this artificial constraint is eliminated so the analysis reflects manufacturers’ applying the most cost effective technologies to achieve compliance with the regulatory alternatives and the final standards; this approach allows

mass reduction to be applied across the fleet. This approach is consistent with industry trends. To the extent that mass reduction is only cost-effective for the heaviest vehicles, the CAFE model would create the outcome predicted by commenters. In reality, however, mass reduction is a cost-effective means of improving fuel economy and does take place across vehicles of all sizes and weights. Accordingly, the model reflects that manufacturers may reduce vehicle mass—regardless of vehicle class—when doing so is cost effective.

The agencies have included one additional mass reduction level for the final rule in response to comments by ICCT and others, and to account for carbon fiber use in vehicles. For the NPRM, the maximum level of mass reduction was limited to 10 percent of a vehicle’s curb weight, and that amount of mass reduction could be applied during the rulemaking timeframe. For the final rule, based on the current state of mass reduction technology and the application rate of different levels of mass reduction technologies, the agencies applied phase-in caps for MR5 and MR6 (15 percent and 20 percent reduction of a vehicle’s curb weight, respectively). The agencies applied a phase-in cap for MR5 level technology so that 15 percent of the vehicle fleet starting in 2016 employed the technology, and the technology could be applied to 100 percent of the fleet by MY 2022. This cap is consistent with the NHTSA lightweighting study that found that a 15 percent curb weight reduction for the fleet is possible within the rulemaking timeframe.¹³⁵² The agencies also applied a phase in cap for MR6 technology so that one percent of the vehicle fleet starting in MY2016 employed the technology, and the technology could be applied to 13 percent of the fleet by MY2025. The agencies believe that this phase-in cap appropriately functions as a proxy for the cost and complexity currently required (and that likely will continue to be required until manufacturing process evolve) to produce carbon fiber components. Again, MR6 technology in this analysis reflects the use of a significant share of carbon fiber content, as seen through the BMW i3 and Alfa Romeo 4c as discussed above.

(d) Mass Reduction Technology Effectiveness

As discussed in Section VI.B.3, Argonne developed a database of vehicle attributes and characteristics for

each vehicle technology class that included over 100 different attributes like frontal area, drag coefficient, fuel tank weight, transmission housing weight, transmission clutch weight, hybrid vehicle component weights, and weights for components that comprise engines and electric machines, tire rolling resistance, transmission gear ratios, and final drive ratio. Argonne used these attributes to “build” each vehicle that it used for the effectiveness modeling and simulation. Important for precisely estimating the effectiveness of different levels of mass reduction is an accurate list of initial component weights that make up each vehicle subsystem, from which Autonomie considered potential mass reduction opportunities.

As stated above, glider weight, or the vehicle curb weight minus the powertrain weight, is used to determine the potential opportunities for weight reduction irrespective of the type of powertrain.¹³⁵³ This is because weight reduction can vary depending on the type of powertrain. For example, an 8-speed transmission may weigh more than a 6-speed transmission, and a basic engine without variable valve timing may weigh more than an advanced engine with variable valve timing. Autonomie simulations account for the weight of the powertrain system inherently as part of the analysis, and the powertrain mass accounting is separate from the application and accounting for mass reduction technology levels (MR0–MR6) that are applied to the glider in the simulations. Similarly, Autonomie also accounts for battery and motor mass used in hybrid and electric vehicles separately. This secondary mass reduction is discussed further, below.

Accordingly, in the Autonomie simulation, mass reduction technology is simulated as a percentage of mass removed from the specific subsystems that make up the glider, as defined for that set of simulations (including the non-powertrain secondary mass systems such as the brake system).

(1) Glider Mass and Mass Reduction

Autonomie accounts for the mass of each subsystem that comprises the glider. For the NPRM, the glider subsystems included the vehicle body and the chassis, but did not include mass from subsystems such as the interior system, brake system, electrical accessory system, and steering and

¹³⁵³ Depending on the powertrain combination, the total curb weight of the vehicle includes glider, engine, transmission and/or battery pack and motor(s).

wheel systems. The agencies described in the PRIA that based on advances in active and passive safety technologies that add some mass to the interior system, certain subsystems were not considered for potential light-weighting to maintain safety performance.¹³⁵⁴ For the NPRM, the A2Mac1 database was used to estimate the average mass of each subsystem considered as part of the glider based on the subsystem assumptions, and to compute the average glider share of vehicle curb weight.¹³⁵⁵ That analysis showed the glider accounted for 50 percent of the vehicle curb weight. The agencies solicited comment on whether systems or components beyond the vehicle body and chassis should be included as part of the glider, and also indicated that the glider weight assumption might increase for the final rule based on further research.

The agencies received several comments on the NPRM glider weight assumptions, with the overarching theme of the comments being that the NPRM did not include all systems and components that should be included, and if those systems and components were included, the glider share would be higher. Commenters also stated that the 50 percent glider share value used for the NPRM reduced the amount of mass reduction that could be applied to vehicles in the analysis.

UCS stated that representing the glider as a reduced fraction of the curb weight caused the agencies significantly to underestimate the potential for mass reduction. UCS noted that because mass reduction is applied at the glider level, reducing the share of the glider inherently caps the potential reduction in the curb weight, and this single change cut the potential improvement from mass reduction by one-third. Similarly, CARB stated that the updated glider weight assumption severely limited the effectiveness of mass reduction, as the most aggressive mass reduction category of 15 to 20 percent mass reduction can only reduce the vehicle curb weight by 10 percent.

UCS cited previous agency analyses and analyses from other organizations that stated the total potential for mass reduction by 2025 is between 15.8 and 32 percent of curb weight, contrasted to the NPRM assumption of a maximum 10

percent reduction.¹³⁵⁶ UCS also cited industry data which showed that the glider represented a higher share of vehicle curb weight than was assumed in the Draft TAR analysis, and both UCS and CARB cited to industry data from vehicles like the Ford F-150, which UCS stated was able to achieve the NPRM maximum achievable mass reduction through the deployment of aluminum alone.¹³⁵⁷ UCS concluded that by capping the total potential for mass reduction at such a low level, the agencies artificially reduced the potential for the cost-effective technology, which increased the use of more expensive and more advanced technologies. CARB concluded that the agencies' 10 percent restriction means that real-world improvements that have already happened on production vehicles were not considered feasible in the NPRM analysis.

Several commenters also stated that the 50 percent glider weight assumption was unexplained and unjustified, and argued that the agencies' own studies showed that the glider weight percentage should range from 75–80 percent.¹³⁵⁸ UCS stated that both the NHTSA-sponsored 2011 Honda Accord study, which showed the glider making up 79 percent of the vehicle, and the NHTSA-sponsored 2014 Chevrolet Silverado study, which showed the glider making up 73.6 percent, showed values substantially higher than the 50 percent value, and were in line with the agencies' prior analyses.¹³⁵⁹ As part of its comments that key assumptions about mass reduction changed from the Draft TAR without any supporting rationale, CARB stated that EPA had previously relied on four studies (two contracted for by EPA and two contracted for by NHTSA), and for the NPRM analysis the agencies only cited two of those studies.¹³⁶⁰ Moreover, ICCT commented that the agencies' previous studies showed a glider fraction greater than 75 percent even with numerous safety features considered. Accordingly, ICCT stated that the agencies must specifically identify the "safety components" referred to in the NPRM and justify the limitations placed on light weighting in response. ICCT affirmatively concluded that the agencies must re-adopt the Draft TAR methodology in which glider mass

is assumed to be 75 percent of vehicle mass, or provide detailed justification and evidence supporting the new value of 50 percent.¹³⁶¹

The agencies carefully considered these comments and reexamined available data and information. The NHTSA-sponsored passenger car light weighting study showed a glider mass of 79 percent, and the NHTSA-sponsored light duty truck light weighting study showed a glider mass of 73.6 percent, and the 75 percent value used for the Draft TAR was a value between the values from these two studies. The agencies determined it would be more rigorous to consider data from a broader array of vehicles with various powertrain combinations and trim levels to assess the glider share for the final rule, considering that the vehicle fleet analyzed in this rule consists of over 2900 vehicle models.

The agencies examined glider weight data available in the A2Mac1 database.¹³⁶² The A2Mac1 database tool is widely used by industry and academia to determine the bill of materials and mass of each component in the vehicle system.¹³⁶³ The A2Mac1 database has been used by the agencies to inform past CAFE and CO₂ rulemakings. The agencies analyzed a total of 147 MY 2014 to 2016 vehicles, covering 35 vehicle brands with different powertrain options representing a wide array of vehicle classes to determine the glider weight for the final rule analysis.¹³⁶⁴

The agencies also considered that the NHTSA passenger car and light truck light-weighting studies examined mass reduction in the body, chassis, interior, brakes, steering, electrical accessory, and wheels subsystems and had developed costs for light weighted components in those subsystems. As a result, the agencies determined it is appropriate to include all of those subsystems as available for mass reduction as part of the glider. Therefore, all of these systems were included for the analysis of glider weight using the A2Mac1 database. Table VI-125 shows the average mass for each subsystem and the glider share for each of the vehicle classes for all powertrain combinations.

| | | | | | | | | | Average | 71.62% |

This data was also compared with the glider weight measured in the NHTSA MY 2014 Chevrolet Silverado light weighting study,¹³⁶⁵ and the glider weight data range was similar to the analysis results. Based on the comments and the agencies' updated assessment, the agencies have increased the glider weight assumption to 71 percent of the vehicle curb weight for the final rule.

As stated above, for the NPRM, the interior, brake system, electrical accessory system, and steering and wheel systems were not included as part of the glider. The decision not to include the interior system was based on an assumption at that time that interior system mass reduction might adversely impact safety. In addition, the decision not to include the brake system was based on an assumption at that time that there would be little or no opportunity for downsizing and reducing mass based on the reduced

weight from body and chassis only. As a result, brake systems were not considered as part of the glider in the NPRM. For the final rule, the agencies included the interior system based on market observations that light-weighted seats, side door trim, frontal dash, and others interior components have been incorporated on production vehicles that meet FMVSSs and perform well on voluntary NCAP and IIHS safety tests. The agencies also considered that interior, brakes, steering, wheel and electrical subsystems were included in the NHTSA light weighting studies. By adding the interior, steering, wheel subsystems and electrical subsystems as part of glider, the agencies believe light weighting the glider increases the opportunity for brake system optimization and mass reduction. Similarly, there is increased opportunity for mass reduction for wheels using gauge optimization, resulting from

including more subsystems in the glider.

By including the interior, brake, steering, electrical accessory, and wheel subsystems in addition to the body and chassis subsystems in the definition of what subsystems comprise the glider, the agencies increased the glider weight from 50 percent of the vehicle curb weight to 71 percent of the vehicle curb weight. This increase in turn means that the potential for vehicle mass reduction was increased from 10 percent of the vehicle curb weight to 20 percent of the vehicle curb weight. Table VI-126 shows the percent of light truck glider weight reduction and the corresponding vehicle curb weight reduction for each level of mass reduction for the glider shares used in the Draft TAR (75 percent), NPRM (50 percent), and final rule (71 percent) analyses.¹³⁶⁶

BILLING CODE 4910-59-C

¹³⁶⁶ Table 6–57 in PRIA showed the vehicle curb weight changes for different glider weight assumptions.

**Table VI-126 – Light Truck Glider Weight and Curb Weight Comparison for the Draft
TAR, NPRM and Final Rule**

| | Glider Weight Percentages by MR Level | Percent of Curb Weight for Light Trucks | | |
|-----|---------------------------------------|---|--------------------------|--------------------------------|
| | | Draft TAR 75% glider share | NPRM 50% glider share | Final Rule 71% glider share |
| MR0 | 0.0% | 0.00% | 0.00% | 0.00% |
| MR1 | 5.0% | 3.75% | 2.50% | 3.55% |
| MR2 | 7.5% | 5.63% | 3.75% | 5.33% |
| MR3 | 10.0% | 7.50% | 5.00% | 7.10% |
| MR4 | 15.0% | 11.25% | 7.50% | 10.65% |
| MR5 | 20.0% | 15.00% | 10.00% | 14.20% |
| MR6 | 28.2% | 21.15% | | 20.00% |

2) Powertrain Mass Reduction

As explained above, any mass reduction due to powertrain improvements is accounted for separately from glider mass reduction. Autonomie considers several components for powertrain mass reduction, including engine downsizing, and transmission, fuel tank, exhaust systems, and cooling system lightweighting.

The 2015 NAS report suggested an engine downsizing opportunity exists when the glider mass is lightweighted by at least 10%. The 2015 NAS report also suggested that 10% lightweighting of the glider mass alone would boost fuel economy by 3% and any engine downsizing following the 10% glider mass reduction would provide an additional 3% increase in fuel economy.¹³⁶⁷ The agencies' lightweighting studies applied engine downsizing (for some vehicle types but not all) when the glider weight was reduced by 10 percent. Accordingly, the NPRM analysis limited engine resizing to several specific incremental technology steps;¹³⁶⁸ important for this discussion, engines in the analysis were only resized when mass reduction of 10% or greater was applied to the glider mass, or when one powertrain architecture was replaced with another architecture.

Argonne performed a regression analysis of engine peak power versus weight for the NPRM based on attribute data taken from the A2Mac1 benchmarking database, to account for the difference in weight for different engine types. For example, to account for weight of different engine sizes like 4-cylinder versus 8-cylinder, Argonne developed a relationship curve between peak power and engine weight based on the A2Mac1 benchmarking data. For the NPRM analysis, this relationship was used to estimate mass for all engine types regardless of technology type (*e.g.*, variable valve lift and direct injection). Weight associated with changes in engine technology was applied by using this linear relationship between engine power and engine weight from the A2Mac1 benchmarking database. When a vehicle in the analysis fleet with an 8-cylinder engine adopted a more fuel efficient 6-cylinder engine, the total vehicle weight would reflect the updated engine weight with two less cylinders based on the peak power versus engine weight relationship.

When Autonomie selects a powertrain combination for a lightweighted glider, the engine and transmission are selected such that there is no degradation in the performance of the vehicle relative to the baseline vehicle. The resulting curb weight is a combination of the lightweighted glider with the resized and potentially new engine and transmission. This methodology also helps in accurately accounting for the cost of the glider and cost of the engine and transmission in the CAFE model.

This is one of the fundamental differences between the analysis for this rulemaking the analysis for the Proposed Determination. For the Proposed Determination, the cost for mass reduction included mass reduction and cost reduction for one specific engine downsizing, and applied it to all vehicle classes without regard for performance and utility. There also was no accounting for the mass of other applied powertrains and the associated effectiveness impacts.

As explained in the introduction, secondary mass reduction is possible from some of the components in the glider after mass reduction has been incorporated in primary subsystems (body, chassis, and interior). Similarly, engine downsizing and powertrain secondary mass reduction is possible after certain level of mass reduction is incorporated in the glider. For the analysis, the agencies include both primary mass reduction, and when there is sufficient primary mass reduction, additional secondary mass reduction. The Autonomie simulations account for the aggregate of both primary and secondary glider mass reduction, and separately for powertrain mass.

The agencies received several comments about secondary mass reduction and powertrain mass reduction. Broadly, CARB commented that the agencies did not include powertrain downsizing and associated secondary mass reduction, which was a departure from the analysis done by

¹³⁶⁷ National Research Council. 2015. Cost, Effectiveness, and Deployment of Fuel Economy Technologies for Light-Duty Vehicles. Washington, DC—The National Academies Press. <https://doi.org/10.17226/21744>.

¹³⁶⁸ 83 FR 43027.

EPA for the Draft TAR.¹³⁶⁹ CARB stated that the agencies “inexplicably” did not consider secondary mass reduction opportunities “including but not limited to drive axles, suspension, and braking components (as a result of the overall vehicle being lighter); fuel tank (and corresponding weight of fuel during certification testing); powertrain (lighter engine and transmission needed to power the lighter vehicle); and thermal systems.” CARB cited both EPA and NHTSA light weighting studies for the proposition that there are significant opportunities for secondary mass reduction that lead to additional cost savings. As a result, CARB stated that the agencies inflated the cost of mass reduction as well as the amount of mass reduction that is feasible and cost-effective, leading to an over estimate in the technology costs to meet the existing standards.

As CARB correctly noted, the NHTSA-sponsored studies have taken into consideration secondary mass reduction benefits such as radiator engine support, and optimized engine cradles, wheels, and suspension systems. As discussed above, in response to comments, the agencies have included additional subsystems such as brakes, wheels, steering, electrical, and interior systems to the glider for the final rule analysis, thereby accounting for mass reduction opportunities for these systems.

Also, as discussed further in Section VI.C.4.e), below, secondary mass reduction is integrated into the mass reduction cost curves. Specifically, the NHTSA studies, upon which the cost curves were built, first generated costs for lightweighting the vehicle body, chassis, interior, and other primary components, and then calculated costs for lightweighting secondary components. Accordingly, the cost curves reflect that, for example, secondary mass reduction for the brake system is only applied after there has been sufficient primary mass reduction to allow the smaller brake system to provide safe braking performance and to maintain mechanical functionality.

CARB appears to have misunderstood how the analysis accounts for powertrain mass reduction. The agencies described in the PRIA that the Autonomie simulations recognize that many powertrain packages have different weights for each vehicle class; for example, an eight-speed transmission may weigh more than a six-speed transmission, and a basic engine with variable valve timing may weigh more than a basic engine without

variable valve timing.¹³⁷⁰ Autonomie varies the weight of these powertrain systems as part of the analysis, and these changes are done separately from the glider mass reduction technology levels (MR0 to MR6) in the simulations. Accordingly, accounting for powertrain mass reduction as part of the mass reduction technology analysis would double count impacts. The use of separate accounting assures that the analysis accounts for mass associated with secondary mass reduction from glider, and engine downsizing, as well as mass associated with each individual engine, transmission, and electrification technology. These mass changes were not accounted for in the Draft TAR and Proposed Determination analyses. Moreover, these are accounted for separately in the cost accounting, which is discussed further in the Section VI.C.4.e), below.

HDS commented that some assumptions in the Autonomie modeling related to engine weight appeared incorrect, such as the assumption that a turbocharged 4-cylinder engine weighed the same as a DOHV V6 engine with 1.5 times the 4-cylinder's displacement, when in fact that engine is often 75 to 100 lbs. lighter.¹³⁷¹

HDS also noted that “mass reduction assumes no reduction of powertrain weight for mass reduction levels of 2.5% and 5%. Mass reduction effectiveness therefore are somewhat more appropriate for reductions over 5% which apparently include some powertrain weight reduction. More transparency in the PRIA regarding powertrain weight changes will allow more detailed comment on engine weight assumptions used.”

We agree with the comment that certain advanced engines could be lighter than a basic engine. For the final rule, the estimated mass levels for engines were updated, as discussed in Section VI.B.3 Tech Effectiveness, based on the A2Mac1 database and other sources that provided more precise mass data for powertrain technologies. Also, the agencies improved upon the precision of estimated engine weights by creating two curves to represent separately naturally aspirated engine designs and turbocharged engine designs.¹³⁷² This update resulted in two benefits. First, small naturally aspirated 4-cylinder engines that adopted turbocharging technology reflected the

increased weight of associated components like ducting, clamps, the turbocharger itself, a charged air cooler, wiring, fasteners, and a modified exhaust manifold. Second, larger cylinder count engines like naturally aspirated 8-cylinder and 6-cylinder engines that adopted turbocharging and downsized technologies would have lower weight due to having fewer engine cylinders. For the final rule analysis, a naturally aspirated 8-cylinder engine that adopts turbocharging technology and is downsized to a 6-cylinder turbocharged engine appropriately reflects the added weight of the turbocharging components, and the lower weight of fewer cylinders. These refinements address the issues identified in HDS's comments.

Regarding HDS's second comment, as discussed in the NPRM, to address product complexity and economies of scale, engine resizing is limited to specific incremental technology changes that would typically be associated with a major vehicle or engine redesign.¹³⁷³ As discussed further in Section VI.B.3.a)(6) Performance Neutrality, the NPRM also referred to the 2015 NAS report conclusion that “[f]or small (under 5 percent [of curb weight]) changes in mass, resizing the engine may not be justified, but as the reduction in mass increases (greater than 10 percent [of curb weight]), it becomes more important for certain vehicles to resize the engine and seek secondary mass reduction opportunities.”¹³⁷⁴ In consideration of both the NAS report and comments received from manufacturers, the agencies determined it would be reasonable to allow allows engine resizing upon adoption of 7.1%, 10.7%, 14.2%, and 20% curb weight reduction, but not at 3.6% and 5.3%.¹³⁷⁵ Resizing is also allowed upon changes in powertrain type or the inheritance of a powertrain from another vehicle in the same platform. The increments of these higher levels of mass reduction, or complete powertrain changes, more appropriately match the typical engine displacement increments that are available in a manufacturer's engine portfolio.

¹³⁷³ See 83 FR 43027 (Aug. 24, 2018).

¹³⁷⁴ National Research Council. 2011. *Assessment of Fuel Economy Technologies for Light-Duty Vehicles*. Washington, DC—The National Academies Press. <http://nap.edu/12924>.

¹³⁷⁵ These curb weight reductions equate to the following levels of mass reduction as defined in the analysis: MR3, MR4, MR5 and MR6, but not MR1 and MR2; additional discussion of engine resizing for mass reduction can be found in Section VI.B.3 Technology Effectiveness.

e) Mass Reduction Costs

The PRIA described the decision to use NHTSA's passenger car light weighting study based on a MY 2011 Honda Accord and NHTSA's full-size pickup truck light weighting study based on a MY 2014 Chevrolet Silverado to derive the estimated cost for each of the mass reduction technology levels.¹³⁷⁶ The agencies relied on the results of those studies because they considered an extensive range of material types, material gauge, and component redesign while taking into account real world constraints such as manufacturing and assembly methods and complexity, platform-sharing, and maintaining vehicle utility, functionality and attributes, including safety, performance, payload capacity, towing capacity, handling, NVH, and other characteristics. In addition, the agencies described that the baseline vehicles assessed in the NHTSA-sponsored studies were reasonably representative of baseline vehicles in

the MY 2016 analysis fleet.¹³⁷⁷ The agencies also noted they made the decision to rely on these studies after reviewing other agency, CARB, ICCT and industry studies.¹³⁷⁸ The other studies often did not consider important factors, made unrealistic assumptions about key vehicle systems, and/or applied secondary mass reduction inappropriately, resulting in unrealistically low costs. The PRIA also described how the cost estimates derived from the NHTSA lightweighting studies were adjusted to reflect the NPRM glider share assumption.¹³⁷⁹

¹³⁷⁷ PRIA at 403.

¹³⁷⁸ As described in the PRIA at 390-91, studies by EPA, CARB, Transport Canada, the American Iron and Steel Institute (AISI), the Aluminum Association, and the American Chemistry Council were all reviewed for potential incorporation into the analysis.

¹³⁷⁹ See PRIA at 396, Tables 6-38 and 6-39; PRIA at 401, Tables 6-41 and 6-42. See also PRIA at 391 ("While the definitions of glider may vary from study to study (or even simulation to simulation), the agencies referenced the same dollar per pound of curb weight to develop costs for different glider definitions. In translating these values, the agencies took care to track units (\$/kg vs. \$/lb.) and the reference for percentage improvements (glider vs. curb weight).").

Furthermore, the agencies changed the cost of mass reduction accounting from a curb weight basis in the Draft TAR to glider weight basis in the NPRM.¹³⁸⁰ Because the mass reduction studies provide mass reduction costs for the glider, this change enabled more direct use of cost curve data from the studies in the CAFE model. This change also allowed independent accounting for powertrain mass, which enabled the CAFE model to account more accurately for the unique mass of each of the powertrains that are available in each vehicle model. The cost of the engine, transmission, and electrification are accounted for separately from the glider in the CAFE model.

The agencies received several comments on the mass reduction costs used in the NPRM. FCA commented that the costs and benefits used the CAFE model were overly optimistic,

¹³⁸⁰ In the Draft TAR, the agencies presented the cost estimates from mass reduction studies sponsored by both NHTSA and EPA. EPA presented the cost of mass reduction as function of vehicle curb weight. To harmonize the cost estimates with EPA, NHTSA also presented the cost of mass reduction as a function of vehicle curb weight.

¹³⁷⁶ PRIA at 391; Table 6-38 and Table 6-41 in PRIA.

stating that although its Ram 1500 pickup truck achieved several hundred pounds of weight reduction, the cost of achieving that weight reduction was greater than that used in the CAFE model.¹³⁸¹ Similarly, as mentioned above, Toyota commented that mass reduction cost values were underestimated.¹³⁸² Conversely, CARB, UCS, and the City of Oakland in California commented that the costs used for mass reduction in the NPRM overstated the cost of mass reduction. The agencies also received several comments relating to the studies used to develop the mass reduction cost curves, how the values from those curves were applied in the CAFE model, and costs for secondary mass reduction; those comments are discussed in turn.

(1) Studies Used To Develop Mass Reduction Cost Curves

The agencies described in the PRIA that since the 2012 final rule, both agencies conducted lightweighting studies to assess the technical feasibility and cost of mass reduction.¹³⁸³ The agencies also stayed apprised of studies performed by other agencies, manufacturers, and industry trade associations, and reviewed them in development of lightweighting assumptions used in the NPRM and final rule analysis.¹³⁸⁴ Among the several lightweighting studies, the agencies used NHTSA's passenger car lightweighting study, based on a MY 2011 Honda Accord, and NHTSA's full-size pickup truck lightweighting study, based on a MY 2014 Chevrolet Silverado, to derive the cost estimates to achieve different levels of mass reduction for the NPRM and final rule.

The agencies described that the decision to rely on those studies included that those studies considered materials, manufacturing, platform-sharing, functional attribute, performance, and noise-vibration- and harshness (NVH), among other constraints pertaining to cost, effectiveness, and safety considerations, in addition to that these vehicles were a reasonable representation of the baseline vehicles in the MY 2016 compliance simulation.¹³⁸⁵ Specifically in regards to safety, the agencies described a preference to use studies that considered small overlap impact tests conducted by the Insurance Institute for Highway Safety (IIHS) and not all studies took that test into

account. In regards to maintaining vehicle functionality, the agencies described that the NHTSA pickup truck study accounted for vehicle functional performance for attributes including towing, noise and vibration, and gradeability, in addition to considering platform sharing constraints.

In contrast, the agencies explained that the other studies often did not consider many important factors, or those studies made unrealistic assumptions about key vehicle systems through secondary downsizing, resulting in unrealistically low costs. Specifically, the agencies referenced EPA's past analysis of a MY 2010 Toyota Venza as an example of a study that employed overly aggressive secondary mass reduction, which translated into cost savings for the initial 10% mass reduction.¹³⁸⁶

The agencies received several comments on the studies used to generate the mass reduction cost curves. Ford commented in support of the agencies' decision to exclude mass reduction studies that were misaligned with tear-down studies.¹³⁸⁷ Ford cited the MY 2010 Toyota Venza Phase II study used to establish the mass reduction cost values used for the Draft TAR and Proposed Determination that suggested the first 7–10% of mass reduction could be accomplished with zero or reduced cost,¹³⁸⁸ which Ford characterized as “a gross underestimation of industry investment and material costs associated with any weight reduction.”

ICCT commented that The National Academies of Science “specifically endorsed tear-down studies as the most appropriate way to get at vehicle technology costs, [as those] studies are typically more accurate and far more transparent than the older method of surveying manufacturers, and such whole-vehicle studies are key to capturing holistic vehicle level mass-reduction technology costs.” ICCT noted that there are many peer-reviewed tear-down studies that demonstrate that at least 20 percent mass reduction is available for adoption across vehicle classes by 2025, including studies by EDAG, FEV, Ford, and Lotus Engineering; however, ICCT alleged that the agencies “have either incorrectly interpreted or invalidly nullified the most relevant detailed engineering teardown studies on mass-reduction technology.” ICCT noted that the

agencies were “well aware” of these studies, as they were performed by CARB in conjunction with the agencies, however, ICCT alleged that the agencies “reinterpreted the results of the main study relied upon in the TAR in order to inflate costs,” and that the “technical assessment by the agencies has a clear technical bias towards reducing CAFE and GHG standards.” ICCT concluded that “[e]xcluding these studies amounted to intentionally disregarding the most pertinent and rigorous engineering studies that are applicable to the rulemaking timeframe.”

ICCT recommended the agencies adjust their technology cost inputs to reflect the “best-available technology studies.” ICCT stated that the correct cost assumption from these studies is that “a 5–10% mass reduction by 2025 reduces vehicle cost, and the auto industry will cost-effectively deploy at least 15% vehicle curb mass reduction in the 2025 timeframe at near zero net cost (and consistently less than \$500).”

CARB asserted that the agencies inflated the costs of mass reduction in the NPRM analysis by only considering NHTSA-sponsored studies and improperly excluding the effects of secondary mass reduction as documented in those studies.¹³⁸⁹ CARB provided a table of studies that largely mirrored the tables of studies the agencies considered in the Draft TAR and PRIA,¹³⁹⁰ and also included the associated mass reduction costs in \$/kg included in each study, noting that for all excluded studies cited in the table, all mass reduction costs were substantially lower than the values used in the agencies' analysis.¹³⁹¹ Similarly, UCS commented that while the PRIA did state that additional studies “often did not consider many important factors or . . . made unrealistic assumptions about key vehicle systems,” the agencies did not specifically identify the factors and assumptions that merited disregarding those studies, which were included previously in agency analysis as part of the record when deriving previous estimates for the costs of mass reduction.¹³⁹²

The agencies agree with ICCT that peer-reviewed tear-down studies present an appropriate method to capture holistic vehicle-level mass reduction technology costs. The agencies also agree with ICCT that the agencies were well aware of studies conducted by EDAG, FEV, Ford, and Lotus Engineering; in fact, the agencies

presented a table listing several of those studies in the PRIA with the qualification that those studies were reviewed in developing lightweight assumptions for the analysis, but those studies did not consider important factors, or those studies made unrealistic assumptions about key vehicle systems through secondary downsizing, resulting in unrealistically low costs.

The agencies also agree with UCS' comment that the language could have been more specific about identifying the factors and assumptions that merited disregarding studies that were previously included as part of the record when deriving previous estimates for the costs of mass reduction. The following discussion briefly summarizes the record since the Draft TAR and differences between NHTSA's and other lightweighting studies' approach to factors listed in the PRIA. Important for this discussion is an understanding of primary versus secondary mass reduction; as described above, when there is sufficient primary mass reduction, other components that are designed based on the mass of primary components may be redesigned and have lower mass. Recall the braking system example used throughout this section; mass reduction in the braking system is secondary mass reduction because it requires primary mass reduction before it can be incorporated. If the mass of primary components is reduced sufficiently, the resulting lighter weight vehicle could maintain braking performance, attributes, and safety with a lighter weight brake system.

Several studies were referenced in the Draft TAR that either used tear-down analyses and computer-aided engineering (CAE) to produce a future engineered lightweight vehicle, or considered future technologies and processes for lightweighting vehicle components.¹³⁹³

EPA developed cost curves for cars and CUVs based on the MY 2010 Toyota Venza study, and pickup truck cost curves based on the MY 2011 Chevrolet Silverado study.¹³⁹⁴ The other studies were considered by EPA, but not used to develop the Draft TAR, Proposed Determination and Final Determination cost curves. In brief, EPA described that the Toyota Venza Phase I was a mass reduction opportunity study only, and the Phase II study was a holistic vehicle study that examined nearly every component in the vehicle for mass reduction potential and calculated a

related cost and mass saved for each. For the cost curve, EPA applied the individual components in sequence from largest cost per kilogram savings to largest cost per kilogram increase. For example, the cost curve for the Draft TAR and Proposed Determination applied engine downsizing and transmission system mass reduction first, and before lightweighting the body, chassis, doors and other components.¹³⁹⁵ EPA stated this methodology was chosen based on the understanding that OEMs will choose the cost saving technologies first and that some cost mass reduction technologies will be paid for by the cost save mass reduction technologies, citing a 2016 publication by CAR and a GM presentation that stated over \$2,000,000,000 was saved in material costs through various lightweighting approaches.¹³⁹⁶

The NHTSA cost curves were developed by rearranging the lightweighted components from the MY 2011 Honda Accord and MY 2014 Chevrolet Silverado studies based on cost effectiveness, assuming the vehicle body, chassis, interior, and other primary components were lightweighted first, followed then by lightweighting powertrain components and other secondary systems.¹³⁹⁷ The cost curves based on the NHTSA studies reflect that, returning to this example, secondary mass reduction for the brake system is only applied after there has been sufficient primary mass reduction to allow the smaller brake system to provide safe braking performance and to maintain mechanical functionality.¹³⁹⁸

The EPA and NHTSA studies took fundamentally different approaches to accounting for the costs of mass reduction technology, and accordingly, EPA needed to translate the cost curves

from the NHTSA studies to use a similar methodology as the cost curves from the EPA studies.¹³⁹⁹ To "normalize" the NHTSA studies with the EPA's studies, EPA listed components identified for lightweighting in the NHTSA studies and reorganized those components from the lowest cost to highest cost along with associated mass reduction per the "whole vehicle" approach mentioned above, distributed mass savings from secondary mass reduction to all points along the cost curve, and included the mass saved from engine downsizing without taking into consideration the cost of added engine technology. This resulted in lower-cost secondary mass reduction opportunities being considered before primary mass reduction opportunities, which in turn resulted in artificially low \$/kg costs for mass reduction.

For the NPRM and final rule, the agencies simply used the original ordered list of components from the MY 2011 Honda Accord study and MY 2014 Chevrolet Silverado study, arranged sequentially for cost effectiveness based on primary then secondary mass reduction opportunities, to generate the cost curves for passenger cars and light trucks. Accordingly, the agencies did not "reinterpret" the results of studies used in the Draft TAR in the NPRM, as ICCT alleged, but rather appropriately represented how primary and secondary mass reduction opportunities are implemented in the real world (to the extent that ICCT is referring to the translation of the study costs to the NPRM glider weight assumptions, that is discussed in Section VI.C.4.e)(1), below). To maintain utility and performance in the real world, primary components must be lightweighted first before the engine and transmission can be resized. Moreover, as described in the Draft TAR, NHTSA's mass reduction studies did not "improperly exclude" the effects of secondary mass reduction, rather those effects were appropriately accounted for after primary components achieved certain levels of mass reduction. As discussed in Section VI.B.3.a)(6) Performance Neutrality, this approach aligned with the NAS approach to consider powertrain downsizing only after the vehicle structural components achieved 10 percent mass reduction.

OEMs have also disagreed with the conclusion that mass reduction could come at a cost savings. For instance, Ford characterized the Toyota Venza studies, which concluded the first 7–10% of mass reduction could come at a negative cost as "a gross

¹³⁹⁷ Draft TAR at 5-421 ("The powertrain components which include engine, transmission, and fuel systems such as fuel filler pipe, fuel tank, fuel pump, etc., exhaust systems and cooling systems were not considered for application of primary mass reduction but benefits of secondary mass reduction were accounted for. These powertrain components are assumed to be downsized only after the primary vehicle structural components (Body-In-White) achieve certain level of mass reduction.").

¹³⁹⁸ Draft TAR at 5-422.

¹³⁹³ Draft TAR at 5-158 through 5-197.

¹³⁹⁴ Draft TAR at 5-367.

¹³⁹⁹ Draft TAR at 5-369.

underestimation of industry investment and material costs associated with any weight reduction.” The agencies believe that the approach to secondary mass reduction followed in the NHTSA passenger car and pickup truck lightweighting studies appropriately incorporated both the costs and real-world constraints associated with employing primary and secondary mass reduction technologies.

Aside from the differences in how studies treated secondary mass reduction, the agencies opted not to use, or could not use, other studies either previously considered in the rulemaking record or mentioned by commenters for several reasons:

Studies were not comprehensive, and therefore could not be used to develop a comprehensive cost curve: Some studies narrowly assessed lightweighting of a portion of vehicle, such as the body in white subsystem, or as stated in the PRIA,¹⁴⁰⁰ were limited to material substitution of the vehicle components, such as replacing steel with aluminum or replacing mild steel with AHSS or replacing mild steel with CFRP in selective components. Factors important to vehicle functionality, like material joining techniques and the feasibility of manufacturing processes or necessary retooling requirements were not considered, and therefore could not be used to develop a comprehensive cost curve representative of the costs required to reduce mass in a vehicle.¹⁴⁰¹

Cost curves were not developed or no cost analysis was performed: For the CARB Holistic Vehicle Mass Reduction/Cost Study, a cost curve was not developed, and the resulting cost per kilogram data points were point estimates. The calculated cost per kilogram was used as one data point of several to indicate the direction for mass reduction beyond EPA’s original passenger car/CUV curve.¹⁴⁰² Or, as in the case of the DOE/Ford/Magna Multi Material Lightweight Vehicle (MMLV) project, no cost analysis was performed for the initial project, and later project(s) concluded that “a 37% to 45% mass reduction in a standard mid-sized vehicle is within reach if carbon fiber composite materials and manufacturing processes are available and if customers are willing to accept a reduction in vehicle features and content, as demonstrated with the Multi-Materials

and Carbon Fiber Composite-Intensive vehicle scenarios.”¹⁴⁰³

Engineered vehicles did not meet functional design or manufacturing requirements: As noted in the update to EPA’s Light-Duty Vehicle Mass Reduction and Cost Analysis for the Toyota Venza, the Phase I engineered Venza did not meet the design target of no expected NVH degradation.¹⁴⁰⁴ The Phase II (High Development) study assumed significant cost savings from reduced parts manufacturing, but did not appropriately explain the methodology used to conclude that the part count reduction was feasible.¹⁴⁰⁵

In addition, the agencies qualified in the PRIA a preference to use studies that considered the small overlap impact test conducted by IIHS, and not all studies took that test into account.¹⁴⁰⁶ NHTSA’s “Update to Future Midsize Lightweight Vehicle Findings in Response to Manufacturer Review and IIHS Small-Overlap Testing” based on the MY 2011 Honda Accord presented results incorporating suggestions from Honda regarding NVH and durability, and updating the engineered vehicle to achieve a “good” rating in seven crash safety tests.¹⁴⁰⁷ EPA studies also accounted for the IIHS small overlap test through an ad hoc estimate of mass and cost, unlike the NHTSA update, which explicitly modeled to account for NVH performance and to comply with the IIHS small overlap test.

The agencies continue to believe that the MY 2011 Honda Accord and MY 2014 Chevrolet Silverado lightweighting studies are the best studies upon which to estimate the costs of mass reduction in the rulemaking timeframe.

(2) How the Cost Curves Are Applied in the Model

Commenters also submitted comments on how the cost curves were applied in the model, including that the studies the agencies relied upon to generate cost curves, discussed above, did not support the 50 percent glider share assumption used in the NPRM, and the agencies did not correctly scale

the costs to match the glider share assumption.

UCS commented that the agencies based the costs for mass reduction on glider weight reduction, however, the need for more expensive materials and more advanced engineering and design strategies only results from the need for greater levels of absolute mass reduction on the vehicle.¹⁴⁰⁸ UCS stated that the cost curves had effectively been derived from the assumption of reductions as great as 16.8 percent reduction in curb weight in the case of the Silverado (Singh et al. 2018) and as great as 18 percent reduction in curb weight in the case of the Honda Accord (Singh et al. 2016), but applied to curb weight reductions approximately two-thirds that magnitude. UCS stated that approach was “completely invalid and significantly overstates the costs for mass reduction.” UCS also commented that the agencies incorrectly scaled the cost curves based on the agencies’ mass reduction studies, which refer to direct manufacturing costs as a function of vehicle curb weight, not just glider weight. UCS stated this incorrectly yielded the same costs for two-thirds the amount of mass reduction.

CARB similarly commented that the mass reduction costs assigned to both passenger cars and light trucks in the CAFE model were inappropriately inflated based on incorrect scaling from the glider share assumptions used in the Honda Accord and Chevy Silverado studies to the NPRM glider share value.¹⁴⁰⁹ CARB analyzed two tables in the PRIA that showed the agencies’ translation of cost numbers derived from the two studies to the cost numbers used in the CAFE model, and asserted that the agencies improperly used costs from the upper end of the mass reduction range rather than the midpoint of the range, leading to cost overestimation.

Similarly, HDS commented that the PRIA passenger car cost curves used data that were not in agreement with the study that they were based upon, noting that the Honda Accord study showed the glider accounting for 78% of curb weight, and this limited absolute weight reduction.¹⁴¹⁰ HDS noted that the truck weight reduction cost data were closer to those cited in the Chevy Silverado teardown study, although the glider share for that study was also 73.6% of vehicle curb weight.

HDS also commented that although the agencies relied on the same Honda Accord study that was used in the Draft

TAR, “the costs have been changed significantly [from the Draft TAR] for unexplained reasons.”¹⁴¹¹ HDS stated that the PRIA showed average costs for mass reduction, whereas earlier studies showed the cost increment for each 5% mass reduction, noting that with increasing incremental cost with increased mass reduction, average cost will always be lower than incremental cost. HDS claimed that it was “unusual” for the Draft TAR incremental costs to decrease between 11% and 19% mass reduction but increase elsewhere, but also noted the unexplained increase in cost, specifically a \$536 cost for 175kg weight reduction, shown in the PRIA.

HDS also compared manufacturing costs from the Draft TAR to the PRIA analysis, noting that the direct manufacturing cost was found to be negative (*i.e.*, a cost saving) in the Draft TAR analysis for mass reduction up to 15 percent, but EPA assumed the indirect costs were positive so that the total cost was a sum of positive and negative costs—meaning the total cost could be positive or negative. In contrast, HDS noted there were no negative costs in the cost curves used for the PRIA analysis, resulting in a very large differential between the costs of mass reduction, with the 2018 average cost being higher than even the 2016 marginal costs.

Three notable changes from the NHTSA Draft TAR to NPRM and final rule analysis impacted how the cost curves for mass reduction are applied in the CAFE Model.

First, the Draft TAR considered mass reduction in the glider and powertrain together, and calculated the percentage mass reduction on a vehicle curb weight basis. In the Draft TAR, only one engine and transmission combination were considered to account for the mass change associated with downsizing the engine, and the cost estimates for mass reduction for this *one* powertrain combination was applied to *all*

powertrain combinations. This approach did not account for the mass changes associated with the application of powertrain technologies (engine, transmission and electrification) technologies, and did not account for the corresponding change in glider mass needed to offset the powertrain mass change and to achieve the specified curb weight mass reduction level. This approach did not reflect the real world, where there are many vehicles with different body styles and powertrain combinations, and therefore did not account for differences in mass for different engines, transmissions, or electrification.

Accordingly, for the NPRM and final rule, the cost of mass reduction was calculated on a glider weight basis so that the weight of each powertrain configuration could be directly and separately accounted for. This approach provides the true cost of mass reduction without conflating the mass change and costs associated with downsizing a powertrain or adding additional advanced powertrain technologies. Hence, the mass reduction costs in the NPRM reflect the cost of mass reduction in the glider and do not include the mass reduction associated with engine downsizing, and therefore appear to be higher than the cost estimates in the Draft TAR.

Second, the glider share of curb weight changes from the Draft TAR to NPRM and from the NPRM to the final rule analysis also affected the absolute amount of curb weight reduction that was applied, and therefore for cost per pound for the mass reduction changes with the change in the glider share. The cost for removing 20 percent of the glider weight when the glider represents 75% of a vehicle’s curb weight is not the same as the cost for removing 20 percent of the glider weight when the glider represents 50% of the vehicle’s curb weight. For example, the glider share of 79 percent of a 3,000-pound curb weight vehicle is 2,370 pounds, while the glider share of 50 percent of a 3,000-

pound curb weight vehicle is 1,500 pounds, and the glider share of 71 percent of a 3,000-pound curb weight vehicle is 2,130 pounds. The mass change associated with 20 percent mass reduction is 474 pounds for 79 percent glider share ($= [3,000 \text{ pounds} \times 79\% \times 20\%]$), 300 pounds for 50 percent glider share ($= [3,000 \text{ pounds} \times 50\% \times 20\%]$), and 426 pounds for 71 percent glider share ($= [3,000 \text{ pounds} \times 71\% \times 20\%]$). The mass reduction cost studies show that the cost for mass reduction varies with the amount of mass reduction. Therefore, for a fixed glider mass reduction percentage, different glider share assumptions will have different costs.

To further illustrate, Table VI–127 and Table VI–128 below shows the associated curb weight percentage mass reduction and the associated average cost per pound for different glider weight assumptions for each glider mass reduction technology level used in the final rule analysis. For reference, the costs from the passenger car light weighting study are presented.¹⁴¹² These costs were the basis for deriving the costs for each mass reduction technology level in the Draft TAR, NPRM, and final rule analyses, using the unique glider share values for each of those analyses. In the light weighting study, NHTSA applied the mass reduction technologies identified for the exemplar vehicle on other vehicle(s) and vehicle types to understand the level of mass reduction that could be achieved. In the case of passenger cars, the maximum level of mass reduction was around 15% of the vehicle curb weight if all the mass reduction technologies are applied. In other words, achieving mass reduction greater than 10% of the curb weight for passenger cars will require extensive use of advanced materials such as high strength aluminum and carbon fiber composite material.

BILLING CODE 4910-59-C

Finally, as explained earlier, to determine the mass reduction technology levels for the NPRM 2016 analysis fleet, a distribution of the residuals from the regression using 50 percent glider weight generally showed

a greater percentage of vehicles achieving higher levels of mass reduction. With this high level of mass reduction already achieved, the opportunities for further mass reduction would be limited and have higher costs.

For the final rule, since the agencies updated the glider share to 71 percent of the vehicle curb weight, the distribution of residuals from the regression shifted some vehicles to lower baseline mass reduction

technology levels, providing more opportunity for further mass reduction, on average. Even as some of the vehicles start further up on the mass reduction cost curve due to higher levels of mass reduction technology (MR3, MR4) already present in the vehicles, there are additional opportunities for further mass reduction to achieve MR5 and above.

Table VI–127 and Table VI–128 show that for the final rule, cost estimates with the 71 percent glider share come closer to the cost estimates used in Draft TAR, which assumed a 79 percent glider share.

(3) Secondary Mass Reduction Costs

As discussed above, the agencies changed the cost of mass reduction calculation from a curb weight basis in the Draft TAR to a glider weight basis in the NPRM.¹⁴¹³ This change allowed us to estimate the cost of mass reduction independently of the cost associated with downsized advanced engines and advanced transmissions, as the cost of downsized advanced engines and transmissions are accounted for separately in the CAFE model.

The MY 2011 Honda Accord and MY 2014 Chevy Silverado studies used to develop the NPRM and final rule cost curves for mass reduction technologies include some non-powertrain secondary mass reduction technologies such as brakes and wheels. The agencies presented the list of mass reduction technologies in NPRM.¹⁴¹⁴ Following the publication of NHTSA's light weighting studies, peer reviewers and manufacturers commented that many components such as drive axles, engine cradles, and radiator engine support that are considered to be non-powertrain secondary mass reduction opportunities cannot be downsized, as the same

components are used across many vehicles with different powertrain options. Even though some of these components may provide opportunities for additional mass reduction, NHTSA agreed with peer reviewers and manufacturers that retaining a common design for all powertrain options provides for cost reductions due to economies of scale.

Commenters faulted the agencies for a perceived lack of accounting for the cost decreases from secondary mass reduction. ICCT commented although the agencies relied on the Honda Accord study, which considered cost savings from downsizing the powertrain, in the NPRM only glider weight reduction was ever considered without the cost-offsetting engine downsizing.¹⁴¹⁵ ICCT stated that this omission had two effects, first that accounting for associated powertrain weight reductions would have allowed for more mass reduction, thus allowing for greater efficiency benefits at a lower cost, and second, that vehicle performance was erroneously improved, contrary to the agencies' assertion that the analysis assumed a level of performance neutrality. ICCT concluded that it was unclear if and how costs were reduced for powertrain downsizing, as well as the precise changes to fuel efficiency.

CARB faulted the agencies for not including secondary mass reduction in the NPRM analysis, and stated that by failing to account for secondary mass reduction as was done in the Draft TAR, the agencies inflated the costs for mass reduction as well as the amount of mass reduction that is feasible and cost-effective leading to an overestimate in the technology costs needed to meet the existing standards.

The agencies note that the cost curves used for the NPRM and this final rule do in fact include secondary mass reduction. The cost curves reflect secondary mass reduction applied when there is sufficient primary mass reduction to implement secondary mass reduction without degrading function

and safety. Specifically, the NHTSA studies, upon which the cost curves were built, first generated costs for light weighting the vehicle body, chassis, interior, and other primary components, and then calculated costs for light weighting secondary components. Accordingly, the cost curves reflect that, for example, secondary mass reduction for the brake system is only applied after there has been sufficient primary mass reduction to allow the smaller brake system to provide safe braking performance and to maintain mechanical functionality.

In addition, CARB stated that the 2011 Honda Accord and the 2014 Chevrolet Silverado studies had “markedly” lower costs than the proposal when secondary mass reduction is included. Again, the agencies believe these comments resulted from a lack of understanding about how the analysis considers primary and secondary mass reduction, even though the NPRM and PRIA explicitly stated how costs are accounted for separately.¹⁴¹⁶ Also, as discussed above, engine mass reduction enabled by mass reduction in the glider is accounted for separately and therefore not included as part of glider mass reduction technology, as doing so would result in double counting the impacts.

(4) Summary of Final Rule Mass Reduction Costs

For the final rule, the agencies continue to use multiple mass reduction technology levels and costs based on the light weighting studies that were presented in PRIA.¹⁴¹⁷ Since the agencies have changed the glider share of curb weight assumption from 50 percent in NPRM to 71 percent in the final rule, the mass reduction costs reflect the updated glider share. Table VI–129 and Table VI–130 show mass reduction costs used in the CAFE model for passenger car and light trucks.

BILLING CODE 4910–59–P

¹⁴¹³ In the Draft TAR, the agencies presented the cost estimates from mass reduction studies sponsored by both NHTSA and EPA. EPA presented the cost of mass reduction as function of vehicle curb weight. To harmonize the cost estimates with EPA, NHTSA also presented the cost of mass reduction as a function of vehicle curb weight.

BILLING CODE 4910-59-C

5. Aerodynamics

The energy required to overcome aerodynamic drag accounts for a significant portion of the energy consumed by a vehicle, and can become the dominant factor for a vehicle's

energy consumption at high speeds. Reducing aerodynamic drag can, therefore, be an effective way to reduce fuel consumption and emissions.

Aerodynamic drag is proportional to the frontal area (A) of the vehicle and coefficient of drag (C_d), such that

aerodynamic performance is often expressed as the product of the two values, C_dA , which is also known as the drag area of a vehicle. The coefficient of drag (C_d) is a dimensionless value that essentially represents the aerodynamic efficiency of the vehicle shape. The

frontal area (A) is the cross-sectional area of the vehicle as viewed from the front. It acts with the coefficient of drag as a sort of scaling factor, representing the relative size of the vehicle shape that the coefficient of drag describes. The force imposed by aerodynamic drag increases with the square of vehicle velocity, accounting for the largest contribution to road loads' higher speeds.

Aerodynamic drag reduction can be achieved via two approaches, either by reducing the drag coefficient or reducing vehicle frontal area, with two different categories of technologies, passive and active aerodynamic technologies. Passive aerodynamics refers to aerodynamic attributes that are inherent to the shape and size of the vehicle, including any components of a fixed nature. Active aerodynamics refers to technologies that variably deploy in response to driving conditions. These include technologies such as active grille shutters, active air dams, and active ride height adjustment. It is

important to note that manufacturers may employ both passive and active aerodynamic technologies to achieve aerodynamic drag values.

The greatest opportunity for improving aerodynamic performance is during a vehicle redesign cycle when significant changes to the shape and size of the vehicle can be made. Incremental improvements may also be achieved during mid-cycle vehicle refresh using restyled exterior components and add-on devices. Some examples of potential technologies applied during mid-cycle refresh are restyled front and rear fascia, modified front air dams and rear valances, addition of rear deck lips and underbody panels, and low-drag exterior mirrors. While manufacturers may nudge the frontal area of the vehicle during redesigns, large changes in frontal area are typically not possible without impacting the utility and interior space of the vehicle. Similarly, manufacturers may improve C_d by changing the frontal shape of the vehicle or lowering the height of the vehicle,

among other approaches, but the form drag of certain body styles and airflow needs for engine cooling often limit how much C_d may be improved.

During the vehicle development process, manufacturers use various tools such as Computational Fluid Dynamics (CFD), scaled clay models, and full size physical prototypes for wind tunnel testing and measurements to determine aerodynamic drag values and to evaluate alternate vehicle designs to improve those values.

The agencies presented a table in the PRIA showing aerodynamic drag improvements from individual technologies based on wind-tunnel testing for a study commissioned by Transport Canada, which is reproduced in Table VI-131 below.¹⁴¹⁸ The individual technologies are present in many of the 2016 and 2017 vehicles in the fleet. Table VI-131 shows the list of aerodynamic technologies and corresponding aero drag improvements.

Table VI-131 – Aerodynamic Technologies and Aero Drag Improvements

| Aero Feature (A-B Testing) | | Aero Drag Reduction (%) | Comments |
|--------------------------------------|---------|--------------------------------|---|
| Fixed Air Dam-Bumper | | 1 - 6% | OEM stock components |
| Active Air Dam – Bumper (Conceptual) | | 4 - 9% (fixed air dam + 3%) | Fixed, prototype parts w/ lowest deployment height used |
| Fixed Air Dam-Wheels | | 1% (front)/4.5% (front & rear) | |
| Underbody Panels | | 1-7% (stock OEM) | Addn'l 0.5%-4% w/ full body panels. Dodge Ram prototype: 8% |
| Increased Tire Size | | -2.0 - 3.2% | 17"/18" stock OEM rims vs. 22" optional OEM rims |
| Wheel Covers | | 1.5 - 3% | Solid wheel covers only; brake cooling affects not considered |
| Front License Plates | | +/- 0.3% | Negligible impact |
| Decorative Grille Optimization | | 1.6% | Smoothing of grille features; function vs. styling trade-offs |
| Pick-up Tailgates | Open | -5.2% | |
| | Removed | -7.5% | Open tailgate + 2.3% |
| Pick-up Tonneau Cover | | 3.7% | |

As discussed in the PRIA and further below, the agencies made several

notable changes for modeling aerodynamic improvement technologies

from the Draft TAR to the NPRM. First, the agencies revised the aerodynamic

¹⁴¹⁸ Table 6-63 in PRIA.

improvements from two levels in the Draft TAR (10% and 20% improvement over the baseline) to four levels (5%, 10%, 15% and 20% aerodynamic drag improvement values over the baseline). This change provided the improved granularity to bin the vehicles with different aerodynamic improvements more appropriately. Next, the agencies assigned levels of aerodynamic technology to the MY 2016 fleet on a relative basis based on confidential business information submitted by the manufacturers, taking steps to verify information submitted by manufacturers with other sources, and making changes particularly for vehicles that showed large improvements over baseline values. Third, the agencies limited the maximum level of aerodynamic improvements that certain body styles (pickup trucks, minivans) could achieve and limited the maximum level of improvements that cars and SUVs with more than 405 horsepower could achieve, based on the agencies' assessment of industry comments. Finally, the agencies updated the cost for aerodynamic improvements based on the assessment of comments that the National Academy of Sciences (NAS) cost estimates used in the Draft TAR underestimated the cost for aerodynamic improvements.

Broadly, Ford commented in support of the approach to aerodynamic improvement modeling in the NPRM, stating that the rule recognized potential constraints like consumer needs and preferences regarding vehicle styling, vehicle utility, and interior space, by among other things, recognizing that the potential for aerodynamic drag differs among different vehicle body styles and vehicle classes.¹⁴¹⁹ Ford stated that these are major factors considered by customers when comparing competing vehicles, and the failure of a manufacturer to deliver in these areas can lead to the production of non-competitive, poor-selling vehicles.

On the other hand, ICCT claimed that the agencies greatly limited the availability of many load reduction technologies (*i.e.*, mass reduction improvements, aerodynamic improvements, and rolling resistance improvements) by pushing very large amounts of these technologies into the 2016 model year baseline fleet, thereby making the technologies unavailable for use in future years.¹⁴²⁰ ICCT commented that these improvements in the analysis fleet would ostensibly amount to massive efficiency improvements, however, these assumed

changes were not substantiated as resulting in any test-cycle efficiency improvements in the model year 2016 fleet versus the 2015 fleet. ICCT concluded that the adjusted baseline had been developed and presented opaquely, apparently based primarily upon estimations from automaker-supplied data, without critical analysis, vetting, or sharing of the necessary data to substantiate the changes and real-world benefits by the agencies.

As discussed further in Section VI.C.5.b) AERO drag analysis fleet assignments below, the agencies believe the updated analysis fleet aerodynamic technology level assignments in the NPRM analysis represent an improvement over the MY 2015 assignments in the Draft TAR, as the updated assignments are based on precise values, not estimated from road load coefficients, and have been corroborated by observed improvements on actual production vehicles. Accordingly, the agencies carried over the NPRM approach for determining the aerodynamic technology levels for the analysis fleet to the final rule.

a) Aerodynamics Drag Reduction Modeling in the CAFE Model

The agencies summarized in the PRIA that the Draft TAR aerodynamic improvement levels were binned into two groups, AERO1 and AERO2. However, market observations showed that many vehicles had aero improvements from 0% to 10%, and some vehicles showed improvements from 10% to 20%.¹⁴²¹ Based on industry feedback and market observations, the agencies revised the aerodynamic improvements from two levels in the Draft TAR (10% and 20% improvement over the baseline) to four levels (5%, 10%, 15% and 20% aerodynamic drag improvement values over the baseline). This revision provided the necessary granularity to bin the vehicles with different aerodynamic improvements appropriately.

ICCT commented that to model appropriately the baseline standards, the agencies would need to include increasing use of aerodynamic off-cycle technology credits across all companies through 2025. ICCT stated that it appeared that the agencies did not use EPA's engineering expertise or compliance data, where EPA would be able to advise better based on their certification data from the off-cycle program.

As discussed further in Sections VI.A and VI.C.8, the NPRM analysis carried

forward manufacturers' off-cycle fuel consumption improvement values (FCIVs) at MY 2016 levels unless an explicitly simulated off-cycle technology, like start-stop systems, was added to a vehicle in the simulation modeling. Specific to aerodynamic improvements, active grille shutters were assumed to be applied at the 20 percent aerodynamic improvement (AERO20) level. For the final rule analysis, based on the assessment of comments that the application of off-cycle technologies in the analysis was too conservative, the agencies agreed and increased each manufacturers' application of off-cycle technologies so that 10 g/mi of technology was applied by 2023, using an extrapolated increase in levels in MYs 2017–2023 based on EPA compliance data.¹⁴²² This approach did not assume any specific mix of off-cycle technologies that would be used by manufacturers to achieve the 10 g/mi off-cycle improvement, because manufacturers currently use a variety of technologies, and different manufacturers likely would implement unique combinations of technologies. It is expected that aerodynamic off-cycle technologies would be included in the mix of off-cycle technologies.

Table VI–132 and Table VI–133 show aerodynamic technologies that could be used to achieve 5%, 10%, 15% and 20% aero improvements in passenger cars, SUVs, and pickup trucks.¹⁴²³ The agencies developed these potential combinations of technologies using aerodynamic data from a National Research Council (NRC) of Canada sponsored wind tunnel testing program that included an extensive review of production vehicles utilizing these technologies, and industry comments.^{1424 1425} These technology combinations are intended to show a *potential* way for a manufacturer to achieve each aerodynamic improvement level; however, in the real world, manufacturers may implement different combinations of aerodynamic technologies to achieve a percentage

b) Aerodynamic Drag Reduction Analysis Fleet Assignments

The agencies described in the PRIA that for the 2015 analysis fleet used in the Draft TAR, the agencies received C_d values for the MY 2015 vehicles' baseline assignments from manufacturers, or used estimated C_d values. In response, the industry commented that C_d values often varied by measurement approach and, therefore, it was important to account for differences in the methodologies used to estimate those values. For instance, aerodynamic drag coefficients for the same vehicle often vary significantly from wind-tunnel to wind-tunnel, complicating cross-comparison and cross-referencing.¹⁴²⁶ The industry commented that, on average, the manufacturer-reported C_d values are nine percent lower than the values reported by USCAR.¹⁴²⁷ For reference, USCAR follows the SAE J2881 test procedure. However, because C_d values are not required to be reported for compliance, manufacturers can and do choose different methods to estimate the C_d values. Therefore, the industry commented that assigning baseline aerodynamic improvement levels

should not simply be comparing the lowest reported C_d value in a vehicle segment to other reported C_d values. The industry commented that such a comparison would not reflect the plausible amount of aerodynamic drag improvement that could be achieved. Accordingly, the industry suggested that the analysis should normalize manufacturer-reported C_d values using SAE J2881.

The commenters stated manufacturers have the option to use other methods (apart from coast down testing) to estimate the C_d values such as wind tunnel testing, cross referencing the C_d value from other vehicles with similar frontal design and aero technologies deployed. Since manufacturers do not have to specify the methodology used to estimate the C_d value, the agencies have limited capability to make accurate comparisons of the C_d value estimates from different testing methods. As a result, the agencies determined using average(s) of the fleet provide a better estimate of C_d levels than using the lowest C_d value in the fleet to assign aerodynamic improvement levels. The agencies determined it is appropriate to continue to use the NPRM approach for the final rule.

The NPRM and final rule analysis used a relative performance approach to assign the current aerodynamic technology level to a vehicle. Different

body styles offer different utility and have varying levels of baseline form drag. In addition, frontal area is a major factor in aerodynamic forces, and the frontal area varies by vehicle. This analysis considered both frontal area and body style as utility factors affecting aerodynamic forces; therefore, the analysis assumed all reduction in aerodynamic drag forces come from improvement in the C_d . Per the process outlined in NHTSA's section of the Draft TAR,¹⁴²⁸ the agencies computed an average C_d for each body style segment in the MY 2015 analysis fleet from drag coefficients published by manufacturers. By comparing the C_d among vehicles sharing body styles, this allowed the agencies to estimate the level of aerodynamic improvement present on specific vehicles.

While some small differences existed between the aggregate MY 2015 and MY 2016 data, the agencies retained the NHTSA-calculated MY 2015 average C_d as the baseline drag coefficient for nearly all body styles. For pickup trucks, the agencies assigned a baseline drag coefficient of 0.42, considering that a large portion of the pickups sold in MY 2015 already included aerodynamic features assumed for advanced levels of aero. The agencies harmonized the Autonomie simulation baselines with

¹⁴²⁶ PRIA at 435.

¹⁴²⁷ Footnote in PRIA at 435: FCA Draft TAR comments. Docket ID: NHTSA-2016-0068-0082.

¹⁴²⁸ Draft TAR at 4-80.

the analysis fleet assignment baselines to the fullest extent possible.¹⁴²⁹

The agencies assigned levels of aerodynamic technology to the MY 2016 fleet based on confidential business information submitted by manufacturers on aerodynamic drag coefficients, and from other information sources such as in product release information. The analysis referenced manufacturer-submitted data (if that data was supplied), and the agencies took industry comments to Draft TAR into account and closely reviewed the manufacturer-submitted C_d data. In the few cases that manufacturers did not submit C_d values as confidential business information, the agencies estimated the C_d based vehicle attributes, design, and aero technologies applied to that vehicle. The agencies noted that the C_d values reported by some manufacturers showed high levels of improvement relative to the previous model year or previous generation. In some cases, the agencies contacted the manufacturers to further discuss differences in C_d estimation methodologies. Where appropriate, the agencies adjusted MY 2016 fleet C_d values after consultation with the manufacturers and used these values to assign baseline technology levels for each vehicle in the NPRM CAFE model simulation.

The Alliance commented that the NPRM analysis fleet had more appropriately assigned aerodynamic technology levels, and the assignments were more accurate than the Draft TAR, where vehicles were generally considered to have little aerodynamic improvement technology, and the CAFE model would add aerodynamic improvement despite the fact that manufacturers had already made significant improvements and there was little opportunity remaining for more.¹⁴³⁰ The Alliance concluded that the Draft TAR approach ultimately led the CAFE model to under-predict how much powertrain technology was required for compliance. The Alliance also commented that it is possible to estimate aerodynamic features of a vehicle using road load coefficients, but the process requires various assumptions and is not very accurate. The Alliance concluded that the agencies' use of CBI to assign initial aerodynamic improvement values is an

accurate and practical solution to support correct baseline assignments.

Ford commented that the use of actual data, like manufacturer confidential information or other sources, to characterize better the aerodynamic improvements already incorporated into the baseline fleet is a substantial improvement over previous analyses that either assumed no aero improvement due to insufficient data, or attempted to infer C_d from the road load coefficients.¹⁴³¹ Ford stated that attempting to infer C_d from road load coefficients is not sufficiently accurate for a vehicle-level determination since the aerodynamic component of the road load coefficients is inextricably confounded with tire, transmission, and other parasitic losses. As part of its comments that the proposed rule analysis recognized constraints like consumer needs and preferences regarding vehicle styling and utility, Ford stated that the baseline C_d for pickup trucks properly recognized that these vehicles already include many advanced-level aerodynamic technologies. Ford concluded that an accurate assessment of the current technological state of the baseline fleet is critical to ensuring that the benefits of technological improvements are not "double-counted" in the modeling.

On the other hand, ICCT commented that the agencies artificially limited the availability of aerodynamic technologies in the CAFE model in future years by assigning approximately three times as many aerodynamic technology packages in the 2016 analysis fleet as they did in the 2015 baseline fleet used in the Draft TAR.¹⁴³² ICCT noted that the 2015 Draft TAR fleet had about 8 percent vehicles with one of the aerodynamic packages, whereas the NPRM's 2016 fleet had about 53 percent, and argued that the agencies did not justify the increase with data to show that automakers actually deployed the technology. ICCT pointed to the agencies' introduction of intermediate aerodynamic improvement steps as the justification for the change, which ICCT argued "redistributes the baseline fleet into more advanced aerodynamic levels without observing or verifying real-world aerodynamic improvements."

ICCT argued that if an improvement of this magnitude were true, it would be evident in fleet level miles-per-gallon and CO₂ levels (e.g., in EPA's *Trends and Manufacturer Performance* reports), but none of the quantifiable mpg or CO₂ benefits that would be associated with these additional aerodynamic

improvements were reflected in any real-world evidence in the model year 2016 fleet. ICCT stated that to show the automakers deployed this level of aerodynamic improvements, the agencies needed to show data on how these improvements are evident in the fleet and delivering benefits. Specifically, ICCT stated that the agencies must share the basis for any aerodynamic calculation and exact estimated percent improvement (rather than binned percentage categories) for each vehicle make and model in the baseline and future modeled fleet, and their technical justification for each value, arguing that not doing so would obscure the agencies' methods. In addition, ICCT stated that the agencies must conduct two sensitivity analysis cases that assume that every baseline make and model is set to 0 percent aerodynamic improvement and set to the previous baseline aerodynamic levels (i.e., from TAR) to demonstrate how much the agencies' decision to load up more baseline technology affects the compliance scenarios. ICCT concluded that because changes in aerodynamic improvement assumptions "are opaquely buried in the agencies' datafiles and unexplained," the agencies must issue a new regulatory analysis and allow an additional comment period for review of the methods and analysis.

ACEEE asserted, as part of its comments that the MY 2016 analysis fleet assignments appeared to contain errors, that the assignment of AERO10 for the MY 2016 Toyota Tundra pickup truck was in error.¹⁴³³ ACEEE stated that Tundra pickup trucks have had similar specs from MY 2011 to today, and the C_d for all Tundra models has been 0.37 or 0.38 for 2WD and 4WD, respectively, since MY 2011. ACEEE noted that this is higher than the AERO10 C_d cut off value of 0.355 for pickups, as shown in the 2016 Draft TAR and referenced in the PRIA.

As described above, the agencies assigned levels of aerodynamic technology to the NPRM MY 2016 analysis fleet on a relative basis based on confidential business information submitted by the manufacturers on aerodynamic drag coefficients and other information sources such as in product release information. In addition, based on the Draft TAR comments, the agencies verified wherever possible the information submitted by manufacturers with other sources (product release information and cross referencing with vehicles with similar design features and aero technologies), and made

¹⁴²⁹ Often, vehicles assigned to technology classes do not perfectly match up with simulated vehicles, but in most cases this analysis assumed the aerodynamic effects and other specifications were comparable and appropriate for use as proxies.

changes particularly for vehicles which showed large improvements over baseline values. Figure 6–175 in PRIA presented the distribution of different levels of aerodynamic drag improvements in MY 2016 vehicle fleet in NPRM relative to MY 2015 vehicle fleet used in Draft TAR. The distribution shows that 46 percent of the MY 2016 vehicle fleet was assigned AERO0 (0 percent improvement), 31 percent of the fleet was assigned AERO5 (5 percent improvement), and 15 percent of the vehicle fleet was assigned AERO10 (10 percent improvement). This distribution clearly shows that there is substantial opportunity for additional aerodynamic drag improvements in the vehicle fleet.

Regarding comments by ACEEE on Toyota Tundra pickup trucks, as just stated, the agencies used manufacturer submitted information and other available information to assign aerodynamic technology levels and the agencies applied the same process for all of the manufacturers for the NPRM and for the final rule. The agencies did assign AERO10 for some Toyota Tundra pickups, but not for all as asserted by ACEEE. Some of the Toyota Tundra pickups with 2WD and short bed and crew cab or double cab were assigned AERO5 and other configurations were assigned AERO10.¹⁴³⁴ For reference, the baseline C_d value used in the NPRM for pickups is 0.395; a 5 percent

improvement in C_d value is 0.375 and 10 percent improvement in C_d value is 0.355. The agencies considered the ACEEE comment and available information and determined the aerodynamic assignments for the Toyota Tundra were reasonable for the final rule analysis.

Table VI–134 below shows the percentage aerodynamic drag improvement assigned to the MY 2015 (Draft TAR), MY 2016 (NPRM) and MY 2017 (final rule) analysis fleets. It is clear from this table that there is natural progression of aero technologies being adopted and the vast majority of the MY 2017 vehicle fleet is at or below AERO10 (81percent).

Table VI-134 – Aerodynamic Technology Assignments in MY 2017, MY 2016 and MY 2015

Vehicle Fleet

| AERO Levels | Final Rule (MY 2017) | NPRM (MY 2016) | Draft TAR (MY 2015) |
|--------------------|---------------------------------|---------------------------|--------------------------------|
| AERO0 | 41% | 46% | 92% |
| AERO5 | 40% | 31% | |
| AERO10 | 13% | 15% | 6% |
| AERO15 | 5% | 7% | |
| AERO20 | 1% | 1% | 2% |

Moreover, notable aerodynamic improvements have actually been observed on production vehicles. As described in PRIA, EPA observed 76 vehicles at the 2015 North American International Auto Show in Detroit (2015 NAIAS).¹⁴³⁵ EPA's observations showed that manufacturers have widely deployed both active and passive aerodynamic drag reduction technologies with significant opportunity remaining to apply aero technologies further in more optimized fashion as vehicles enter redesign cycles in the future.¹⁴³⁶ Although EPA did not identify the aerodynamic drag coefficient values for these vehicles, Figure 6–167 in PRIA showed the distribution of some aero technologies identified by EPA during this informal survey.

The survey showed that wheel dams and underbody panels are the most widely used aero technologies, followed by front bumper air dams and active

grill shutters. Since this survey, many pickup trucks and passenger cars have active grill shutters installed to improve aerodynamic drag, and to get off-cycle credit. Table 6–67 in PRIA shows the “active grill shutter” by itself will improve aerodynamic drag reduction improvement by 3 percent. Combined with other aero technologies, this can improve the aerodynamic drag reduction values significantly in pickup trucks and SUVs. As a result, there has been overall fleet wide aerodynamic drag reduction improvement; however, the above Table VI–134 shows that only 19 percent (13 percent from AERO10, 5 percent from AERO15 and 1 percent from AERO20) of the MY 2017 vehicle fleet has aerodynamic drag reduction improvement greater than 10 percent. This shows that there is significant opportunity for the vehicle fleet to improve aero technologies by MY 2025.

The agencies also described examples of how production vehicles in different

technology classes improved aerodynamic drag reduction values relative to their previous generation model since the 2012 final rule.¹⁴³⁷ The PRIA described how aerodynamic technologies were being deployed on production vehicles, using the MY 2015 Nissan Murano and MY 2015 Ford F150 as examples. For example, MY 2015 Ford F150 has the passive and active aerodynamic technologies as shown in Table VI–135.

The air curtain technology in the MY 2015 F150 guides the air flow across the front wheels to reduce wind turbulence.¹⁴³⁸ For reference, the wind tunnel testing by NRC of the MY 2015 Ford F150 showed a drag coefficient value of 0.37 while the coast down testing by EPA pegged the drag coefficient value between 0.35 to 0.40 depending on the type of powertrain, cab and cargo box combination. The prior generation F150 was released in 2008 as a MY 2009 and this vehicle had

¹⁴³⁴ The variations could be from coast down testing with different powertrains and with different pickup bed length and crew cab configurations.

very few aerodynamic technologies applied. The agencies do not have the MY 2009 C_d value to estimate the percentage improvement. Since the

F150 also included significant light weighting and powertrain improvements including a downsized turbocharged engine, the effectiveness

improvement attributable to aerodynamic technologies is uncertain.

| Aero Technologies | Active grill shutters |
| | Underbody Cover |
| | Front corners and head lamps canted back for smooth air flow |
| | Rear spoiler integrated with the Tail gate (Air from the roof lands on the spoiler before trailing off thereby reducing turbulence behind the truck |
| | Cargo box narrower than the cab and trim piece between the cab and pickup box |
| | Rear tail lamps shaped for smooth air flow tailing off and reducing turbulence |
| | Duct under head lamp channels air to the wheel house thereby reducing wake generated by the wheel, Cross sectional area slightly larger than previous gen which resulted in some loss of benefits. More information is provided by Ford at the following link |

The Nissan Murano is an example of a mid-size SUV with greater than fifteen percent improvement in aerodynamic drag values compared to the previous generation. The SAE paper published in 2015 outlines the specifics of aerodynamics in the Nissan Murano,¹⁴³⁹ and they include those listed in Table VI-136 below.

The exterior of this vehicle was completely redesigned from the MY 2013–2014 generation with the goal of

minimizing aerodynamic drag by combining passive aerodynamic devices with an optimized vehicle shape. The primary passive devices employed include optimization of the rear end shape to reduce rear end drag, and addition of a large front spoiler to reduce underbody air flow and redirect it toward the roof of the vehicle, thus augmenting the rear end drag improvements. Other passive improvements include plastic fillet

moldings at the wheel arches, raising the rear edge of the hood, shaping the windshield molding and front pillars, engine under-cover and floor cover, and air deflectors at the rear wheel wells. An active lower grille shutter also redirects air over the body when closed. Together, these measures for the MY 2015 model achieved a drag coefficient of 0.31, representing a 16 to 17 percent improvement over the 0.37 C_d of the previous model.

New Nissan Murano," SAE Technical Paper 2015–

01–1542, 2015, <https://doi.org/10.4271/2015-01-1542>.

Table VI-136 – Aerodynamic Technologies on MY 2015 Nissan Murano

| Design | Detail |
|---|---|
| Ideal Flow Features | |
| Minimum airflow into engine compartment | Reduces resistance (just enough to cool) |
| Airflow under front bumper toward underbody minimized | Reduce as much flow as possible underbody to reduce resistance caused by the uneven floor |
| Flow around ends of front bumper toward body sides | Reduce drag, covers front of front tires |
| Airflow at front wheel arches is routed alongside surfaces of front tires | Reduce resistance that occurs at the front surfaces of the tires |
| Separation angle at rear of hood is large | Minimize resistance by reducing pressure at low end of windshield, 'hide' windshield wipers and reduce rain droplets in area of air flow |
| Smooth area at front pillars toward body sides | Vertical vortices are minimized to reduce drag |
| Optimize of the rear end shape | Assure clean separation of airflow from rear to minimize drag, and equate velocity of airflow from over roof and along body sides as much as possible to minimize vortices. |
| Floor -lower bottom edge of front bumper | Reduces airflow toward underbody, route airflow toward vehicle rear in straight path to minimize flow resistance caused by the uneven floor. Airflow at front of wheelhouses is minimized and wheelhouse design is optimized to direct the air trapped inside rearward - all to reduce resistance at the back of the wheel arches. |
| Computational Fluid Dynamics (CFD) Simulations (80 simulations) | |
| Active Lower grille shutter at lower opening | Redirects air over the body when closed Higher opening allows sufficient air when grill shutter closed Duct type structure is used to provide direction to the airflow to the heat exchanger and minimize entry into engine compartment elsewhere |
| Large front spoiler beneath front bumper | Reduces underbody airflow and redirect toward roof of the vehicle Bottom edge is provided with a lip to increase the flow separation angle to reduce airflow further under the body (similar impact as a further lowering the bottom edge of the front spoiler) |
| Plastic fillet moldings at the wheel arches | To assure air flows along the side surfaces of the front tires (avoid adjusting design of front bumper ends) |
| Optimize shape of rear edge of hood | To promote separation by increasing flow separation angle, distance windshield wipers from airflow, reduce collection of water droplets |
| Optimize windshield molding shape | To smooth for wind, flow |
| Outside mirrors optimized for placement | Avoid airflow coming over rear edge of hood and lower edge of front pillar |

| Design | Detail |
|---|--|
| Ideal Flow Features | |
| Optimize shape of vehicle rear end | Shape of rear spoiler, rear combination lamps and rear bumper optimization. Secure larger roof approach resulted in increased pressure recovery and reduced drag by wake flow. |
| Overall vehicle shape and equal airflow | Balance roof flow and body side flow to reduce vortices |
| Design optimization to increase airflow to roof | Reduces rear drag caused by wake flow |
| Rear Spoiler part of roof approach | Tapered toward vehicle rear |
| Engine under-cover and floor cover | Covers beneath front bumper and over suspension links and muffler piping, raise fuel tank, resulting in smooth underbody flow of air (not full cover) |
| Reduce airflow into wheelhouses | Large front spoiler extends as far as the front of the wheelhouses and deflectors (optimally shaped) in front of the rear tires, bottom of front spoiler lowered on both sides as capable (governed by ground clearance) |
| Smoother fenders | Reduce gaps between closure panels |
| Small vortex-creators | Put vortices in desired places to minimize drag |

BILLING CODE 4910-59-C

A combination of a slightly lighter MY 2015 Nissan Murano (on average lighter by 94 lbs. considering all trim levels), relative to the previous generation, and engine improvements (comparing 3.5L V6 in MY 2014 to 3.5L V6 in MY 2015), and transmission improvements resulted in an overall improvement in fuel economy.¹⁴⁴⁰ Accordingly, the real-world fuel economy improvement directly attributable to the package of aerodynamic technologies included on either vehicle is uncertain, as each vehicle included other fuel economy improving technologies along with the improvements in aerodynamic technologies.

The agencies considered a sensitivity case that assumed no mass reduction, rolling resistance, or aerodynamic improvements had been made to the MY 2017 fleet (*i.e.*, setting all vehicle road levels to zero—MRO, AERO and ROLLO), in response to ICCT's comment. While this is an unrealistic characterization of the initial fleet, the agencies conducted a sensitivity analysis to understand any affect it may have on technology penetration along other paths (*e.g.*, engine and hybrid technology). Under the CAFE program, the sensitivity analysis shows a slight decrease in reliance on engine technologies (HCR engines, turbocharge engines, and engines utilizing cylinder deactivation) and hybridization (strong

hybrids and plug-in hybrids) in the baseline (relative to the central analysis). The consequence of this shift to reliance on lower-level road load technologies is a reduction in compliance cost in the baseline of about \$300 per vehicle (in MY 2026). As a result, cost savings in the preferred alternative are reduced by about \$200 per vehicle. Under the CO₂ program, the general trend in technology shift is less dramatic (though the change in BEVs is larger) than the CAFE results. The cost change is also comparable, but slightly smaller (\$200 per vehicle in the baseline) than the CAFE program results. Cost savings under the preferred alternative are further reduced by about \$100. With the lower technology costs in all cases, the consumer payback periods decreased as well. These results are consistent with the approach taken by manufacturers who have already deployed many of the low-level road load reduction opportunities to improve fuel economy.

Second, as discussed above, EPA's baseline aerodynamic levels in the Draft TAR were based on road load coefficients, leading to baseline assignments that were not accurate. In the NPRM, the agencies discussed in the tradeoffs between building the analysis fleet using confidential information from manufacturers and publicly available data on the vehicles.¹⁴⁴¹ In the case of drag coefficient values, which cannot be gleaned from publicly available information, except in cases where a manufacturer chooses to publicly release that data, or by simply observing a vehicle, the agencies decided that the improved accuracy

associated with using manufacturer-provided C_d values outweighed the benefits of using publicly releasable C_d estimates based on road load coefficients, especially as manufacturer-provided C_d values are only used to assign initial aerodynamic improvement levels relative to C_d values for each body style segment in the analysis fleet.

In addition, manufacturers had submitted comments that the Draft TAR approach to baseline fleet assignments had underestimated technology already present on vehicles, leading the analysis to apply more aerodynamic drag reduction technology than could be applied in the real world. In response to those comments, as described in the Proposed Determination TSD, EPA stated that they "agree[] with the commenters that it is appropriate to account for aerodynamic drag reductions already present in the baseline fleet in order to avoid overestimating the amount of additional improvement that can be achieved at a given cost."¹⁴⁴² Accordingly, EPA "applied some level of aerodynamic drag reduction to a significant portion of the MY2015 baseline fleet."¹⁴⁴³ Consequently, the agencies believe that ICCT's statement that if aerodynamic improvements between the MY 2015 analysis fleet used in the Draft TAR and the MY 2016 analysis fleet were true it would be evident in the fleet is incorrect. It is inappropriate to compare the Draft TAR MY 2015 analysis fleet, which notably included too few aerodynamic technology assignments, with the fleet's achieved fuel economy in the real world. The agencies disagree

¹⁴⁴⁰ <https://www.fueleconomy.gov/feg/Find.do?action=sbs&id=34457&id=37198> (last visited 12.12.2019) shows 20 mpg (combined) in MY2014 Nissan Murano (3.5L VQ35DE V6 with Variable gear ratio transmission) and 24 mpg (combined) in MY2015 Nissan Murano (3.5L VQ35DE V6 with Automatic AV S7 transmission)).

¹⁴⁴¹ 83 FR 43004.

¹⁴⁴² Proposed Determination TSD at 2-406.

¹⁴⁴³ Proposed Determination TSD at 2-408.

with ICCT that the availability of aerodynamic technologies was artificially limited by appropriately assigning baseline aerodynamic technology levels in the analysis fleet.

This also relates to ICCT's comment that the agencies must share the basis for any aerodynamic calculation and exact estimated percent improvement (rather than binned percentage categories) for each vehicle make and model in the baseline and future modeled fleet, and their technical justification for each value. As discussed above, the agencies shared the relative performance approach methodology for assigning baseline aerodynamic levels to vehicles in the analysis fleet in detail in the PRIA,¹⁴⁴⁴ and this approach was the basis for the aerodynamic calculation performed for every vehicle make and model in the analysis fleet. The agencies provided the summary of aerodynamic drag coefficients (including averages for MY 2016 vehicles) by vehicle body style,¹⁴⁴⁵ and the baseline aerodynamic improvement assignments for each vehicle model were included in the 2018 NPRM market inputs ref.xlsx. In addition, because aerodynamic drag information from manufacturers is provided as confidential business information, the agencies are unable to disclose that specific information. However, as discussed above, the agencies are closely examining the data provided and comparing it to other available information to assess the best estimate for aerodynamic technology for each vehicle in the analysis fleet.

For these reasons, the agencies continued to use the NPRM methodology to assign aerodynamic drag reduction improvements for the MY 2017 vehicle fleet for this final rule.

c) Aerodynamic Drag Technology Adoption Features

As discussed above, the agencies used a relative performance approach to assign current aerodynamic technology level to a vehicle. For some body styles with different utility, such as pickup trucks, SUVs and minivans, frontal area can vary, and this can affect the overall aerodynamic drag forces. In order to maintain vehicle utility and functionality related to passenger space and cargo space, the agencies assumed all technologies that improve aerodynamic drag forces would do so through reducing the C_d while maintaining frontal area.

In the NPRM, the agencies noted that the Proposed Determination analysis

assumed that some vehicles from all body styles could (and would) reduce aerodynamic forces by 20 percent, which in some cases led to future pickup trucks having aerodynamic drag coefficients better than some of today's typical cars, if frontal area were held constant in order to preserve interior space and cargo space. The agencies further noted that for some vehicle types, there was limited practical capability to significantly improve aerodynamic drag coefficients over baseline levels. In those cases, the agencies deemed the most advanced levels of aerodynamic drag simulated as not technically practicable given the need to maintain vehicle functionality and utility, such as interior volume, cargo area, and ground clearance.

The industry had also commented in response to EPA's Proposed Determination on the difficulty to achieve AERO20 improvements for certain body styles. In the NPRM, the agencies considered the industry comments along with the observations made in the MY 2016 fleet, and tentatively determined the maximum feasible improvement in C_d that could be achieved for pickup trucks is AERO15.¹⁴⁴⁶ Similarly, the agencies determined the maximum feasible improvement in C_d that could be achieved for minivans is AERO10. Next, the NPRM analysis did not apply 15 percent or 20 percent aerodynamic drag coefficient reduction to cars and SUVs with more than 405 horsepower. The agencies noted that many high-performance vehicles already include advanced aerodynamic features despite middling aerodynamic drag coefficients. In these high-performance vehicle cases, the agencies recognized that manufacturers tune aerodynamic features to provide desirable downforce at high speeds and to provide sufficient cooling for the powertrain, and, therefore, manufacturers may have limited ability to improve aerodynamic drag coefficients for high performance vehicles with internal combustion engines without reducing horsepower. Accordingly, the agencies did not allow application of AERO15 and AERO20 technology for all vehicles with more than 405 HP. Approximately 400,000 units of volume in the MY 2016 market

¹⁴⁴⁶ The agencies noted in the NPRM that although ANL created full-vehicle simulations for trucks with 20 percent drag reduction, those simulations were not used in the CAFE modeling. The agencies concluded that level of drag reduction was likely not technologically feasible with today's technology, and the analysis accordingly restricted the application of advanced levels of aerodynamics in some instances, such as in that case, due to bodystyle form drag limitations.

data file included limited application of aerodynamic technologies because of vehicle performance. The agencies sought comment on limiting the C_d improvement in these circumstances.

Ford commented in support of the agencies' decision to limit the application of AERO20 on pickup trucks, noting that limiting AERO20 on pickups is appropriate given the high inherent form drag associated with pickups' aerodynamic profile.¹⁴⁴⁷

CARB commented that the agencies excluded AERO20 inconsistently across the fleet, noting that while some of the restrictions may be valid, the broad rule the agencies used resulted in technology being inappropriately excluded from too many vehicles.¹⁴⁴⁸ Specifically, CARB took issue with the majority of luxury sedans and SUVs being excluded from AERO20 because they had high horsepower engines, while the agencies did assign AERO20 to vehicles like the Tesla Model S and Model X SUVs, which have horsepower in excess of 405. CARB stated that while electrification provides a higher motivation to minimize road load through technologies such as aerodynamic reductions, implementing AERO20 reductions on high horsepower sedans and SUVs is clearly feasible and should not be artificially restricted in the CAFE model.

In addressing these comments, the agencies considered the relative cooling requirements for all electric powertrains and for high performance internal combustion engine powertrains since airflow diverted for cooling adversely impacts a vehicle's C_d . The peak heat rejection and engine cooling needs for high performance internal combustion engines is significantly higher than for all electric powertrains. Internal combustion engines convert a lower percentage of energy contained in gasoline into mechanical work (and other useful work, such as lighting and sound), and the energy not converted into mechanical work (or other useful work) is converted into heat. A significant amount of the waste heat must be handled by the cooling systems. Battery electric vehicles convert most of the electrical energy stored in the battery into mechanical work and other useful work, and therefore convert less energy into heat that must be handled by the cooling system. Also, electric powertrains can provide a degree of electric braking, whereas internal combustion engines exclusively use friction braking, which generates heat and requires greater cooling.

¹⁴⁴⁷ NHTSA-2018-0067-11928.

¹⁴⁴⁸ NHTSA-2018-0067-11873.

¹⁴⁴⁴ PRIA at 441.

¹⁴⁴⁵ PRIA at 443.

particularly on vehicles with substantial braking performance capabilities. In the case of high-performance BEVs, since the cooling needs are not as demanding as with high-performance vehicles that use internal combustion engines, manufacturers can (and do, as can be observed in the fleet) apply higher levels of aerodynamic technologies. The agencies believe it is appropriate to account for these differences in considering the amount of aerodynamic improvement that can be implemented, and determined there are valid technical reasons for allowing BEVs with greater than 405 horsepower to adopt AERO20 technology.

d) Aerodynamic Drag Technology Effectiveness

The NPRM analysis included four levels of aerodynamic improvements, AERO5, AERO10, AERO15, and AERO20, representing 5, 10, 15, and 20 percent C_d improvements, respectively. Notably, the NPRM analysis assumed that aerodynamic drag reduction could only come from reduction in the aerodynamic drag coefficient and not from reduction of frontal area, to maintain vehicle functionality and utility, such as passenger space, ingress/egress ergonomics, and cargo space.¹⁴⁴⁹

Ford commented in support of the agencies' decision to consider the frontal area and body style as "utility factors" and requiring that aerodynamic improvements come from reductions in Coefficient of Drag (C_d) and not from reductions in frontal area.¹⁴⁵⁰

CBD commented that EPA staff had critiqued NHTSA's characterization of research on aerodynamic drag coefficients and the NPRM did not appear to incorporate or respond to this input.^{1451 1452} Specifically, CBD stated that EPA staff had commented in response to the characterization that "[f]or some bodystyles, the agencies have no evidence that manufacturers may be able to achieve 15 percent or 20 percent aerodynamic drag coefficient reduction relative to baseline (for instance, with pickup trucks)" and noted that "[i]n the past, EPA has assigned aero tech in the baseline relative to a 'Null' and then applied drag reduction level against that Null in order to ensure that the maximum aero level (*i.e.*, 15 or 20 percent) would always be achievable for all body styles." This comment reflects deliberative, in-process input from EPA staff. In fact, the NPRM text

was developed by the agencies with the benefit of this and other input from EPA staff, and the NPRM clarified that reducing frontal area would likely degrade other utility features like interior volume or ingress/egress.

CARB commented, as part of its broader comments, that the agencies' effectiveness values were reduced relative to what EPA's LPM calculated, that the benefits of aerodynamic improvements were underestimated.¹⁴⁵³ Specifically, CARB cited the H-D Systems comparison of LPM benefits for AERO10 and AERO20 of 2.1 percent and 4.3 percent, respectively, compared with Autonomie benefits of 1.51 percent and 3.03 percent, respectively, and stated that the agencies' analysis provided no description or cited any new data or evidence as to why they reduced the projected assumptions compared to what EPA's Lumped Parameter Model calculated.

HDS also commented that the Autonomie modeling assumed no engine change when aerodynamic drag and rolling resistance reductions were implemented, as well as no changes to the transmission gear ratios and axle ratios, which vary by transmission type but not by the tractive load.¹⁴⁵⁴ HDS stated that the EPA ALPHA model adjusted for this effect, which accounted for the difference in technology effectiveness estimates that HDS characterized between the Draft TAR and NPRM. HDS provided a "correct estimate" for AERO20 effectiveness improvements of 4.3 percent, with the justification that there was no gear/axle ratio adjustment in the Autonomie analysis.

In response to HDS's comment, the Alliance submitted supplemental comments questioning the extent to which aerodynamics (and changes in top gear ratio) affect performance metrics held constant in the analysis, like low- and high-speed acceleration performance and gradeability.¹⁴⁵⁵ The Alliance cited a study for the proposition that vehicle acceleration is most influenced by engine power and weight, and also that bodystyle differences have a lesser impact on acceleration performance. The Alliance further commented that "[r]egarding changes in top gear ratios in response to aerodynamic changes, the Alliance is not aware of any examples in which a top gear ratio was changed solely due to aerodynamic improvements. There may be examples where a vehicle's top gear ratio was changed at the same time

aerodynamic changes were made, but such changes would be made in response to the cumulative changes across the entire vehicle, not just aerodynamic improvements." The Alliance concluded that "[t]here are also practical manufacturing and investment constraints which limit the potential for applying engine changes in response to improved vehicle aerodynamics," citing the agencies decision to only resize engines with significant design changes, to account for product complexity and economies of scale.

In response to the Alliance's supplemental comment, HDS submitted supplemental comments stating that "[d]rag reduction is usually accomplished when a vehicle body is redesigned, so gear and axle ratios are typically re-optimized for the entire set of changes, but these changes include the drag reduction."¹⁴⁵⁶ HDS commented that the Alliance's comments acknowledged that calibration changes are made in response to tractive load changes, while the Autonomie analysis recalibrates the powertrain in response only to large mass reduction improvements, and not any other vehicle changes that reduce tractive load, like aerodynamic improvements, even when those changes would result in a greater tractive load reduction than a 10 percent mass reduction. HDS reiterated its statement that "[i]n the real world (and as captured in EPA's prior ALPHA model), automakers typically alter many vehicle attributes affecting tractive load simultaneously, including aerodynamics," and the Autonomie outputs underrepresent the benefit of tractive load reduction strategies by not optimizing engine efficiency after most changes in tractive load because the model employees fixed shift points, gear ratios, and axle ratios when drag or tire rolling resistance is reduced.

Regarding the first set of comments that the aerodynamic effectiveness values were reduced from EPA's values presented in the Draft TAR, that results from differences in the two modeling approaches. As discussed above, for this analysis the agencies decided that aerodynamic drag reduction could only come from reduction in the aerodynamic drag coefficient, and not from a reduction in vehicle frontal area, at least without reducing other attributes of the vehicle. EPA's process for assigning road load technologies to baseline vehicles used road load coefficients from coast downs, which aggregated individual aero, mass and tire reduction technologies. In contrast,

¹⁴⁵⁶ NHTSA-2018-0067-12395, at 4-5.

the CAFE Model and Autonomie used individually assigned road load technologies for each vehicle to appropriately assign initial road load and to appropriately capture benefits of subsequent individual road load technologies. The differences in using road load coefficients from coast downs and individually isolating the improvements from existing and future road load technologies in the Autonomie modeling resulted in the differences noted by commenters. And so, the resulting effectiveness from the incremental adoption of individual technologies to a newer analysis fleet will have different result than what was estimated by the previous analyses. For further discussion of the analysis fleet see Section VI.B.1.

In Section VI.B.3 Tech Effectiveness and Modeling and Section VI.C.2 Transmissions, the agencies provide a full discussion of the issues associated with assuming the engine and transmission can be optimized for every combination of technologies. It would be unreasonable and unaffordable to resize powertrains, including engines and transmission and axle ratios, for every unique combination of technologies, and exceedingly so for every unique combination technologies across every vehicle model due to the extreme manufacturing complexity that would be required to do so. Product

complexity and economies of scale are real, and in the NPRM, engine resizing was limited to specific incremental technology changes that would typically be associated with a major vehicle or engine redesign.¹⁴⁵⁷ As noted by HDS, the EPA Draft TAR and Proposed Determination analyses adjusted the effectiveness of every technology combination, including for aerodynamics technologies, assuming performance could be held constant for every combination. However, those analyses did not recognize or account for the extreme complexity nor the associated costs for that impractical assumption. The NPRM and final rule analyses account for these real-world practicalities and constraints, and doing so explains some of the effectiveness and cost differences between the Draft TAR/Proposed Determination and the NPRM/final rule. The agencies believe the NPRM and the final rule approach appropriately resizes powertrain components for specific incremental technology changes that would typically be associated with a major vehicle or engine redesign.

For the NPRM, and carried into the final rule analysis, Autonomie simulates all road load conditions (*e.g.*, MR, AERO, and ROLL technology levels) for each engine and transmission

combination. In addition, engines are resized for appropriate specific technology changes that would be associated with a major vehicle or engine redesign. Also, as discussed further in Section VI.C.2 Transmissions, many commenters seemed to conflate the practice in the analysis of using a common (same) gear set across vehicle configurations (to address manufacturing complexity) with using the same shift maps. As commenters stated, they assumed the same shift maps were applied across vehicle models. However, the shift initializer routine was run for every unique Autonomie full vehicle model configuration and generated customized shifting maps. The algorithms' optimization was designed to balance minimization of energy consumption and vehicle performance. This balance was necessary to achieve the best fuel efficiency while maintaining customer acceptability by meeting performance neutrality requirements. The agencies believe the level of optimization of engine size, transmissions, gear ratios and shift schedules reasonably approximate what is achievable and what manufacturers actually do.

Figure VI-47 below shows the range effectiveness used for AERO technologies for the NPRM analysis.

BILLING CODE 4910-59-C

e) Aerodynamic Drag Technology Cost

For the Draft TAR, the agencies relied on the 2015 NAS report to estimate the cost of AERO1 and AERO2 levels of aerodynamic drag coefficient improvements. The agencies received several comments related to the cost assumptions used in the Draft TAR, mainly that they were too low to meet AERO1 and AERO2 levels. The industry submitted confidential business information on the costs of passive aerodynamic technologies needed to achieve AERO1 (10 percent improvement in drag improvement), which showed a significantly higher estimated costs than assumed for the Draft TAR. Similarly, the industry submitted confidential business

information on the costs of active aerodynamic technologies, including some high cost technologies. The industry also commented that some active aerodynamic technologies could only be implemented during vehicle redesigns and not during a mid-cycle vehicle refresh.

The agencies considered these comments and performed additional research to assess the costs for passive and active aerodynamic technologies. The agencies revised the cost estimates for the NPRM, based in part on confidential information from the automotive industry, and from the agencies' own assessment of manufacturing costs for specific aerodynamic technologies from available sources. In general, the NPRM

cost estimates were higher than Draft TAR cost estimates. The agencies included a high-level discussion in the PRIA that the cost to achieve AERO5 is relatively low, as most of the improvements can be made through body styling changes. The cost to achieve AERO10 is higher than AERO5, due to the addition of several passive aero technologies, and the cost to achieve AERO15 and AERO20 is higher than AERO10 due to use of both passive and active aero technologies.

The agencies did not receive any comments on the costs of aerodynamic improvements, and accordingly, for the final rule, as shown in Table VI-137 and Table VI-138 below, the agencies used the same aerodynamic improvement costs presented in NPRM.

Table VI-137 – Aerodynamic Improvement Technology Costs for Passenger Cars and SUVs for MY 2017 (in 2018\$)

| Aero Improvements for Passenger Cars and SUV | \$ DMC (2018\$) | Total Cost (includes RPE and Learning) |

| 20% | \$525.06 | \$787.59 |

6. Tire Rolling Resistance

Tire rolling resistance is a road load force that arises primarily from the energy dissipated by elastic deformation of the tires as they roll. Tire design characteristics (for example, materials, construction, and tread design) have a strong influence on the amount and type of deformation and the energy it dissipates. Designers can select these characteristics to minimize rolling resistance. However, these characteristics may also influence other performance attributes, such as durability, wet and dry traction, handling, and ride comfort.

Low rolling resistance tires are increasingly specified by OEMs in new vehicles and are also increasingly available from aftermarket tire vendors. They commonly include attributes such as higher inflation pressure, material changes, tire construction optimized for lower hysteresis, geometry changes (e.g., reduced aspect ratios), and reduced

sidewall and tread deflection. These changes are commonly accompanied by additional changes to vehicle suspension tuning and/or suspension design to mitigate any potential impact on other performance attributes of the vehicle.

Lower-rolling-resistance tires have characteristics that reduce frictional losses associated with the energy dissipated mainly in the deformation of the tires under load, thereby improving fuel economy and reducing CO₂ emissions. The agencies considered two levels of improvement for low rolling resistance tires in the analysis: The first level of low rolling resistance tires considered reduced rolling resistance 10 percent from an industry-average baseline, while the second level reduced rolling resistance 20 percent from the baseline.

Walter Kreucher commented that the agencies should eliminate low rolling resistance tires from the list of viable technologies, in recognition of the safety

impacts of low rolling resistance tires in relation to stopping distance and accident rates.¹⁴⁵⁸ Separately, Mr. Kreucher argued that the model should reflect the safety impact of low rolling resistance tires.

The agencies have been following the industry developments and trends in application of rolling resistance technologies to light duty vehicles. As stated in the NAP special report on Tires and Passenger Vehicle Fuel Economy,¹⁴⁵⁹ cited by Mr. Kreucher, national crash data does not provide data about tire structural failures specifically related to tire rolling resistance, because the rolling resistance of a tire at a crash scene cannot be determined. However, other metrics like brake performance compliance test data

¹⁴⁵⁸ NHTSA–2018–0067–0444.

¹⁴⁵⁹ Tires and Passenger Vehicle Fuel Economy: Informing Consumers, Improving Performance—Special Report 286 (2006), available at <https://www.nap.edu/read/11620/chapter/6>.

are helpful to show trends like that stopping distance has not changed in the last ten years,¹⁴⁶⁰ during which time many manufacturers have installed low rolling resistance tires in their fleet—meaning that manufacturers were successful in improving rolling resistance while maintaining stopping distances through tire design, tire materials, and/or braking system improvements. In addition, NHTSA has addressed other tire-related issues through rulemaking,¹⁴⁶¹ and continues to research tire problems such as blowouts, flat tires, tire or wheel deficiency, tire or wheel failure, and tire degradation.¹⁴⁶² However, there are currently no data connecting low rolling resistance tires to accident or fatality rates.

With better tire design, tire compound formulations and improved tread design, tire manufacturers have tools to balance stopping distance and reduced rolling resistance. As stated in one article referenced by Mr. Kreucher, tire manufacturers can use “higher performance materials in the tread compound, more silica as reinforcing fillers and advanced tread design features” to mitigate issues related to stopping distance.¹⁴⁶³ The agencies do not believe that there is sufficient data or other information to support removing low rolling resistance tires as a viable technology considered in the CAFE and CO₂ analysis at this time.

HDS argued, as discussed further below, that based on available data on current vehicle models and the likely possibility that there would be additional tire improvements over the next decade, the agencies should consider ROLL30 technology, or a 30 percent reduction of tire rolling resistance over the baseline.¹⁴⁶⁴

As stated in Joint TSD for the 2017–2025 final rule, tire technologies that enable rolling resistance improvements of 10 and 20 percent have been in existence for many years.¹⁴⁶⁵ Achieving improvements of up to 20 percent involves optimizing and integrating multiple technologies, with a primary contributor being the adoption of a silica tread technology. Tire suppliers have indicated that additional innovations are necessary to achieve the next level of low rolling resistance technology on a commercial basis, such as improvements in material to retain tire pressure, tread design to manage both stopping distance and wet traction, and development of carbon black material for low rolling resistance without the use of silica to reduce cost and weight.¹⁴⁶⁶ The agencies are continuously monitoring these and other tire technology improvements. The agencies believe that the tire industry is in the process of moving automotive manufacturers towards the first level of low rolling resistance technology across the vehicle fleet (10 percent reduction in rolling resistance), and that 20 percent improvement is achievable in the rulemaking timeframe. However, the agencies believe that at this time, the emerging tire technologies that would achieve 30 percent improvement in rolling resistance, like changing tire profile, strengthening tire walls, or adopting improved tires along with active chassis control,¹⁴⁶⁷ among other technologies, will not be available for commercial adoption in the fleet during the rulemaking timeframe. As a result, the agencies decided not to incorporate 30 percent reduction in rolling resistance technology for this final rule.

a) Rolling Resistance Modeling in the CAFE Model

The two levels of rolling resistance technology considered in the analysis

include ROLL10 and ROLL20, which represent a 10 percent and 20 percent rolling resistance reduction from the baseline (ROLL0), respectively.

To understand the following discussions about rolling resistance analysis fleet assignments and effectiveness values, it is important to understand how the agencies developed the baseline value (ROLL0) used in prior analyses, and how the agencies developed the baseline value used in the NPRM and final rule. In the Draft TAR, the agencies used unique baseline rolling resistance coefficients for each vehicle class. Specifically, the compact car class value was 0.0075, the midsize car value was 0.008, the small SUV value was 0.0084, the midsize SUV value was 0.0084, and the pickup truck value was 0.009. The PRIA described that since the Draft TAR, the agencies had reassessed rolling resistance values for contemporary tires through discussions with vehicle manufacturers, tire manufactures, and independent bench testing. Based on a thorough review of confidential business information submitted by industry, and a review of other literature, including the CARB/CONTROLTEC study mentioned below, the baseline rolling resistance coefficient for all vehicle classes was updated to 0.009 for the NPRM analysis. The agencies concluded that the updated baseline value brought the NPRM simulations into better alignment with tires in the MY 2016 analysis fleet. The agencies also discussed that updated value was consistent with the findings of the CONTROLTEC study on vehicle road loads, sponsored by CARB.¹⁴⁶⁸ The following figure shows the distribution of estimated tire rolling resistance coefficient values for the 1,358 MY 2014 vehicles evaluated in the CONTROLTEC/CARB study.

Figure VI-49 – Estimated tire rolling resistance for all vehicles from CONTROLTEC study

BILLING CODE 4910-59-C

ICCT commented that it was “quite confusing and perhaps troubling” that the agencies adopted a higher average rolling resistance coefficient than that of the Draft TAR, “as it would imply that the fleet rolling resistance got worse, but the agencies are deciding to provide baseline credit as if there was more rolling resistance technology deployed.”¹⁴⁶⁹ ICCT stated that the change appeared to be attributed to the agencies’ use of CBI on tire rolling resistance received since the Draft TAR.

As described in the PRIA, the values used in the Draft TAR represented the “Best in Class” values in each of the vehicle classes and this did not necessarily reflect the average “Rolling Resistance Coefficient” (RRC) of the fleet. For the Draft TAR, the agencies did not have access to manufacturer confidential business information and relied on estimates from CONTROLTEC. As stated earlier, Figure VI-49 shows the distribution of the estimated RRC for 1,358 vehicles models. The average RRC from the CONTROLTEC study (0.009) aligned with the NPRM estimate which was based in part on manufacturer submitted confidential business information. CONTROLTEC compared the estimated RRC data with the values provided by Rubber Manufacturers Association (renamed as USTMA–U.S. Tire Manufacturers Association) for original equipment tires. The average RRC from the data provided by RMA

was 0.0092,¹⁴⁷⁰ compared to average of 0.009 from CONTROLTEC.

CONTROLTEC attributed the difference due to analysis assumption, tire loading during coast down vs. load during tire testing, inflation pressure during coast down vs. inflation pressure during tire testing, coast down test reporting issues, tire types represented in the sample, tire break-in, and advancement in tire rolling resistance since the time RMA collected the data.

CONTROLTEC also stated that RRC values for some vehicles fell below the average RRC (indicating better performance) due to estimation assumptions for vehicles where manufacturer data was not available, and coast down test reporting issues.¹⁴⁷¹ Further, CONTROLTEC performed a sensitivity study by mathematically removing aerodynamic contribution from the coast down coefficients. It was observed that the average RRC without the aerodynamic contribution is around 0.011. Accordingly, the agencies believe that it was reasonable to use 0.009 as the average RRC for the fleet for the NPRM and to continue to use that value for the final rule, based on the latest available data from manufacturers and alignment with the average RRC to the CONTROLTEC study estimate.

¹⁴⁷⁰ Technical Analysis of Vehicle Load Reduction by CONTROLTEC for California Air Resources Board (April 29, 2015) at page 40.

¹⁴⁷¹ Technical Analysis of Vehicle Load Reduction by CONTROLTEC for California Air Resources Board (April 29, 2015) at page 38.

H-D Systems (HDS) commented that the CONTROLTEC/CARB study showed that there is a very significant fraction of the fleet with tire rolling resistance coefficients above 10kg/1000 kg, and a small percentage of vehicles with rolling resistance coefficients already at 0.05 or 0.06. HDS stated that NHTSA’s baseline of 0.09 appeared “a little low but may be appropriate if the distribution was sales weighted.” HDS argued that a number of vehicle models already have tires below 0.07, and the likelihood that there would be additional tire improvements over the next decade are likely, meaning that ROLL30 technology—or a 30 percent reduction of the tire rolling resistance coefficient to 0.063—is possible and appropriate for MY 2025.

Roush commented that rolling resistance is erroneously assumed to be the same across different vehicle classes, and that rolling resistance would vary depending upon the vehicle size, power, acceleration and performance package.¹⁴⁷²

As explained earlier, the RRC values used in the CONTROLTEC study were a combination of manufacturer information, estimates from coast down tests for some vehicles, and application of tire RRC values across other vehicles on the same platform. CONTROLTEC stated that some RRC values were below the estimated average (showing significant improvement from the baseline) due to assumptions that were

¹⁴⁶⁹ NHTSA–2018–0067–11741 full comments.

¹⁴⁷² NHTSA–2018–0067–11984.

applied to some vehicles when manufacturer data was not available. Further, some of the RRC estimates were based on vehicle coast down tests which had errors.¹⁴⁷³ As a result, some of the RRC values used in the Draft TAR showed significant improvements (30 percent reduction in rolling resistance relative to baseline), as observed by HDS. Based on a review of manufacturer-submitted confidential business information and other sources, the agencies are unaware of any tires in production which have 30 percent reduction in rolling resistance relative to baseline values.

As stated earlier, the baseline values used for the Draft TAR analysis were “Best in Class” values from the estimates developed by CONTROLTEC and not representative of the average of the fleet or average for the vehicle classes. For the NPRM, the agencies revisited the ROLL technology assignments based on the RRC values provided by manufacturers, and the average RRC for each of the vehicle class was near the fleet average (RRC = 0.009). As shown in Figure VI–50, a vast majority of the vehicles in the fleet are in the ROLL0 bin across the different vehicle class, vehicle size, power, acceleration and performance configurations. For these reasons, the agencies will continue to use the fleet average of RRC = 0.009 as the baseline value to assess ROLL technology improvements.

b) Rolling Resistance Analysis Fleet Assignments

As discussed above, NHTSA’s Draft TAR analysis showed little rolling resistance technology in the baseline fleet for three reasons: the simulations used baseline values already reflecting best-in-class tire rolling resistance, credible tire rolling resistance values for all vehicles from bench data were not available to the agencies at the time of Draft TAR, and few manufacturers submitted rolling resistance values for the Draft TAR analysis.

For the NPRM, baseline (ROLL0) rolling resistance values were updated to 0.009, and any better rolling resistance values were assigned based on whether information indicated that vehicle had technology at least 10 percent better than baseline (.0081 or better for ROLL10), or at least 20 percent better than baseline (.0072 or better for ROLL20). The agencies used confidential business information provided by manufacturers to assign

initial rolling resistance values for each vehicle make and model.

The Alliance commented that the NPRM MY 2016 analysis fleet had been updated with appropriate ratings of rolling resistance improvements, compared to the Draft TAR where vehicles were generally considered to have unimproved tires (meaning the Draft TAR assumed additional improvements were more achievable than in reality).¹⁴⁷⁴ The Alliance noted that the Draft TAR approach led to the CAFE model adding additional tire rolling resistance improvements even though manufacturers had already made significant improvements with that technology. This meant that the real-world fleet had little remaining opportunity for additional tire-related improvements, ultimately leading to the Draft TAR analysis underpredicting the amount of powertrain technology required for compliance.

The Alliance noted that it is possible to estimate rolling resistance features of a vehicle using road load coefficients, but the process requires various assumptions and is not very accurate. The Alliance concluded that the agencies’ use of CBI to assign baseline technology levels correctly was an accurate and practical solution. Similarly, Ford commented in support of the agencies’ low rolling resistance tire assignments in the baseline fleet, stating that the accuracy of the baseline fleet assessment had been considerably improved using actual tire rolling resistance data.¹⁴⁷⁵

HDS commented that the analysis fleet “accounts for the distribution of tires below 0.09 as 19% of vehicles in MY 2016 are modeled as having used ROLL10 and 25% of vehicles as having used ROLL20 in the base year, but there is no accounting for the ~25% of vehicles having RRC values 10 to 20% above the 0.09 RRC average.”¹⁴⁷⁶ HDS concluded that “[a] stricter accounting of the baseline and, possibly setting specific lower limits for 2025 RRC by vehicle type (as done for aero drag in the PRIA) will show significant additional fleetwide effectiveness from RRC reduction which is a very cost-effective technology.”

ICCT commented that the agencies made a “dramatic and unjustified” shift in baseline tire rolling resistance assignments from the 2015 fleet used in the Draft TAR to the 2016 fleet used in the NPRM.¹⁴⁷⁷ ICCT noted that per the agencies’ updated baseline value, nearly

20 percent of all vehicles in the MY 2016 analysis fleet achieved 0.0081 (or better) rolling resistance value, and more than 26 percent achieved 0.0072 (or better). ICCT argued that rather than changing the definition of rolling resistance technology to include improvements beyond the baseline, the agencies instead redefined the technology available, reducing the number of vehicles that can use tire improvements in future compliance years within the modeling framework, which artificially forced companies to use other, more expensive technologies.

ICCT stated that to substantiate the baseline rolling resistance assignments, the agencies need to show data on how these improvements are evident in the fleet and delivering benefits. ICCT alleged that if an improvement of that magnitude were true, it would be evident in fleet level miles-per-gallon and CO₂ levels; however, “none of the quantifiable mpg or CO₂ benefits that would be associated with these additional rolling resistance improvements were reflected with any real-world evidence in the model year 2016 fleet.” ICCT stated this seemed to be a case of the agencies “artificially burying efficiency technology in the baseline, rendering it unusable in the post model year 2016 compliance scenarios.”

ICCT also stated that the agencies must share absolute road load coefficients for each vehicle make and model in the baseline fleet, and the technical justification for each value, in addition to conducting two sensitivity analysis cases “assum[ing] that every baseline make and model is set to 0% rolling resistance improvement and set to the previous baseline rolling resistance (from the Draft TAR) to demonstrate how much the agencies’ decision to load up more baseline technology affects the compliance scenarios, as it appears that the agencies may have made a unsupportable and non-rigorous assumption about rolling resistance technology across the models.” ICCT concluded that because the changes were buried in the datafiles and unexplained, the agencies must issue a new regulatory analysis and allow an additional comment period for review of the methods and analysis.

Based on the comments from HDS and ICCT, the agencies reexamined available tire rolling resistance data. The assignment of ROLL20 technology was revised for some vehicle models based on information on the use of common tires across vehicles that shared a platform. As a consequence, for the final rule, only 20 percent of the MY2017 vehicle fleet is assigned ROLL20. The

¹⁴⁷⁴ NHTSA–2018–006712039 at 136.

¹⁴⁷³ Technical Analysis of Vehicle Load Reduction by CONTROLTEC for California Air Resources Board (April 29, 2015) at page 38.

agencies will continue to investigate additional methods to improve the accuracy of this method, however as the Alliance and Ford noted, the accuracy of the baseline levels had been significantly improved over prior analyses by using actual tire RRC data. The agencies approach is consistent with the NAS recommendation to have two ROLL technology levels. The agencies determined that 30 percent rolling resistance improvement while maintaining other tire characteristics is unlikely to be available in the rulemaking timeframe.

The agencies considered a sensitivity case that assumed no mass reduction, rolling resistance, or aerodynamic improvements had been made to the MY 2017 fleet (*i.e.*, setting all vehicle road levels to zero—MRO, AERO and ROLL0), in response to ICCT's comment. While this is an unrealistic characterization of the initial fleet, the agencies conducted a sensitivity

analysis to understand any affect it may have on technology penetration along other paths (*e.g.* engine and hybrid technology). Under the CAFE program, the sensitivity analysis shows a slight decrease in reliance on engine technologies (HCR engines, turbocharge engines, and engines utilizing cylinder deactivation) and hybridization (strong hybrids and plug-in hybrids) in the baseline (relative to the central analysis). The consequence of this shift to reliance on lower-level road load technologies is a reduction in compliance cost in the baseline of about \$300 per vehicle (in MY 2026). As a result, cost savings in the preferred alternative are reduced by about \$200 per vehicle. Under the CO₂ program, the general trend in technology shift is less dramatic (though the change in BEVs is larger) than the CAFE results. The cost change is also comparable, but slightly smaller (\$200 per vehicle in the baseline) than the CAFE program

results. Cost savings under the preferred alternative are further reduced by about \$100. With the lower technology costs in all cases, the consumer payback periods decreased as well. These results are consistent with the approach taken by manufacturers who have already deployed many of the low-level road load reduction opportunities to improve fuel economy.

Figure VI-50 shows the distribution of ROLL technology for the Draft TAR, NPRM and final rule. For the NPRM, 64 percent of the MY 2016 vehicle fleet was assigned ROLL0 and for the final rule, 59 percent of the MY2017 vehicle fleet is assigned ROLL0. This shows that the majority of the fleet is still at the ROLL0 technology level and there is still significant opportunity for the vehicle fleet to improve ROLL technology.

BILLING CODE 4910-59-P

Figure VI-50 – Distribution of tire rolling resistance technology for the Draft TAR, NPRM and Final Rule

| ROLL | Draft TAR (MY 2015 vehicle fleet) | NPRM (MY2016 vehicle fleet) | Final Rule (MY2017 vehicle fleet) |
|-------------|--|--|--|
| ROLL0 | 99.80% | 64% | 59% |
| ROLL10 | 0.1% | 10% | 21% |
| ROLL20 | 0.1% | 26% | 20% |

BILLING CODE 4910-59-C

c) Rolling Resistance Adoption Features

In some cases, low rolling resistance tires can affect traction, which may adversely impact acceleration, braking and handling characteristics for some high-performance vehicles. Similar to past rulemakings, the agencies recognized in the NPRM that to maintain performance, braking and handling functionality, some high-performance vehicles would not adopt low rolling resistance tire technology. For cars and SUVs with more than 405 horsepower (hp), the agencies restricted the application of ROLL20. For cars and SUVs with more than 500 hp, the agencies restricted the application of any additional rolling resistance technology (ROLL10 or ROLL20). The agencies developed these cutoffs based on a review of confidential business information and the distribution of rolling resistance values in the fleet.

Ford commented that the NPRM analysis appropriately limited the application of ROLL technology where it would be infeasible or would be at odds with the vehicles' intended function, characterizing that the decision to restrict application of ROLL10 and ROLL20 for high performance vehicles as reasonable.¹⁴⁷⁸

Accordingly, the agencies continued with the NPRM methodology of restricting certain ROLL technology for high performance vehicles. In the final rule, the agencies restricted the ROLL technology to ROLL0 and ROLL10 for vehicles with greater than 405 hp and below 505hp. For vehicles greater than 505hp, the agencies restricted the ROLL technology to ROLL0.

¹⁴⁷⁸ NHTSA-2018-0067-11928.

d) Rolling Resistance Effectiveness Modeling and Resulting Effectiveness Values

As discussed above, the agencies updated the baseline rolling resistance value to 0.009, based on a thorough review of confidential business information submitted by industry, and a review of other literature. To achieve ROLL10 in the NPRM and for the final rule analysis, the tire rolling resistance must be at least 10 percent better than baseline (.0081 or better). To achieve ROLL20, the tire rolling resistance must be at least 20 percent better than baseline (.0072 or better).

HDS commented that the Autonomie modeling assumed no engine change when drag and rolling resistance reductions were implemented, as well as no change to the transmission gear ratios and axle ratios, which vary by transmission type but not by the tractive

load.¹⁴⁷⁹ HDS stated that “reduction in rolling resistance is accompanied by axle ratio adjustments so that the engine operates at about the same load but at lower RPM. The EPA ALPHA model adjusts for this effect, which accounts for the difference in benefit estimates” between Autonomie and the ALPHA model simulations.

As stated in Section VI.B.3 Tech Effectiveness and Modeling, Autonomie builds performance-neutral vehicle models by resizing engines, electric machines, and hybrid electric vehicle battery packs only at specific incremental technology steps. To address product complexity and economies of scale, engine resizing is limited to specific incremental technology changes that would typically be associated with a major vehicle or engine redesign.¹⁴⁸⁰ Manufacturers have repeatedly told the agencies that the high costs for redesign and the increased manufacturing complexity that would result from resizing engines for small technology changes preclude them from doing so. It would be unreasonable and unaffordable to resize powertrains for every unique combination of technologies, and exceedingly so for every unique combination technologies across every vehicle model due to the extreme manufacturing complexity that would be required to do so. The agencies explained in the NPRM that the analysis should not include engine resizing with the application of every technology or for combinations of technologies that drive small performance changes to reflect better what is feasible for manufacturers.¹⁴⁸¹

Compliance modeling in the CAFE model also accounts for the industry practice of platform, engine, and transmission sharing to manage component complexity and associated costs.¹⁴⁸² At a vehicle refresh cycle, a vehicle may inherit an already resized powertrain from another vehicle within the same engine-sharing platform that adopted the powertrain in an earlier model year. In the Autonomie modeling, when a new vehicle adopts fuel saving technologies (such as ROLL technology) that are inherited, the engine is not resized (the properties from the baseline reference vehicle are used directly and unchanged) and there may be a small change in vehicle performance.

Regarding customizing transmission gear ratios as rolling resistance changes are implemented, the agencies explained in Section VI.C.2 Transmissions that it is an observable practice in industry to use a common gear set across multiple platforms and applications. The most recent example is the GM 10L90, a 10-speed automatic transmission that used the same gear set in both pick-up truck and passenger car applications.¹⁴⁸³ In Autonomie, optimization of transmission performance is achieved through shift control logic rather than customized hardware (e.g., gear ratios) for each vehicle line. The shift initializer routine was run for every unique Autonomie

smaller engine without floor mats. This example demonstrates small levels of mass reduction. If manufacturers resized engines for small changes, manufacturers would have dramatically more part complexity, losing economies of scale.

¹⁴⁸² Ford EcoBoost Engines are shared across ten different models in MY 2019. <https://www.ford.com/powertrains/ecoboost/>. Last accessed Nov. 05, 2019.

¹⁴⁸³ “GM Global Propulsion Systems—USA Information Guide Model Year 2018” (PDF). General Motors Powertrain. Retrieved September 26, 2019. https://www.gmpowertrain.com/assets/docs/2018R_F3F_Information_Guide_031918.pdf.

full vehicle model configuration to generate customized shifting maps. The algorithms’ optimization was designed to balance minimization of energy consumption against vehicle performance.¹⁴⁸⁴ This balance was necessary to achieve the best fuel efficiency while maintaining customer acceptability by meeting performance neutrality requirements. See Section VI.B.3.a)(6) Performance Neutrality for more details. If the systems were over-optimized for the agencies’ modeling, such as applying a unique gear set for each individual vehicle configuration, the analysis would likely over-predict the reasonably achievable fuel economy improvement for the technology. Over-prediction would be exaggerated when applied under real-world large-scale manufacturing constraints necessary to achieve the estimated costs for the transmission technologies.

As HDS noted, the EPA Draft TAR and Proposed Determination analyses performed using the ALPHA model adjusted the effectiveness of every technology combination assuming performance could be held constant for every combination, and did not recognize or account for the extreme complexity nor the associated costs for that impractical assumption. The NPRM and final rule analyses account for real-world practicalities and constraints related to both engine adoption and transmission adoption when other vehicle technologies are implemented, which explains some of the effectiveness and cost differences between the Draft TAR/Proposed Determination and the NPRM/final rule.

Figure VI–51 below shows the range of effectiveness used for the NPRM analysis for ROLL technologies.

7. Other Vehicle Technologies

Four other vehicle technologies were included in the analysis—electric power steering (EPS), improved accessory devices (IACC), low drag brakes (LDB), and secondary axle disconnect (SAX) (which may only be applied to vehicles with all-wheel-drive or four-wheel-drive). The effectiveness of these technologies was applied directly by the CAFE model, with unique effectiveness values for each technology and for each technology class. This methodology was used in these four cases because the effectiveness of these technologies varies little with combinations of other technologies. Also, applying these technologies directly in the CAFE model significantly reduces the number of Autonomie simulations that are needed.

a) Electric Power Steering (EPS)

Electric power steering reduces fuel consumption and CO₂ emissions by reducing load on the engine. Specifically, it reduces or eliminates the parasitic losses associated with engine-driven power steering pumps, which pump hydraulic fluid continuously through the steering actuation system even when no steering input is present.

By selectively powering the electric assist only when steering input is applied, the power consumption of the system is reduced in comparison to the traditional “always-on” hydraulic steering system. Power steering may be electrified on light duty vehicles with standard 12V electrical systems and is also an enabler for vehicle electrification because it provides power steering when the engine is off (or when no combustion engine is present).

Power steering systems can be electrified in two ways. Manufacturers may choose to eliminate the hydraulic portion of the steering system and provide electric-only power steering (EPS) driven by an independent electric motor, or they may choose to move the hydraulic pump from a belt-driven configuration to a stand-alone electrically driven hydraulic pump. The latter system is commonly referred to as electro-hydraulic power steering (EHPS). As discussed in the NPRM, manufacturers have informed the agencies that full EPS systems are being developed for all types of light-duty vehicles, including large trucks.

EPS is also discussed in Section VI.C.3.a) Electrification Modeling in the CAFE model.

b) Improved Accessories (IACC)

Engine accessories typically include the alternator, coolant pump, cooling fan, and oil pump, and are traditionally mechanically-driven via belts, gears, or directly by other rotating engine components such as camshafts or the crankshaft. These can be replaced with improved accessories (IACC) which may include high efficiency alternators, electrically driven (*i.e.*, on-demand) coolant pumps, electric cooling fans, variable geometry oil pumps, and a mild regeneration strategy.¹⁴⁸⁵ Replacing lower-efficiency and/or mechanically-driven components with these improved accessories results in a reduction in fuel consumption, as the improved accessories can conserve energy by being turned on/off “on demand” in some cases, driven at partial load as needed, or by operating more efficiently.

For example, electric coolant pumps and electric powertrain cooling fans provide better control of engine cooling. Flow from an electric coolant pump can be varied, and the cooling fan can be shut off during engine warm-up or cold ambient temperature conditions,

¹⁴⁸⁵ IACC in this analysis excludes other electrical accessories such as electric oil pumps and electrically driven air conditioner compressors.

reducing warm-up time, fuel enrichment requirements, and, ultimately reducing parasitic losses.

IACC is also discussed in Section VI.C.3.a) Electrification Modeling in the CAFE model.

c) Low Drag Brakes (LDB)

Low or zero drag brakes reduce or eliminate brake drag force by separating the brake pad from the rotor, either by mechanical or electric methods. Conventional disc brake systems are designed such that the brake pad is in contact with the brake rotor at all times. This is true even when the brakes are not being applied, and although the contact pressure is light in this case, this still produces some drag force on the vehicle.

LDBs have historically employed a caliper and rotor system that allows the piston in the caliper to retract,¹⁴⁸⁶ in turn pulling the brake pads away from the rotor. However, if pads are allowed to move too far away from the rotor, the first pedal application made by the vehicle operator can feel spongy and have excessive travel. This can lead to customer dissatisfaction regarding braking performance and pedal feel. For this reason, in conventional hydraulic-only brake systems, manufacturers are limited by how much they can allow pads to move away from the rotor.

Recent developments in braking systems have resulted in brakes with the potential for zero drag. In these systems, the pedal feel is separated from hydraulics by a pedal simulator. This system is similar to the brake systems designed for hybrid and electric vehicles, where some of the primary braking is done through the recuperation of kinetic energy in the drive system. However, the pedal feel and the deceleration the operator experiences is tuned to provide a braking experience equivalent to that of a conventional hydraulic brake system. These “brake-by-wire” systems have highly tuned pedal simulators that feel like typical hydraulic brakes and seamlessly transition to a conventional system as required by different braking conditions. The application of a pedal simulator and brake-by-wire system is new to non-electrified vehicle applications. By using this type of system, vehicle manufacturers can allow brake pads to move farther away from the rotor and still maintain the initial pedal feel and deceleration associated with a conventional brake system.

In addition to reducing brake drag, the zero drag brake system provides

ancillary benefits. It allows for a faster brake application and greater deceleration than is normally applied by the average vehicle operator. It also allows manufacturers to tune the braking for different customer preferences within the same vehicle. This means manufacturers can provide a “sport” mode, which provides greater deceleration with less pedal displacement and a “normal” mode, which might be more appropriate for day-to-day driving.

The zero drag brake system also eliminates the need for a brake booster. This saves cost and weight in the system. Elimination of the conventional vacuum brake booster could also improve the effectiveness of stop-start systems. Typical stop-start systems need to restart the engine if the brake pedal is cycled because the action drains the vacuum stored in the booster. Because the zero drag brake system provides braking assistance electrically, there is no need to supplement lost vacuum during an engine off event.

Finally, many engine technologies being considered to improve efficiency also reduce pumping losses through reduced throttling, and in turn there is less engine vacuum available to power-assist a conventional brake system. The reduction in throttling could require a supplemental vacuum pump to provide vacuum for a conventional brake system. This is the situation in many diesel-powered vehicles. Diesel engines have no throttling and require a supplemental vacuum for conventional brake systems. A zero drag brake system both eliminates brake drag and avoids the need for a supplemental vacuum pump.

d) Secondary Axle Disconnect (SAX)

All-wheel drive (AWD) and four-wheel drive (4WD) vehicles provide improved traction by delivering torque to the front and rear axles, rather than just one axle. When a second axle is rotating, it tends to consume more energy because of additional losses related to lubricant churning, seal friction, bearing friction, and gear train inefficiencies.^{1487 1488} Some of these losses may be reduced by providing a secondary axle disconnect function that disconnects one of the axles when driving conditions do not call for torque to be delivered to both.

The terms AWD and 4WD are often used interchangeably, although they

have also developed a colloquial distinction, and are two separate systems. The term AWD has come to be associated with light-duty passenger vehicles providing variable operation of one or both axles on ordinary roads. The term 4WD is often associated with larger truck-based vehicle platforms providing a locked driveline configuration and/or a low range gearing meant primarily for off-road use.

Many 4WD vehicles provide for a single-axle (or two-wheel) drive mode that may be manually selected by the user. In this mode, a primary axle (usually the rear axle) will be powered, while the other axle (known as the secondary axle) is not. However, even though the secondary axle and associated driveline components are not receiving engine power, they are still connected to the non-driven wheels and will rotate when the vehicle is in motion. This unnecessary rotation consumes energy,¹⁴⁸⁹ and leads to increased fuel consumption and CO₂ emissions that could be avoided if the secondary axle components were completely disconnected and not rotating.

Light-duty AWD systems are often designed to divide variably torque between the front and rear axles in normal driving to optimize traction and handling in response to driving conditions. However, even when the secondary axle is not necessary for enhanced traction or handling, in traditional AWD systems it typically remains engaged with the driveline and continues to generate losses that could be avoided if the axle was instead disconnected. The SAX technology observed in the marketplace disengages one axle (typically the rear axle) for 2WD operation, but detects changes in driving conditions and automatically engages AWD mode when it is necessary. The operation in 2WD can result in reduced fuel consumption. For example, Chrysler has estimated the secondary axle disconnect feature in the Jeep Cherokee reduces friction and drag attributable to the secondary axle by 80% when in disconnect mode.¹⁴⁹⁰

e) Analysis Fleet Assignments for Other Vehicle Technologies

The agencies described in the PRIA that the aforementioned technologies have been applied, to some extent, in the MY 2016 fleet. However, these technologies are difficult to observe and

¹⁴⁸⁶ The brake caliper pistons are used to push the brake pad against the brake rotor, or disc.

assign to the analysis fleet, and the agencies relied heavily on industry engagement and feedback to assign the technologies properly to the NPRM analysis fleet vehicles. In the NPRM, the agencies noted that the Draft TAR analysis did not properly account for the presence of these technologies in the analysis fleet, and far too few were assigned. Accordingly, the NPRM analysis reflected higher EPS and IACC application rates than the Draft TAR analysis.

The agencies received a handful of comments stating that the additional technologies were incorrectly applied to the analysis fleet. ICCT stated that the inclusion of EPS, IACC, and LDB in the analysis fleet was unsubstantiated, and removed the technologies from potential use during the subsequent simulated years.¹⁴⁹¹ ACEEE commented that IACC should not have been applied to certain vehicles in the analysis fleet because those vehicles do not in actuality display the fuel consumption reduction that would confirm the presence of these additional technologies.¹⁴⁹² In addition, ACEEE commented that the CAFE model assumes significant baseline SAX penetration that they

could not corroborate from Ford F-150 product information brochures.¹⁴⁹³ HDS compared the available levels of IACC improvements from the Draft TAR to the NPRM analysis, noting that the NPRM only employed one level of improved accessory technologies.¹⁴⁹⁴ HDS stated that this implied the effectiveness of what was previously considered IACC1 (the first level of IACC technology improvement available in the Draft TAR) was completely used up in the 2016 analysis fleet for this rule.

As the agencies stated in the PRIA, in part because of the difficulty in observing EPS, IACC, LDB, and SAX on actual vehicles, far too few of those technologies were assigned to vehicles in the Draft TAR analysis fleets. For the final rule, each vehicle in the MY 2017 analysis fleet was studied using confidential and publicly available information to determine whether, as commenters suggested, the agencies had improperly applied any of these additional vehicle technologies. This resulted in some adjustments in the application of the technologies in the analysis fleet. In regard to ACEEE's comment on SAX penetration in the analysis fleet, for the NPRM and final rule analysis, the agencies considered

all 4WD vehicles to have the capability manually to disconnect either the front or rear wheel axle and associated rotating components, thus shifting to a 2WD mode. When 4WD operation is required for safety and utility, the consumer can enable this feature. As stated above, this capacity to shift between 2WD and 4WD modes is another form of SAX. For AWD vehicles, publicly available manufacturer information was reviewed to identify the specific vehicles that have SAX technology. Based on market observations and feedback from OEMs, the entire analysis fleet for NPRM and the final rule was considered to have a basic level of improved accessories (comparable to what Draft TAR referred to as IACC1). The application of IACC in the NPRM and final rule analysis fleets represents further improvements to accessories such as electric water pumps and higher efficiency alternators with mild regeneration capacity.

The following distribution of technologies in the analysis fleet from the NPRM to the final rule analysis shows a slight decrease in the portion of total vehicles produced that have EPS and IACC, a very slight increase in the portion of total vehicle production that have LDB, and a slight increase in the portion of 4WD/AWD vehicles with SAX technology.

f) Effectiveness Estimates for Other Vehicle Technologies

The effectiveness estimates for these four technologies rely on previous work published as part of the rulemaking process, both for the 2012 rule for MYs 2017–2025 and the Draft TAR. The effectiveness values are unchanged from the Draft TAR.

The effectiveness of both EPS and EHPS is derived from the decoupling of the pump from the crankshaft, and is considered to be practically the same for both. Thus, a single effectiveness value

is assigned to all vehicles in the analysis fleet that possess either EPS or EHPS, and the “EPS” designation is applied.

For the Draft TAR analysis, two levels of IACC were offered as a technology path (a low improvement level and a high improvement level). Since much of the market has incorporated some of these technologies in the baseline MY 2016 and 2017 fleets, the NPRM and final rule analyses assumed all vehicles have incorporated what was previously the low level, so only the high level remained as an option for vehicles. The figure above shows the distribution of

IACC for NPRM and FRM, which is the equivalent type of technology as the high-level IACC in the DRAFT TAR.

The NPRM analysis carried forward work on the effectiveness of SAX systems conducted in the Draft TAR and EPA Proposed Determination. This work involved gathering information by monitoring press reports, holding meetings with suppliers and OEMs, and attending industry technical conferences. The resulting effectiveness estimates used in the Draft TAR, NPRM, and this final rule are shown below.

g) Cost Estimates and Learning Rates for Other Vehicle Technologies

The cost estimates for these technologies rely on previous work published as part of the rulemaking process, both for the 2012 rule for MYs 2017–2027 and the Draft TAR. The cost values are from the same sources as the Draft TAR and were updated to 2016 dollars for the NPRM and 2018 dollars for the final rule analysis. Learning rates for these technologies are also unchanged since the NPRM, and can be seen in Section VI.B.4.d)(4) Cost Learning as Applied in the CAFE Model.

CARB noted that the IACC costs in Tables 6–32 and 6–33 of the PRIA did not align with the Technologies central

analysis input file.¹⁴⁹⁵ HDS commented, as part of its comparison of IACC penetration in the analysis fleet from the Draft TAR to NPRM, that IACC costs were based on the difference between IACC1 and IACC2 costs and this appeared to be inconsistent with the cost of accessory electrification which is more expensive.¹⁴⁹⁶

In the PRIA, the cost of IACC was reported in some tables as an absolute cost (the cost of adding IACC to a base vehicle), while the NPRM Technologies central analysis input file showed IACC cost incremental to EPS. This was necessary in the model input file because the accounting method of the NPRM CAFE model utilized incremental costs. In contrast, a change in the CAFE model accounting method for this final rule allows all costs in the

input file to be reported as absolute costs, incremental to a base vehicle. It was assumed that EPS must be present on a vehicle in order for it to adopt IACC, and as such the cost of IACC includes the cost of EPS. For further detail on the use of absolute costs in place of incremental costs, see Section VI.C.7.g). Although HDS commented that accessory electrification has a higher cost than what is being used in the analysis, no specific additional input was given; the cost of IACC, as was done for Draft TAR (where it was referred to as IACC2), was taken from the 2015 NAS Report.¹⁴⁹⁷

Table VI–141 below shows the absolute costs for these technologies for select model years. The FRM Technologies central analysis input file shows the costs for all model years.

| LDB | \$92.08 | \$84.60 | \$78.35 | \$73.97 |
| SAX | \$97.41 | \$86.69 | \$80.34 | \$75.98 |

8. Simulating Off-Cycle and A/C Efficiency Technology Adjustments

Off-cycle and air conditioning (A/C) efficiency technologies can provide fuel economy improvements in real-world vehicle operation, but that benefit cannot be adequately captured by the 2-cycle test procedures used to demonstrate compliance with fuel economy and CO₂ emissions standards.¹⁴⁹⁸ Off-cycle technologies include technologies like high efficiency alternators and high efficiency exterior lighting.¹⁴⁹⁹ A/C efficiency technologies operate mainly by reducing the operation of the compressor, which pumps A/C refrigerant around the system loop. The less the compressor operates or the more efficiently it operates, the less load the compressor places on the engine, resulting in better fuel efficiency and lower CO₂ emissions.

Vehicle manufacturers have the option to generate credits for off-cycle technologies and improved A/C systems under the EPA's CO₂ program and receive a fuel consumption improvement value (FCIV) equal to the value of the benefit not captured on the 2-cycle test under NHTSA's CAFE program. The FCIV is not a credit in the NHTSA CAFE program, but the FCIVs increase the reported fuel economy of a manufacturer's fleet, which is used to determine compliance. EPA applies FCIVs during determination of a fleet's final average fuel economy reported to NHTSA.¹⁵⁰⁰ FCIVs are only calculated

and applied at a fleet level for a manufacturer and are based on the volume of the manufacturer's fleet that contain qualifying technologies.¹⁵⁰¹

As discussed further in Section IX.D Compliance Issues that Affect Both the CO₂ and CAFE Programs, three pathways can be used to determine the value of A/C efficiency and off-cycle adjustments. First, manufacturers can use a predetermined list or "menu" of credit values established by EPA for specific off-cycle technologies.¹⁵⁰² Second, manufacturers can use 5-cycle testing to demonstrate and justify off-cycle CO₂ credits;¹⁵⁰³ the additional tests allow emission benefits to be demonstrated over some elements of real-world driving not captured by the 2-cycle compliance tests, including high speeds, rapid accelerations, and cold temperatures. Third, manufacturers can seek EPA approval, through a notice and comment process, to use an alternative methodology other than the menu or 5-cycle methodology for determining the off-cycle technology improvement values.¹⁵⁰⁴

The agencies have been collecting data on the application of these technologies since implementing the programs.¹⁵⁰⁵ Most manufacturers are

generating A/C efficiency and off-cycle credits; in MY 2017, 15 manufacturers generated A/C efficiency credits and 15 manufacturers generated off-cycle credits, through the level of deployment varies by manufacturer.¹⁵⁰⁶

a) A/C and Off-Cycle Effectiveness Modeling

The NPRM analysis used the off-cycle FCIVs and credits earned by each manufacturer in MY 2016 and carried these forward at the same levels for future years for the CO₂ analysis and beginning in MY 2017 for the CAFE analysis. The 2016 values for off-cycle FCIVs for each manufacturer and fleet, denominated in grams CO₂ per mile,¹⁵⁰⁷ are provided in Table VI-142.¹⁵⁰⁸ Additional off-cycle FCIVs were added in future years if a manufacturer applied a technology that was explicitly simulated in the analysis and also was an off-cycle technology listed on the predefined menu.¹⁵⁰⁹ Technologies explicitly simulated in the analysis that are also on the off-cycle menu include start-stop systems that reduce fuel consumption during idle and active grille shutters that improve aerodynamic drag at highway speeds,

rule and NHTSA adopted equivalent provisions for MYs 2017 and later in the MY 2017–2025 rule.

¹⁵⁰⁶ The 2018 EPA Automotive Trends Report, EPA-420-R-19-002, March 2019 at Chapter 5.B., Figures 5.10 and 5.11.

¹⁵⁰⁷ For the purpose of estimating their contribution to CAFE compliance, the grams CO₂/mile values in Table I-1 are converted to gallons/mile and applied to a manufacturer's 2-cycle CAFE performance. When calculating compliance with EPA's CO₂ program, there is no conversion necessary (as standards are also denominated in grams/mile).

¹⁵⁰⁸ 2016 GHG Manufacturer Performance Report. EPA-420-R-18-002. January 2018. <https://nepis.epa.gov/Exe/ZyPDF.cgi?Dockkey=P100TGIA.pdf>. ¹⁵⁰¹ 40 CFR 600.510–12(c)

¹⁵⁰² See 40 CFR 86.1869–12(b). The Technical Support Document (TSD) for the 2012 final rule for MYs 2017 and beyond provides technology examples and guidance with respect to the potential pathways to achieve the desired physical impact of a specific off-cycle technology from the menu and provides the foundation for the analysis justifying the credits provided by the menu. The expectation is that manufacturers will use the information in the TSD to design and implement off-cycle technologies that meet or exceed those expectations in order to achieve the real-world benefits of off-cycle technologies from the menu.

¹⁵⁰³ See 40 CFR 86.1869–12(c). EPA proposed a correction for the 5-cycle pathway in a separate technical amendments rulemaking. See 83 FR 49344 (Oct. 1, 2019). EPA is not approving credits based on the 5-cycle pathway pending the finalization of the technical amendments rule.

¹⁵⁰⁴ See 40 CFR 86.1869–12(d).

¹⁵⁰⁵ See 77 FR at 62832, 62839 (Oct. 15, 2012). EPA introduced A/C and off-cycle technology credits for the CO₂ program in the MYs 2012–2016 rule and revised the program in the MY 2017–2025

¹⁴⁹⁸ See 49 U.S.C. 32904(c) ("The Administrator shall measure fuel economy for each model and calculate average fuel economy for a manufacturer under testing and calculation procedures prescribed by the Administrator. . . . the Administrator shall use the same procedures for passenger automobiles the Administrator used for model year 1975 (weighted 55 percent urban cycle and 45 percent highway cycle), or procedures that give comparable results.").

¹⁴⁹⁹ See 83 FR 43057. A partial list of off-cycle technologies is included in Tables II–21 and II–22 of the NPRM.

¹⁵⁰⁰ 49 U.S.C. 32904(c)–(e). EPCA granted EPA authority to establish fuel economy testing and calculation procedures. See Section IX for more information.

among others. Any off-cycle adjustments that accrued as the result of applying these technologies were calculated dynamically in each model year the technology was applied, with adjustments accumulating up to the 10 g/mi cap. As a practical matter, most of

the adjustments for which manufacturers can claim off-cycle FCIVs exist outside of the CAFE model technology tree so the off-cycle menu cap was rarely reached for the NPRM analysis.

The agencies sought comment on both the A/C and off-cycle data that was used for the NPRM analysis as well as the assumptions for applying those technologies.

BILLING CODE 4910-59-C

Universally, stakeholders believed the application of off-cycle adjustments in the analysis was too conservative. Stakeholders believed the A/C and off-cycle technologies would be rapidly deployed and manufacturers would reach the cap values within the rulemaking timeframe.

The Institute for Policy Integrity (IPI) questioned the position the agencies assumed in the NPRM analysis, and suggested the agencies “assume that

manufacturers will efficiently deploy all cost-saving offset opportunities, especially in the face of increasingly stringent standards.”¹⁵¹¹

ICCT stated “far greater use of the off-cycle provisions will occur by 2025” and emphasized that off-cycle technologies are “highly cost-effective and being deployed in greater sales penetrations than many of the test-cycle efficiency technologies that the agencies are analyzing.”¹⁵¹² ICCT supported manufacturers maximizing the use of

off-cycle technologies, and supported the analysis estimating “fleetwide off-cycle credit use at over 10 g/mile by 2020,” and further suggested fleetwide achievement of 15 g/mile by 2025.¹⁵¹³

FCA, General Motors and the Auto Alliance all provided similar observations, stating “[m]anufacturers have rapidly deployed technology in response to this all new regulatory

¹⁵¹⁰ See 83 FR 43159-60 (“... this analysis uses the off-cycle credits submitted by each manufacturer for MY 2017 compliance and carries these forward to future years with a few exceptions.”).

¹⁵¹¹ Comments from Institute from Policy Integrity, Attachment 1, NPRM Docket No. NHTSA-2018-0067-12213, at 20-21.

¹⁵¹² Comments from ICCT, Attachment 1, NPRM Docket No. NHTSA-2018-0067-11741, at 140-141.

¹⁵¹³ Note there is a regulatory “cap” on menu technologies of 10 g/mi (see Section IX for further discussion of the cap), however a manufacturer can receive additional off-cycle credit/FCIV by using the pathways described above to petition for off-menu technologies. ICCT’s comment suggests that manufacturers will reach the regulatory menu cap and apply additional technologies to get an additional 5 g/mi credit above the menu cap.

mechanism.” Each of the commenters provided support for an argument of rapid off-cycle technology adoption, stating “[i]n the MY2021–2026 timeframe of the proposed rule, it is likely that manufacturers will hit the existing 10 g/mi cap.”¹⁵¹⁴

The DENSO Corporation further supported the increased use of off-cycle technologies, commenting that “[a]vailable data on OEM off-cycle technology credit utilization within the past few years demonstrates that the use of off-cycle technologies is expected to grow—particularly technologies on the credit menus.”¹⁵¹⁵

However, Toyota Motors North America asked for constraints on considerations of off-cycle technology in the analysis.¹⁵¹⁶ Toyota expressed concern for over-reliance on off-cycle technologies to provide flexibilities for compliance, as “most of the technologies provide little tangible value proposition for customers.” In additional comments, Toyota repeated the concern noting, “most of these

technologies lack consumer demand.” Finally, Toyota specifically cautioned against overusing off-cycle technologies in the analysis, stating “[t]he suggested pursuit of maximum credits overlooks the associated costs and market acceptance challenge for certain off-cycle technologies.” Toyota listed costs versus risk of customer acceptance and agency approval as factors that “introduce a high level of uncertainty for an auto manufacturer’s planning and make investments in off-cycle technologies risky and less appealing.”

After carefully considering the comments, the agencies agree that A/C and off-cycle technologies are likely to be more broadly applied by manufacturers within the rulemaking timeframe. The final rule analysis has been updated to reflect an increased application of the technologies. Similar to the NPRM, the final rule analysis used the A/C and off-cycle FCIVs earned by each manufacturer in the baseline fleet (MY 2017 for the final rule analysis) as a starting point. However, the final rule analysis increased these values in subsequent model years. In addition to the dynamic application of off-cycle FCIVs, as in the NPRM, each manufacturer’s fleet FCIVs were increased by extrapolating the manufacturers’ historical rate of FCIV application through 2017.¹⁵¹⁷ In line with most commenters, the agencies increased the FCIVs for each manufacturer such that the maximum value of 10 g/mi will be reached by MY

2023. For manufacturers who did not reach maximum values prior to 2023 through data extrapolation, a linear increase to the cap was assumed. The agencies believe this approach balances a greater application of FCIV technologies across the fleet, while avoiding uncertain over-reliance on flexibilities for the analysis.

The agencies disagreed with the proposal to model the application of 15 g/mi of FCIVs universally in the rulemaking timeframe. Based on historical data and industry comments from both manufacturers and suppliers, the agencies expect there will be an increase in off-cycle technology application. However, there are two issues with assuming manufacturers will exceed the existing off-cycle caps. First, only a few manufacturers approached the cap limit in MY 2018, and the fleet average menu credit was 4.7 grams/mile, less than half the cap value.¹⁵¹⁸ Second, new off-cycle technologies may address the same inefficiencies as menu technologies, rather than work in conjunction. Accordingly, the agencies believe there is a reasonable basis for assuming manufacturers could, and would only achieve 10 g/mi on average by MY 2023, and used that assumption for the final rule analysis.

Table VI–143 shows passenger car values for FCIVs and Table VI–144 shows light truck values for FCIVs applied for the final rule analysis.

A/C Efficiency, A/C Leakage and Off-Cycle Costs

As discussed above, the only A/C efficiency and off-cycle technologies applied dynamically in the NPRM analysis were explicitly simulated technologies like stop-start systems and active aerodynamic technologies. The NPRM analysis fully accounted for both the effectiveness and cost of these technologies and therefore separate cost

accounting was not needed. For example, when stop-start or active aerodynamics technology was added by the model to a vehicle, the corresponding off-cycle FCIVs were applied and the technology costs were captured the same as every other technology on the decision trees.

For the final rule analysis, A/C and off-cycle technologies are applied independently of the decision trees using the extrapolated values, so it is

necessary to account for the costs of those technologies independently. Table VI-145 shows the costs used for A/C and off-cycle FCIVs the final rule analysis. The costs are shown in dollars per gram of CO₂ per mile (\$ per g/mile). The A/C costs and off-cycle technology costs are the same costs used in the EPA Proposed Determination and described in the EPA Proposed Determination TSD.¹⁵¹⁹

BILLING CODE 4910-59-C

D. Impacts that Result From Simulating Manufacturer Compliance with Regulatory Alternatives

1. Simulating Economic Impacts of Regulatory Alternatives

a) What Economic Impacts Occur When Vehicle Manufacturers Comply With Different CAFE and CO₂ Standards?

1) The NPRM Framework for Analyzing Economic Impacts

In the proposed rule, the agencies noted the importance of identifying the mechanisms by which vehicle manufacturers' compliance with different CAFE and CO₂ standards generated impacts on manufacturers, owners of new and used vehicles, and the remainder of the U.S. The agencies

organized the analysis of alternative standards using a framework that clarified the economic impacts on vehicle producers, illustrated how costs were transmitted to buyers of new vehicles, highlighted the collateral economic effects on owners of used vehicles, and identified how these responses created various indirect costs and benefits. Throughout the analysis, the agencies stressed the distinction between the proposal's economic consequences for private businesses and households, and its "external" economic impacts—those ultimately borne by the rest of the U.S. economy.

To clarify the framework used in the proposal, the agencies used Table VI-146 below (which is based on Tables II-25 to II-28 from the NPRM)¹⁵²⁰ to

report costs and benefits and to trace how they pass through the economy. As the table shows, the economic impacts of standards initially fall on vehicle manufacturers, but ultimately are borne by consumers who purchase and drive new models. Smaller, indirect economic effects of the proposal would be borne by owners of used cars and light trucks (vehicles produced during model years prior to those affected by the proposal, but still in use) as well as by the general public and government agencies. On balance, the agencies projected that most of the proposal's economic effects would fall on private businesses and households, with the remainder of the U.S. economy bearing much smaller impacts.

BILLING CODE 4910-59-C

More specifically, the agencies' analysis showed that the proposal would initially have saved manufacturers the costs of adding the technologies that would otherwise have been necessary to enable their new cars

and light trucks to comply with the baseline fuel economy and CO₂ emissions regulations, with the estimated dollar value of those savings shown in line 1 of Table VI-146. The proposal also enabled some

manufacturers to make lower civil penalty payments for failing to comply with the more demanding standards that were supplanted (line 2), although these savings would have been exactly offset by lower civil penalty revenue to the

Federal Government (line 16). The analysis assumed that manufacturers would have the ability, in a competitive market, to pass their savings in technology costs and any reduction in civil penalties paid on to buyers, by charging lower prices for new vehicles. Although lower prices reduced their revenues (line 3), on balance, their savings in compliance costs, reduced civil penalty payments, and lower sales revenue were assumed to leave manufacturers financially unaffected (shown by the zero entry in line 4 of the table).

Under the proposal, the analysis showed that buyers of new cars and light trucks benefited directly from those vehicles' lower purchase prices and financing costs (line 5). They also avoided the increased risk of crash-related injuries that would have resulted from reductions in the weight of some new models, as manufacturers attempted to improve fuel economy to comply with the baseline standards. The economic value of this reduction in risk represented an additional benefit from the proposal to reducing the stringency of the standards vis-à-vis the baseline (line 6).

At the same time, however, the lower fuel economy that some new cars and light trucks were expected to offer with less stringent standards in place would have imposed various additional costs on their buyers and users. Drivers experienced higher fuel costs as a consequence of new vehicles' increased fuel consumption (line 7), as well as the added time and inconvenience of having to make more frequent refueling stops required by reduced driving range (line 8). They also forfeited some mobility benefits as they drove newly-purchased cars and light trucks less in response to their higher fuel costs (line 9). On balance, the agencies' analysis of the proposal showed that buyers of new cars and light trucks produced during the model years it affected would experience significant economic benefits (line 10).

A novel feature of the agencies' evaluation of the proposal showed that lowering prices for new cars and light trucks, some owners of used vehicles retired them from service earlier than they otherwise would have done. In combination with increased sales of new models, this transferred some driving that would have occurred with used cars and light trucks to newer and safer models, thus reducing the total costs of fatalities and injuries sustained in motor vehicle crashes.¹⁵²¹ In the

proposal, this reduction in injury risks provided benefits to owners and drivers of older cars and light trucks that had not been recognized or quantified in its analyses of previous CAFE and CO₂ standards (line 11).

Table VI-146 also showed that the changes in fuel consumption and vehicle use resulting from the proposal would in turn generate both benefits and costs to the remainder of the U.S. economy. The analysis described these as "external" effects, in the sense that they were by-products of households' choices among new vehicle models, decisions about keeping older cars and light trucks in service, and allocations of driving across the fleet that were experienced broadly throughout the U.S. economy, rather than by the individuals making such decisions. The largest of these was additional refining and consumption of petroleum-based fuel and the associated increases in emissions of carbon dioxide and other gases, which were projected to increase the cost of economic damages inflicted on the U.S. economy by future changes in the global climate (line 13). Added fuel production and use under the proposal also led to higher emissions of localized air pollutants, and the resulting increase in the U.S. population's exposure and its adverse effects on health imposed additional external costs (line 14).

Increased consumption of petroleum-derived fuel also imposed higher external costs on the U.S. economy, in the form of potential losses in economic output and costs to businesses and households for adjusting to any sudden changes in energy prices (line 15 of the table). Reduced driving by buyers of new cars and light trucks in response to their higher operating costs also reduced the external costs from their contributions to traffic delays and noise, benefits that were expected to be experienced throughout the U.S. economy (line 17). Finally, some of the higher fuel costs to buyers of new cars and light trucks will consist of increased fuel taxes; this increase in revenue was projected to enable Federal and State government agencies to improve upkeep of roads and highways, fund increases in other services, or reduce other tax burdens (line 18).¹⁵²²

progressively more protective in crashes over time (and also slightly less prone to certain types of crashes, such as rollovers). Thus, shifting some travel from older to newer models reduced injuries and damages sustained by drivers and passengers because they were traveling in inherently safer vehicles, rather than because of changes to driver risk profiles.

¹⁵²² In some States, levies on gasoline include both general sales taxes as well as excise taxes, and

The net economic effect (line 22) of the proposal consisted of the benefits and costs imposed directly on car and light truck manufacturers, accompanying indirect effects on buyers of new vehicles and owners of used ones, external costs driving decisions generated throughout the U.S. economy, and changes in revenue to government agencies. The agencies' organization was intended to convey the causal connections among these impacts, by highlighting how the proposed change in fuel economy standards faced by manufacturers would set in motion the sequence of behavioral responses that determined its economy-wide costs and benefits. This contrasted with the way benefits and costs of previous proposals to establish CAFE and CO₂ standards were analyzed and presented, which obscured their sequence and causal connections.

In those previous analyses, most economic effects other than manufacturers' costs to comply with proposed standards and anticipated changes in fuel consumption were grouped together and reported as "co-benefits." This obscured how these various consequences arose from the proposed standards, providing no information about who would ultimately experience the costs of complying with the standards, or who would experience their direct and indirect benefits. In contrast, the recent analysis spelled out how each category of benefits and costs resulted from the proposed change in standards, identified the mechanisms that translated direct economic impacts into indirect costs and benefits, and distinguished between those arising from changes in fuel consumption, and safety consequences of changes in vehicle use. The proposal's framework also clarified who would bear each category of impacts, distinguishing between the proposal's economic impacts on private actors—vehicle manufacturers, new car and light truck buyers, and owners of used vehicles—and the external economic consequences for the general public and government agencies that stem indirectly from such private impacts.

2) Final Rule Framework

While the agencies received several comments about which economic effects are included in the analysis, the agencies received no comments about the specific structure of the framework. Substantive comments about individual

not all proceeds are dedicated to transportation purposes.

¹⁵²¹ This improvement in safety resulted from the fact that cars and light trucks have become

effects are addressed over the next several sections.

The agencies have expanded the accounting framework for benefits and costs shown in Table VI-146 above to include two additional entries, as well as to distinguish financial impacts on government agencies from externalities borne broadly across the remainder of the U.S. economy. The revised accounting framework for costs and benefits is shown in Table VI-147, below. Line 6 of the revised table reports the change in consumer surplus experienced by buyers of new cars and light trucks when prices and sales of those vehicles adjust in response to changes in CAFE and CO₂ standards. The gain in consumer surplus that occurs when production costs and prices for vehicles fall and sales increase in response represents a benefit to buyers, while any loss in consumer surplus that occurs when more stringent standards increase costs and prices and cause sales to decline appears as a loss to new car and light truck buyers.

Line 7 of Table VI-147 reports the estimated value of changes to attributes

of new cars and light trucks other than fuel economy that their manufacturers make to comply with changes in CAFE and CO₂ standards. In the case where standards are less stringent, manufacturers are able to employ many of the same resources they would have deployed to increase fuel economy for the alternative purpose of improving other attributes of vehicles that their potential buyers value more highly than the forgone improvements in fuel economy. This response provides an additional benefit to purchasers of new cars and light trucks that was not recognized in the agencies' analysis of the proposal, but is included in the analysis of this final rule. Of course, if CAFE and CO₂ standards are made more stringent, manufacturers employ those technologies to increase fuel economy, thus sacrificing potential improvements in competing attributes—those that entail tradeoffs with higher fuel economy—and the value of improvements in those other attributes that is sacrificed or forgone represents an opportunity cost to those buyers.

This implicit opportunity cost is analyzed in a sensitivity analysis and is not included in the primary analysis.

Finally, the agencies revised the framework for reporting costs and benefits of changes in CAFE and CO₂ standards to identify government agencies separately from the entry previously labeled "Rest of U.S. Economy." This minor revision is intended to distinguish more clearly between changes in external costs imposed by externalities that result from fuel production and use, and the revenue effects on government agencies from changes in tax and civil penalty payments. While both effects ultimately result from manufacturers' compliance with revised standards and the resulting changes in fuel consumption, externalities represent real economic costs; in contrast, changes in tax revenues received by government agencies are financial transfers, whose offsetting effects on manufacturers and vehicle buyers are also recognized elsewhere in the accounting framework.

BILLING CODE 4910-59-P

Table VI-147 – Benefits and Costs of Final CAFE and CO₂ Standards

| Line | Affected Party | Source | Private Benefits and (Costs) |
|------|-----------------------|---------------------------------|--|
| 1 | Vehicle Manufacturers | CAFE model | Savings in technology costs to increase fuel economy |
| 2 | | | Reduced penalties for non-compliance |
| 3 | | assumed = -(1+2) | Net loss in revenue from lower vehicle prices |
| 4 | | net = 1+2+3 | Net benefits to manufacturers |

BILLING CODE 4910-59-C

b) Economic Assumptions

The agencies' analysis of CAFE and CO₂ standards for the model years covered by this final rule rely on a range of forecast information, estimates of economic, safety, and environmental variables, and input parameters. While the analysis accompanying the proposal largely resembled previous CAFE and CO₂ analyses, the agencies updated

many of the underlying inputs and assumptions—based on the most up-to-date data—and expanded the central analysis to account for changes in new vehicle sales and the retirement of older vehicles.

EDF, UCS, CARB and others commented that the agencies acted arbitrarily and capriciously by changing inputs and assumptions from previous analyses, and argued that the agencies failed to provide “good reasons” for the

changes.¹⁵²³ In the following sections, the agencies will respond directly to these comments. However, the agencies note that it would be uncommon to retain inputs and assumptions from prior analyses—which are typically informed by transitory empirical observations—on the basis of precedent. The agencies are “neither required nor

¹⁵²³ See, e.g., IPI, Appendix, NHTSA-2018-0067-12213, at 99-100.

supposed to regulate the present and the future within the inflexible limits of yesterday.”¹⁵²⁴

The agencies also received a number of comments focused on the agencies’ attempt to incorporate the effects of changes in new vehicle prices on new vehicle sales, retirement rates of used vehicles, and the resulting “turnover” of the vehicle fleet. Some comments endorsed the agencies’ more comprehensive analysis, although many of those same commenters later disagreed with aspects of the results. For example, RFF noted that “Incorporating sales and scrappage effects represents a step in the right direction for modeling the effects of the regulation.”¹⁵²⁵ Similarly, NRDC stated that “it is reasonable and appropriate to develop a mechanism for estimating future vehicle populations, and the NPRM documents appropriately present considerable discussion on the topic and the derivation of the utilized algorithm.”¹⁵²⁶ One commenter explicitly recognized that the narrower analysis utilized in previous rules likely led to incorrectly estimating costs and benefits, and endorsed the broader approach used by the proposal. Specifically, American Fuel & Petrochemical Manufacturers stated that the absence of scrappage in prior rules “likely led to a significant overestimation of the existing standard’s benefits with respect to fuel and air pollutant emission reductions and an underestimation of safety risks and societal costs.” FCA also expressed general support for the agency’s expanded analysis.¹⁵²⁷

In contrast, some commenters objected to the inclusion of ‘new’ impacts, including the effect of fuel economy regulations on new vehicle prices, the resulting changes in their sales, and retirement rates for used cars. Workhorse Group, Inc. noted that the agencies “made novel assumptions about the safety impacts of consumers delaying vehicle purchases due to the increased costs of fuel economy improvements that contradicts the analytical approach NHTSA has followed in all prior safety and CAFE rulemakings.”¹⁵²⁸ Honda agreed “that significantly higher-priced new vehicles

have the potential to depress the new vehicle market and thus increase the fleet of used vehicles, with concomitant increased safety risks associated with driving greater numbers of older vehicles in lieu of newer ones,” but found it “premature and ill-advised” to model the impact of fleet turnover.¹⁵²⁹ CBD et. al. argued that the sales and scrappage effects were too uncertain to include in the analysis and cited EPA’s 2016 proposed determination as stating, “a reasonable qualitative assessment is preferable to a quantitative estimate lacking sufficient basis, or (due to uncertainties like those here) having such an enormous range as to be without substantial value.”¹⁵³⁰

As was done repeatedly throughout the proposal, the agencies acknowledge that dynamically modeling fleet turnover is new for this rulemaking; however, the agencies disagree that the analysis relied on ‘novel’ assumptions or contradicted previous analyses. The agencies have described the sales and scrappage responses similarly in prior rulemakings,¹⁵³¹ and have expressed an interest in quantitatively measuring them.¹⁵³² The agencies agree with commenters that—like many of the effects included in today’s analysis—there remains a degree of uncertainty about the magnitude of the sales and scrappage responses. However, *CBD v. NHTSA* stressed that a variable should not be excluded from the analysis simply because it is uncertain when the effect is quantifiable, “certainly not zero,” and the analysis “monetize[s] other uncertain benefits.”¹⁵³³ As discussed in the coming sections, the agencies are confident that (a) changes in new vehicle prices impact the volume of new vehicle sales and rate of retirement of older vehicle, (b) of the direction of those effects, and (c) their ability to reasonably estimate the impacts. As such, the agencies strongly believe that including the sales and scrappage responses improves the thoroughness of the analysis, is consistent with case law, and is necessary to comprehensively analyze the cost-benefits of the rule.

The following subsections briefly describes the sources of the agencies’ estimates of each of the economic, environmental, and safety estimates. In reviewing these variables and the agencies’ estimates of their values for purposes of this final rule, NHTSA and

EPA considered comments received in response to the proposed rule and, in response, made several changes to the economic assumptions used for the final analysis.

1) Macroeconomic Assumptions That Affect the Agencies’ Analysis

As the proposed rule noted, the more comprehensive economic impact analysis of CAFE and CO₂ included in this rulemaking requires a more detailed and explicit explanation of the macroeconomic context in which regulatory alternatives are evaluated. The agencies continued to rely on projections of future fuel prices to evaluate manufacturers’ use of fuel-saving technologies, the resulting changes in fuel consumption, and various other benefits. Furthermore, the agencies expanded the scope of their analysis to include projecting future sales of new cars and light trucks, as well as the retirement of used vehicles under each regulatory alternative. In addition to projections of future fuel prices, constructing these forecasts requires explicit projections of macroeconomic variables, including U.S. Gross Domestic Product (GDP), labor force participation (the number of persons employed or actively seeking employment), and bellwether interest rates, which are likely to vary according to roughly the same pattern as interest rates on new car loans.

The analysis presented in the proposal as well as the accompanying RIA and EIS employed forecasts of future fuel prices developed by the agencies using the U.S. Energy Information Administration’s (EIA’s) National Energy Model System (NEMS). An agency within the U.S. Department of Energy (DOE), EIA collects, analyzes, and disseminates independent and impartial energy information to promote sound policymaking, efficient markets, and public understanding of energy and its interaction with the economy and the environment. EIA uses NEMS to produce its Annual Energy Outlook (AEO), which presents forecasts of future fuel prices, among many other energy-related variables. AEO projections of energy prices and other variables are not intended as predictions of what will happen; rather, they are projections of the likely course of these variables that reflect their past relationships, specific assumptions about future developments in global energy markets, and the forecasting methodologies incorporated in NEMS. Each AEO includes a “Reference” case as well as a range of alternative scenarios that each incorporate

somewhat different assumptions from those underlying the Reference Case.

For the proposal, the agencies used the AEO2017 version of NEMS, as this was the most current version of the model that was available at the time. Using this version of NEMS, the agencies reevaluated the “Reference,” “Low Oil Price,” and “High Oil Price” cases described in AEO2017, by setting aside their assumption that mandates by California and other States to sell “Zero Emission Vehicles” (ZEVs) would be enforced. The agencies used the resulting modified Reference case fuel prices as inputs to the proposal’s central case results, and used the modified “Low Oil Price” and “High Oil Price” case fuel prices, which were generated using NEMS, as inputs to several of the sensitivity analysis cases that were presented in the proposal. The sensitivity analysis also included a case that applied the Reference case fuel prices from the then recently issued AEO2018, which did not reflect the modification of EIA’s forecasting model to set aside state mandates for ZEV sales.¹⁵³⁴

The analysis supporting the proposed rule simulated the economic impacts of car and light truck manufacturers’ compliance with alternative CAFE and CO₂ standards through model year 2032, and in doing so estimated the number of vehicles originally produced and sold in each model year that would remain in service during each year of their useful lives (assumed to extend for a maximum of 40 years), as well as their usage, fuel consumption, and safety performance. This required the forecasts of macroeconomic variables that affect vehicle sales, use, and retirement rates, which include U.S. Gross Domestic Product (GDP), the size of the domestic labor force, and key interest rates, to extend well beyond calendar year 2050. One of the few sources that provides forecasts of these variables spanning such a long time horizon was the 2017 OASDI Trustees Report from the U.S. Social Security Administration, and the analysis supporting the proposed rule relied on this source for forecasts of these key macroeconomic measures.¹⁵³⁵

¹⁵³⁴ The results of these and other sensitivity analyses were reported in NHTSA and EPA, “Notice of Proposed Rulemaking: The Safer Affordable Fuel-Efficient (SAFE) Vehicles Rule for Model Years 2021–2026 Passenger Cars and Light Trucks,” *Federal Register* Vol. 83, No. 165, August 24, 2018, Tables VII-90 to VII-98, pp. 43353–69.

(a) Comments on the Fuel Price Forecasts and Macroeconomic Assumptions Used in the NPRM Analysis

The agencies received relatively few comments on the projections of fuel prices and macroeconomic variables that were used in their analysis supporting the proposed rule, virtually all of them focused on the fuel price projections the agencies employed. While only one comment questioned the agencies’ use of price projections that rely on EIA’s methodology and assumptions, a few commenters called attention to the unreliability of price projections reported in earlier editions of AEO. Other comments noted the importance of updating projections used to analyze the proposal to reflect more recent developments in energy markets, without necessarily questioning the reliability of EIA’s fuel price projections. Several comments emphasized the implications for the agencies’ analysis of the wide variation in alternative fuel price projections reported in both EIA’s 2017 and 2018 Annual Energy Outlooks, with most stressing the possibility that future prices might be above even those projected in their High Oil Price cases. Only a single comment identified a potential alternative source of fuel price projections, but noted that it was within the range of projections the agencies considered.

One commenter claimed that AEO’s projections of fuel prices are “inappropriate” for the agencies to employ in analyzing the consequences of CAFE and CO₂ standards; because EIA “does not speculate on changes in international policy or geopolitics,” which contribute to the uncertainty surrounding future prices.¹⁵³⁶ However, this commenter did not identify an alternative source for fuel price projections that reflect such considerations; and because projections of fuel prices are a central element in the agencies’ evaluation of alternative future standards, the observation that EIA’s projections do not incorporate some sources of uncertainty is unhelpful by itself.

Some commenters asserted that by relying on the AEO2017 Reference Case projections of fuel prices in their central analysis of the proposed rule while considering the significantly higher fuel prices projection in the AEO High Oil

¹⁵³⁶ NHTSA–2018–0067–11837, Alliance to Save Energy, p. 2 (“EIA takes a transparently conservative approach in modeling future oil prices, and does not speculate on changes in international policy or geopolitics. As a result, their projections are an inappropriate measure of future fuel prices.”).

Price scenario only in the accompanying sensitivity analyses, the agencies inadequately considered the possible effect of higher fuel prices on the estimated economic benefits from alternatives that would have relaxed the aural standards, including the preferred alternative.¹⁵³⁷ Surprisingly, none of these comments acknowledged that the fuel price projections reported in the High Oil Price cases accompanying past editions of the Annual Energy Outlook have so far proven to be significantly above actual prices, or that EIA has consistently lowered its fuel price projections in more recent editions of the AEO. In any case, supplemental material included in the NPRM regulatory docket showed that the ranking of regulatory alternatives by their estimated net economic benefits remained unchanged from the central analysis in the sensitivity analysis that substituted the AEO2017 High Oil Price case projection of fuel prices.

None of the commenters who argued that the agencies inadequately considered the possibility of higher fuel prices observed that the agencies’ analogous use of lower fuel price projections from the AEO2017 Low Oil Price case only in their sensitivity analyses inadequately considered the possibility that future fuel prices might prove to be *lower* than projected in the AEO2017 Reference Case, and its potential effect on the proposal’s estimated benefits. Nor did any of the commenters offer substantive guidance about how the agencies might revise their analysis to accord greater emphasis to fuel price projections above (or below) those from the AEO Reference Case.¹⁵³⁸

Other comments stressed the fact that EIA’s current projections of future fuel prices are significantly lower than those the agencies relied on when they established CAFE standards through

¹⁵³⁷ See e.g., Securing America’s Future Energy (SAFE), NHTSA–2018–0067–11981, pp. 12 & 30 and Institute for Policy Integrity, NHTSA–2018–0067–12213, p. 31.

¹⁵³⁸ One commenter did refer to guidance to EPA contained in a National Research Council report on incorporating and conveying uncertainty about key inputs directly into that agency’s estimates of benefits from reducing air pollution, rather than simply recognizing it in supplemental sensitivity analyses. This was presumably intended as potential guidance to the agencies about how they might do so in their evaluations of fuel economy and CO₂ standards, although that was not stated explicitly. See American Fuel & Petrochemical Manufacturers, NHTSA–2018–0067–12078, p. 19, citing National Research Council (2002), *Estimating the Public Health Benefits of Proposed Air Pollution Regulations*, 2002, available at <https://www.nap.edu/catalog/10511/estimating-the-public-health-benefits-of-proposed-air-pollution-regulations>.

model year 2021 and introduced the augural standards for subsequent model years in the rulemaking they conducted in 2012, citing this as support for the agencies' reconsideration of the augural standards in the current rulemaking.¹⁵³⁹

One comment compared the range of fuel price projections spanned by the High and Low Oil Price cases from AEO2017 and AEO2018 to the range of future prices spanned by another widely-recognized and relied-upon projection, concluding that the alternative scenarios included in AEO2017 incorporated an even wider range of uncertainty about future prices, and noted that the net economic benefits of the preferred alternative were positive over this entire range of alternative future fuel prices. This same commenter noted that by combining high and low fuel price projections with alternative assumptions about other key economic variables (such as GDP growth) and parameter assumptions (principally payback period), the agencies' sensitivity analyses captured potentially important interactions between uncertainty regarding fuel prices and other key economic inputs.¹⁵⁴⁰

(b) Macroeconomic Assumptions Used To Analyze Economic Consequences of the Final Rule

After considering these comments, the agencies have concluded that there is no convincing reason to rely on sources other than EIA's NEMS model to project future energy prices, or to rely on alternatives to the Reference Case scenario in the current edition of AEO as their basis for using NEMS. The agencies agree that the resulting projections will be uncertain, but note that EIA regularly publishes

retrospective analyses comparing past Reference case projections to subsequent market price outcomes, thus enabling an assessment of this uncertainty. Although EIA does not identify its Reference case as a "most likely" outcome, in the agencies' judgment that case's design—which assumes future trends are consistent with historical and current market behavior—makes it a reasonable and appropriate basis for projecting fuel prices to use in the agencies' central analysis of alternative CAFE and CO₂ standards.

The agencies also conclude that the wide range of uncertainty about future petroleum prices encompassed in EIA's "Low Oil Price" and "High Oil Price" cases means that including them in the accompanying sensitivity analyses provides a meaningful basis for assessing the potential economic consequences of future energy prices that prove to be considerably lower or higher than those reflected in the Reference case. Although these alternative cases do not incorporate unbridled speculation regarding hypothetical changes in "international policy or geopolitics," the agencies believe that this restraint means that relying on them produces a more, rather than less, meaningful test of the effect of the inherent uncertainty surrounding projections of fuel prices.

For today's final rule, the agencies have therefore used the AEO2019 version of NEMS to develop projections of future prices for transportation fuels, as this was the most current version available when this analysis was conducted. Using this version of NEMS, the agencies modified EIA's AEO2019 Reference case by (1) setting aside presumed enforcement by California and other States of any mandates to sell "Zero Emission Vehicles" (ZEVs), (2) setting aside post-2020 increases in the stringency of CAFE and CO₂ standards, and (3) modifying inputs regarding battery costs, in order to bring those costs down to levels more consistent with battery cost estimates applied in

the CAFE model analysis.¹⁵⁴¹ All other NEMS inputs used to develop the AEO2019 Reference case were left unchanged in this analysis.

Setting aside enforcement of state mandates to sell ZEVs makes the supporting analysis consistent with the agencies' recent One National Program Action,¹⁵⁴² under which EPA withdrew aspects of a Clean Air Act Preemption waiver previously granted to California, and NHTSA concluded that EPCA expressly and implied preempted State ZEV mandates. Setting aside the post-2020 increase in the stringency of CAFE and CO₂ standards ensures that the fuel prices used in the agencies' analysis are at least as high as those that would prevail under the least stringent regulatory alternative considered, since that alternative produces the highest level of fuel consumption and thus the highest fuel prices.

Figure VI-55 and Figure VI-56 below show the resulting modified projections of BEV prices and sales, and compare them to the projections reported in EIA's AEO2019 Reference case. As they illustrate, the combination of these modifications led NEMS to project significantly lower BEV prices and correspondingly higher BEV sales volumes. Figure VI-57 and Figure VI-58 show the modified projections of gasoline and electricity prices, and again compare these to the projections reported in EIA's AEO2019 Reference case. As those figures indicate, the agencies' modifications to NEMS did not significantly affect its projections of future prices for transportation fuels.

BILLING CODE 4910-59-P

¹⁵³⁹ For example, Fiat Chrysler Automobiles (FCA) pointed out that the AEO 2017 Reference Case forecast of gasoline prices through 2025 is approximately 36% lower than that in the AEO 2012 Reference Case, which the agencies relied on in the analysis supporting that earlier rulemaking; see NHTSA-2018-0067-11943, p. 33.

¹⁵⁴⁰ See Alliance of Automobile Manufacturers, NHTSA-2018-0067-1207, p. 108.

¹⁵⁴¹ These inputs are all contained in the "trnldvx.xlsx" NEMS input file. The input file utilized for today's analysis is available in regulatory docket NHTSA-2018-0067, <https://www.regulations.gov/docket?D=NHTSA-2018-0067> (see Supporting Documents), as is the corresponding output file from which reference case fuel and electricity prices were obtained to be used as inputs to the CAFE model. The version of NEMS utilized for today's analysis is available at https://www.eia.gov/outlooks/aeo/info_nems_archive.php.

Figure VI-57 – NEMS-Based Gasoline Prices

BILLING CODE 4910-59-C

The agencies used the resulting Reference case fuel prices as inputs to the rule's central analysis. The agencies also used the as-published (by EIA) "Low Oil Price" and "High Oil Price" case fuel prices as inputs to several of the cases included in the sensitivity analysis presented in the accompanying RIA.

For the projections of macroeconomic variables used in the analysis supporting this rule, the agencies elected to rely on different sources from

those that informed their analysis of the proposed rule. Specifically, the agencies rely on projections of future growth in U.S. GDP reported in AEO2019 to support their central analyses of the final rule's impacts on new car and light truck sales and the retirement of used vehicles. These incorporate underlying projections generated using the IHS Markit Global Insight long-term macroeconomic model, as modified via this model's interaction with NEMS' representation of global energy markets

and their future outcomes. The alternative projections of future growth in GDP used in the agencies' accompanying sensitivity analyses are drawn from the AEO2019 High Economic Growth and Low Economic Growth cases. These reflect alternative future trends in U.S. labor force and productivity growth, and are also consistent with the energy market outcomes projected by NEMS under the resulting future performance of the U.S. economy.

Figure VI-58 – NEMS-Based Electricity Prices (Average to All Users)

For estimates of the number of U.S. households during future years, which influence the projections of new car and light truck sales used in the analysis, the agencies rely on projections of new household formation developed by the Harvard University Joint Center for Housing Studies.¹⁵⁴³ These are consistent with the most recent projections of future growth in the nation's population prepared by the U.S. Bureau of the Census.¹⁵⁴⁴

(2) Approach To Estimating Sales Response Under Different Standards

Prior to the NPRM, all previous CAFE and CO₂ rulemaking analyses used static fleet forecasts that were based on a combination of manufacturer compliance data, public data sources, and proprietary forecasts (or product plans submitted by manufacturers). When simulating compliance with regulatory alternatives, those analyses projected identical sales across the alternatives, for each manufacturer down to the make/model level—where the exact same number of each model variant was assumed to be sold in a given model year under both the least stringent alternative (typically the baseline) and the most stringent alternative considered (intended to represent “maximum technology” scenarios in some cases). To the extent that an alternative matched the assumptions made in the production of the proprietary forecast, using a static fleet based upon those assumptions may have been warranted. However, a sales forecast is unlikely to be representative of a broad set of regulatory alternatives with significant variation in the cost of new vehicles. A number of commenters on previous regulatory actions encouraged consideration of the potential impact of fuel efficiency standards on new vehicle prices and sales, and the changes to compliance strategies that those shifts could necessitate.¹⁵⁴⁵ In particular, the continued growth of the utility vehicle segment creates compliance challenges within some manufacturers' fleets as sales volumes shift from one region of the footprint curve to another, or as mass is added to increase the ride height of a vehicle on a sedan platform to create a crossover utility vehicle, which

exists on the same place of the footprint curve as the sedan upon which it might be based.

However, some NPRM commenters referenced the agencies' previous omission of this effect as justification to continue ignoring this issue in the current rulemaking. EDF commented,¹⁵⁴⁶ “use of a sales response model constitutes an unexplained reversal in the agency's position on the feasibility of doing so.” To say that the agencies never used a model is a misrepresentation. Assuming that sales never change in any model year, even at the individual nameplate level, regardless of the stringency of fuel economy regulations or the technology costs required to comply with those regulations, is, itself, a model. It is a model that implicitly asserts that, while fuel economy regulation impacts vehicle prices, such regulations have no impact on the quantity or mix of new vehicle sold, regardless of stringency. This is an implicit argument that new vehicle demand is perfectly inelastic—and that no change in vehicle prices can impact the number of cars consumers will buy. Logically, however, there must exist a level of stringency that would have a negative impact on new sales. Picking an extreme example to prove the point, if the agencies set standards at an extraordinarily stringent level that forced all vehicles into battery electric propulsion systems next year, sales would obviously be impacted. The increase in new vehicle price or changes to other relevant attributes like range, refueling time, or operating cost would surely affect the decisions of some buyers. But, by arguing that the agencies should continue to model new vehicle sales as if they are entirely unaffected by standards, commenters are effectively asking the agencies to assume that the alternatives considered in this rule are insufficiently stringent to affect the market. By endorsing the approach from the 2012 final rule, which assumed no impact on the new vehicle market from standards as stringent as 7 percent increase, year-over-year, beginning in 2017, commenters are suggesting that even *those* standards would have no impact on new vehicle sales. Manufacturers have asserted in their comments that fuel economy regulations change both the cost of producing new vehicles and consumer demand for them. In the recent peer review of the NPRM release of the CAFE model, all reviewers encouraged the inclusion of a sales response to fuel economy regulations (albeit not necessarily the

version of the response model that appeared in the NPRM).¹⁵⁴⁷ Based on earlier comments and the agencies' own analysis, the agencies were persuaded to include a sales response mechanism in the NPRM, and do so again in this final rule.

While several commenters (CARB, NCAT, CBD, Aluminum Association) discouraged the agencies from attempting to account for the effect of regulations on new vehicle sales, other commenters stated that the NPRM analysis was improved by explicitly considering this effect (RFF, Toyota, the Alliance of Automobile Manufacturers). CBD cited EPA's 2016 proposed determination, stating “[a] reasonable qualitative assessment is preferable to a quantitative estimate lacking sufficient basis, or (due to uncertainties like those here) having such an enormous range as to be without substantial value.”¹⁵⁴⁸ However, RFF supported the inclusion of the effect (with caveats about the specific implementation, for which they suggested alternative approaches), stating “[i]ncorporating sales and scrappage effects represents a step in the right direction for modeling the effects of the regulation.”¹⁵⁴⁹ It is reasonable to conclude that regulations as transformative as fuel economy standards will impact the market for new vehicles, and excluding the effect (as CBD and others suggested) is equivalent to stating that it does not exist.

The NPRM version of the sales response relied on differences in the average price of new vehicles to produce sales differences between regulatory alternatives. Some commenters (ACEEE, IPI, CBD, UCS, Aluminum Association, and Alliance to Save Energy) argued that new vehicle prices do not increase with the addition of technology required to comply with fuel economy regulations. Some argued that manufacturers will choose not to “pass through” the full incremental cost of fuel saving technologies to consumers, instead absorbing those costs into their profit margin.¹⁵⁵⁰ The question of cost pass-through is one that academic and industry researchers have considered for decades—and two of the

agencies' recent peer reviewers addressed this issue in their comments.

Dr. John D. Graham, one of the peer reviewers, argued that the assumption of complete cost pass-through is defensible, and more likely in the long-run than the short-run.¹⁵⁵¹ The reviewer also suggested that changes to the CAFE (and subsequent CO₂) program that base a manufacturer's standard on the mix of vehicle footprints in each fleet more equitably spreads the impact of the standards across the industry, and that industry shifts toward increasingly competitive market models (rather than the oligopolistic models that existed earlier in the last century) both act to increase the likelihood that manufacturers will pass regulatory costs through to consumers. In particular, this reviewer stated:¹⁵⁵²

In a classic study, Gron and Swenson (2000) examined list prices of automobiles at the model level in the U.S. from 1984 to 1994 coupled with data on production, vehicle characteristics, foreign versus domestic firm ownership, wages of employees, exchange rates, imported parts content, tariffs and other variables. Although their work rejects the hypothesis of 100% pass through of cost to consumer price, they find higher rates of pass through than previous studies, and much of the incomplete pass through occurs when cost increases impact only a few models or firms. Confirming earlier studies, they show that U.S. auto manufacturers engage in more aggressive pass-through pricing than Asian and European manufacturers (greater than 100% in some specifications), possibly due to the eagerness of importers to enlarge market share in lieu of recovering regulatory costs, at least in the short run (see Dinopolous and Kreinin, 1988;¹⁵⁵³ Froot, 1989¹⁵⁵⁴). This study helps explain why pass-through pricing is a more viable hypothesis in the long run than in the short run.

The original design of the CAFE program is a contrasting case where pass-through pricing was difficult for some automakers. All auto makers, regardless of their product mix, were subject to the same fleet-wide average CAFE standard, such as 27.5 miles per gallon for cars in 1990. In practice, those standards impacted only three high-volume companies (General Motors, Ford and Chrysler) because the Big Three produced a

higher proportion of large and performance-oriented vehicles than did Japanese companies. As a result, manufacturers such as Toyota and Honda consistently surpassed the federal fleet-wide standard for cars without any regulatory cost (*i.e.*, partly due to their smaller product mix). In the 1975–2007 period, the Big Three were not able to pass on all of their compliance costs to consumers and thus experienced some declines in profitability due to CAFE (Kleit, 1990;¹⁵⁵⁵ Kleit, 2004;¹⁵⁵⁶ Jacobsen, 2013¹⁵⁵⁷).

When the CAFE program was reformed for light trucks in 2008 (and for cars in 2011) on the basis of vehicle size (the so-called “footprint” adjustments to CAFE stringency), the, the technology costs of CAFE standards were spread more evenly among automakers, although the overall societal efficiency of the regulation diminished due to the removal of downsizing as a compliance option.¹⁵⁵⁸ Given that the size-based fuel economy programs are not concentrating the costs of compliance on one or two automakers, it is reasonable to predict a fairly high degree of pass-through pricing for the 2021–2025 fuel economy standards. In related literature on manufacturer pricing responses to a national carbon tax, Bento and Jacobsen (2007)¹⁵⁵⁹ and Bento (2013)¹⁵⁶⁰ report high rates of pass-through pricing (on the order of 85%). Carbon taxes are more efficient than footprint-based CAFE standards, but both instruments are likely to impact a wide range of companies in the auto sector and result in a high degree of pass-through pricing by impacted companies.

Also, it should be noted that the U.S. automotive industry is much more competitive today than it was from 1970 to 2000. The market share of General Motors, once the dominant, majority producer in the U.S. market, has declined dramatically, and a variety of Japanese and Korean companies have captured substantial market share. Moreover, the rise of startups (*e.g.*, Tesla and other electric vehicle start-ups) and ride-sharing services (*e.g.*, Uber) are adding a new competitive dimension in the U.S. industry. As a result, some of the most recent auto regulatory studies have given more emphasis to analytic results based on competitive

models than oligopolistic models (see, *e.g.*, Davis and Knittel (2016)¹⁵⁶¹).

Another peer reviewer, Dr. James Sallee, suggested that costs would pass through to new vehicle buyers to different degrees, depending upon the stringency of the standards.¹⁵⁶² The reviewer argued that more stringent standards, which result in larger increases to the cost of production, are likely to induce greater degrees of pass-through than less stringent standards, which automakers may, as some commenters have suggested, be able to absorb in the form of lost profit. If the degree of cost pass-through should vary by the stringency of the alternative, the agencies are underestimating the difference in price between the most and least stringent alternatives—which would favor alternatives with higher stringency.

Other commenters argued that manufacturers are able to compensate fully for the costs of fuel economy standards by increasing the prices of luxury vehicles—which would increase the average new vehicle price, but leave large sections of the market unaffected by the increased cost of producing fleets that comply with the standards. While it seems likely that manufacturers employ pricing strategies that push regulatory costs (as well as increases in costs like pension obligations and health care costs for employees) into the prices of models and segments with less elastic demand, the extent to which any OEM is able to succeed at this is unknown by the agencies. At some point, however, price increases on even luxury models will merely price more and more purchasers out of the market, and make competition with other manufacturers and market segments that much more difficult. And the more that avoided price increases for lower ends of the vehicle market are subsidized by luxury vehicles, the more either prices for luxury models would need to be increased, or (if moderately increasing prices) more of those luxury models would need to be sold. It is worth noting that luxury vehicles tend to be more powerful and content-rich, and often have fuel economy levels below (or CO₂ levels above) their targets on the curves—so that selling more of them to compensate for lost profit elsewhere

further erodes the compliance levels of the fleets in which they reside.

While manufacturers could conceivably push some small cost increases into the prices of their vehicle segments that have less elastic demand to cover accordingly small increases in stringency, larger stringency increases would exhaust the ability of such segments to absorb additional costs. In addition, the agencies do not attempt to adjust the mix of vehicle models based on their own price elasticity of demand; doing so would require a pricing model that takes the compliance cost for each manufacturer (which the agencies' model estimates dynamically) and apportions that cost to the prices of individual nameplates and trim levels. The agencies have experimented with pricing models (when integrating vehicle choice models, pricing models are a necessity), but each manufacturer almost certainly has a unique pricing strategy that is unknown to the agencies, and involves both strategic decisions about competitive position within a segment and the volumes needed fully to amortize fixed costs associated with production. To the extent that the agencies assume all regulatory costs are passed through and affect the average regulatory cost of each vehicle instead of being priced in a fashion to minimize the impact on aggregate sales, the agencies note that—more stringent alternatives are provided an artificial analytical advantage because manufacturers are better positioned to incorporate smaller price adjustments into their current strategic pricing models. The agencies opted to take the conservative approach instead of speculating on manufacturer's private business models.

Finally, some commenters have argued that, even if regulations *do* increase the cost of producing vehicles and those costs *are* passed on to new vehicle buyers, it does not matter because sales have increased in recent years under both rising standards and rising prices. EDF, CARB, Aluminum Association, SAFE, CBD, and CA et al. and Oakland et al., all make some version of this argument in their comments.¹⁵⁶³ The commenters are confusing correlation with causation and failing to consider the counterfactual case. Higher prices of

new vehicles certainly did not cause sales to increase since 2012. Sales increased over that period, in large part, as a result of economic expansion following the great recession.¹⁵⁶⁴ The statistical model used in the NPRM attempted to isolate the effect of average price on new vehicle sales, independent of the overall health of the US economy which plays an obviously important role. That model showed a negative relationship between sales and price (albeit a modest one), and positive relationships with GDP and employment. Even under the most stringent alternative in the NPRM, sales increased over time. However, in other alternatives, where the same macroeconomic conditions prevailed but average new vehicle prices were lower, sales increased relative to the baseline. That is the counterfactual case that is relevant for regulatory analysis—it attempts to answer the question, “would sales have been even higher if average prices had been lower?”

As discussed below, identifying the independent contribution of price to new vehicle sales is econometrically challenging. In the NPRM, the agencies stated that the simultaneous nature of price and sales—where transaction prices are higher in periods of higher demand, because the market will bear them, and lower in periods of lower demand, because the market will not, for an otherwise identical vehicle—creates a form of reverse causality. As commenters suggested, in recent years sales have increased along with average transaction price increases—and transaction price increases will occur when regulation forces manufacturers to add content, and their corresponding costs, to the vehicles they sell. Thus, it is understandable that some commenters could interpret the recent increase in new vehicle sales following the recession as evidence that standards (and maybe prices) have no impact on new sales. However, that view confuses correlation for causation (or lack thereof, in this case).

In response to these comments, the agencies have modified their approach to modeling the sales impacts of regulatory alternatives. In order to isolate the impact of the standards, the agencies have broken the sales response module into two discrete components. The first captures the effects of broader economic forces such as GDP growth. The second measures how changes in vehicle prices influence sales. As elaborated in more detail in the following passages, the agencies

considered alternative approaches and specific changes suggested by commenters, but concluded that the comments either lacked enough information to implement a change, failed to remedy identified alleged weaknesses of the NPRM model, or created new limitations for which there were no practical solutions. Furthermore, the two-pronged approach addresses many of the concerns raised by commenters better than any specific modeling alteration. First, the structural changes to the model address many of the econometric concerns raised by commenters. Second, by modeling sales in the first step as a function of macroeconomic conditions, and then applying an independent own-price elasticity to estimate the change in sales across alternatives, the agencies are able to more clearly distinguish between demand-side and supply-side impacts on prices, the issue that appears to have tripped up some of the commenters.

Comments on the Econometric Model Used in the NPRM

Any model of sales response must satisfy two requirements: It must be appropriate for use in the CAFE model, and it must be based in both sound economic theory and appropriate empirical analysis. The first of these requirements implies that forecasts of any variable used in the estimation of the econometric model must also be available as a forecast throughout the duration of the years covered by the simulations (this analysis explicitly simulates compliance through MY 2050). Some values the model calculates endogenously, making them available in future years for sales estimation, but others must be known in advance of the simulation. As the CAFE model simulates compliance, it accumulates technology costs across the industry and over time. By starting with the last known average transaction price (associated with MY 2016, in this analysis) and adding accumulated regulatory costs to that value, the model is able to represent an estimated average selling price in each future model year, assuming that manufacturers are able to pass their compliance costs on to buyers of new vehicles. Other variables used in the estimation can be entered into the model as inputs prior to the start of the compliance simulation.

The NPRM analysis was based on an econometric model that attempted to estimate the price elasticity of aggregate demand for new light-duty vehicles based on exogenous factors, intended to represent (1) macroeconomic forces that influence demand for new vehicles, and (2) average new vehicle price, intended

¹⁵⁶³ See, e.g. EDF, Appendix B, NHTSA–2018–0067–12108, at 37; CARB, Detailed Comments, NHTSA–2018–0067–11873, at 198–204; Aluminum Association, Comments, NHTSA–2018–0067–11952, at 19–21; SAFE, Comments, NHTSA–2018–0067–11981 at 36; CBD et al., Attachment 1, NHTSA–2018–0067–12123, at 20. ¹⁵⁶⁴ Table VI–148 below shows a large and statistically significant effect of GDP on sales.

to represent the impact of regulation. A number of commenters voiced opposition to the approach. Some disagreed with the theoretical framing of the issue—arguing that the model of sales response should have acknowledged the relevance of other vehicle attributes, included consumer valuation of fuel savings for new vehicles, based the response on something other than price, and considered the effect at a lower level of aggregation, rather than average price across the industry.

In the NPRM, the agencies relied upon an autoregressive distributed lag (ARDL) statistical model to estimate the impact of price differences between regulatory alternatives and to produce a time series of total new vehicle sales in each year of the analysis. The statistical model estimated new vehicle sales per year based on two lagged variables of new sales (new sales in the previous period, and the period before that), GDP and lagged GDP, and labor force participation and lagged labor force participation. The model used quarterly data and seasonally adjusted annual rates to increase the number of observations over the sample period for which reliable sales data existed (1978–2015). The ARDL model used in the NPRM was chosen to address sales impacts at a high level of aggregation, namely the total new vehicle market (across all vehicle brands and body styles), and to resolve the econometric issues associated with the time series data related to total new vehicle sales.

Stock et al. commented at length on the econometric specification of the NPRM sales response model, identifying limitations and suggesting alternative approaches.¹⁵⁶⁵ In particular, they argued that the length of the response to price shocks should dissipate faster than the NPRM model allows—an artifact of using quarterly data and seasonally adjusted annual rates to estimate the effect and implementing it on an annual basis in the CAFE model. The agencies agree that this was a flaw in the implementation of the NPRM model. While this approach produced the correct units (*i.e.*, annual sales) the response to changes in price should have dissipated at a quarterly rate, rather than an annual rate. As a result, a single price shock, which appears in one year and disappears the next, was projected to have a longer impact on sales in future years than was appropriate given the specification. The sales response in the final rule corrects

for this objective error and takes a more conservative approach to price shocks.

Stock et al. commented that “it is important to estimate the dynamic effect on sales of a price increase, that is, the causal effect on current and future demand of a price increase” because “it allows the response to an intervention—here, a one-time price increase or sequence of such increases—to evolve over time.”¹⁵⁶⁶ The comment suggests that the agencies should include future responses in sales to a one-time price increase that exists for a single period and then disappears. In our analytical framework, this implies that a price difference between any alternative and the baseline that causes a difference in sales in that year should also produce a difference in sales in the following year (and possibly subsequent years), though of smaller magnitude, even if the price difference only exists for a single period. The Stock et al. comment illustrates a quickly diminishing response to a single price shock. The final rule assumes (more conservatively) that each price shock lasts only for a single year, and produces no future “ripple” effects in the new vehicle market in subsequent years. Furthermore, the regulatory alternatives considered in this analysis do not produce single period price shocks (in the form of price differences between alternatives), but rather persistent price differences between alternatives that result from continued differences in stringency. The persistent nature of the price differences resulting from fuel economy and CO₂ regulations further reduce the importance of capturing these multi-period effects caused by single-period price shocks.

Stock et al. also objected to the use of an ARDL model to estimate the impact of price on new vehicle sales. In order for the estimation of causality to be valid in a time series model, the current price movements must be uncorrelated with unobserved demand shocks in the past, present, and future; so-called strict exogeneity. The commenters argue that the NPRM fails this test because actions taken in the market (by both buyers and sellers) can influence the response to price changes in the next period. They suggest the use of a vector autoregression (VAR) model to address the relationship between past demand disturbances and current prices to address the temporal exogeneity issues they identify. However, an important caveat is that this approach still does not resolve the largest econometric challenge—that of contemporaneous endogeneity between price and sales (in

the same period). To address that challenge, one needs to employ instrumental variable methods.

The agencies attempted several modifications to the statistical model developed for the NPRM based on the Stock et al. comment. The agencies reviewed the initial approach and attempted several specifications that would explicitly address the temporal endogeneity bias identified in the comment. In particular, the agencies addressed data limitations that were raised by Stock et al. (and also by EDF), who encouraged us to reconsider the quarterly specification and to use quality-adjusted price data for new vehicles in order to ensure a more consistent definition of the average vehicle over the time series, as the “average vehicle” has consistently improved in a myriad of ways over successive model years. The quarterly price series was statistically interpolated in the NPRM to increase the number of observations,¹⁵⁶⁷ but represented a less-than-ideal solution. The interpolating process may have impacted the underlying quarterly data generating process, resulting in unreliable, or potentially biased, regression results. This issue was remedied by sourcing both vehicle sales and price data from IHS Markit, which provides these data at the same base frequency (quarterly) and obviates the need for any interpolation. In addition, the macroeconomic data used in the model specification were also sourced from IHS, which provides consistency between historical and forecast data (*i.e.*, forecasts of sales, price, personal income, etc., were all based on a consistent set of input assumptions and modeling framework during testing).

Historical quarterly series for new light vehicle average price and total sales are presented in Figure VI–59 below. Due to the lack of data availability for business investment in light vehicles, the historical series for average vehicle price begins in 1987. Average prices were transformed into quality adjusted real terms using the CPI for new motor vehicles, and both series were seasonally adjusted.¹⁵⁶⁸ Quality adjusted prices have risen overtime, while total sales have remained relatively flat in recent years with the major exception being the significant economic downturn of 2008–2009. The difference in these trends suggests that the number of vehicles purchased per

¹⁵⁶⁷ Interpolation is the practice of adding unobserved data points based on observed trends to provide more observations to a limited data set.

¹⁵⁶⁸ Seasonal adjustment was made using X.12 in EViews.

¹⁵⁶⁵ EPA–HQ–OAR–2018–0283 and NHTSA–2018–0067.

¹⁵⁶⁶ *Ibid.*

household does not necessarily change, or grow, over time, as income grows, but rather households adjust the “amount” of new vehicle they are willing to

purchase (*i.e.*, switching from sedan to an SUV).¹⁵⁶⁹ Moreover, while disposable income has steadily increased during this period, sales have

not seen the same type of upward trend, and instead only returned to its pre-recession average of around 17 million annual sales.

Figure VI-59 – New Light Duty Vehicle Average Price and Total Sales

Even as real disposable income has risen since 2000, and outside of the great recession, new vehicle sales have remained relatively steady. This, in turn, suggests there are other economic, or behavioral, factors beyond disposable income influencing the decision to purchase a new vehicle. Given the significant cost to purchase a new vehicle, and the long multiyear timeframe over which they are typically financed, households’ forward-looking view on the health of the economy likely plays a role in their willingness

to purchase a new vehicle. Put differently, households may delay their purchasing decisions if their view outlook on the economy sours, regardless of income level. These observations are consistent with the framework of the NPRM model, and Figure VI-60 presents the consumer sentiment index and total new sales, with both series exhibiting similar trends over this period. Some commenters advocated that consumer sentiment (also known as consumer confidence) should be included in the

sales forecast. For example, the Aluminum Association indicated that prior sales models have shown consumer behavior to be “highly sensitive to macroeconomic conditions, consumer confidence and employment levels.” While consumer sentiment was not included in the NPRM model, it was included in specifications that the agencies tested and considered and is a component of the forecasting model used in the final rule.¹⁵⁷⁰

¹⁵⁶⁹ Aggregate light duty vehicle sales data does not allow for observing the distribution of vehicles being sold, which will have an effect on the average price.

¹⁵⁷⁰ Commenters mentioned consumer confidence as a predictor of consumer behavior. For instance, the Aluminum Association indicated that prior sales models have shown consumer behavior to be

“highly sensitive to macroeconomic conditions, consumer confidence and employment levels.” Comments, NHTSA–2018–0067–11952, at 14.

Figure VI-60 – Consumer Sentiment and Total Sales

All macroeconomic data were sourced from IHS including real disposable income, number of US households, and

the University of Michigan's consumer sentiment index. The summary statistics

for all series are presented below in Table VI-148.

Table VI-148 – Summary Statistics

| Variable | Obs. | Mean | Std. | Min | Max |
|--|------|----------|----------|----------|-----------|
| Quality Adjusted Real Avg. LDV Price (Thousands, 2012\$) | 127 | 24.13 | 5.29 | 15.74 | 32.89 |
| Total LDV Sales (SA Annual Rate, Millions) | 127 | 15.23 | 1.93 | 9.38 | 18.53 |
| Real Disposable Income (Billions, 2012\$) | 127 | 9,979.94 | 2,432.22 | 6,113.99 | 14,358.03 |
| Number of Households (Millions) | 127 | 110.36 | 9.19 | 93.53 | 126.35 |
| Consumer Sentiment Index | 127 | 87.66 | 11.68 | 57.67 | 110.13 |

Each series was transformed into natural logarithms and tested for stationarity using the modified Dicky-

Fuller test.¹⁵⁷¹ Results presented in Table VI-149 indicate each variable containing contained a unit-root, while

being differenced stationary (*i.e.*, integrated of order one).

¹⁵⁷¹ Using nonstationary variables would generate unreliable estimates of their influence, as prior

values of those variables are correlated with their

future values, and this violates the assumption that values variables take on are independent over time.

Table VI-149 – Modified Dickey-Fuller Test (1 lag)

| | DF-GLS Test Stat. | 1% Critical Value | 5% Critical Value | 10% Critical Value |
|---|-------------------|-------------------|-------------------|--------------------|
| NL Quality Adjusted Real Avg. LDV Price | -1.224 | -3.548 | -2.995 | -2.704 |
| Δ NL Quality Adjusted Real Avg. LDV Price | -5.803 | -3.549 | -2.996 | -2.706 |
| NL Total LDV Sales | -1.841 | -3.548 | -2.995 | -2.704 |
| Δ NL Total LDV Sales | -6.352 | -3.549 | -2.996 | -2.706 |

| Δ NL Total LDV Sales per Household | -6.375 | -3.549 | -2.996 | -2.706 |
| NL Real Disposable Income | -0.855 | -3.548 | -2.995 | -2.704 |
| Δ NL Real Disposable Income | -4.593 | -3.549 | -2.996 | -2.706 |
| NL Real Disposable Income per Household | -1.091 | -3.548 | -2.995 | -2.704 |
| Δ NL Real Disposable Income per Household | -4.589 | -3.549 | -2.996 | -2.706 |
| NL Consumer Sentiment Index | -2.332 | -3.548 | -2.995 | -2.704 |
| Δ NL Consumer Sentiment Index | -8.991 | -3.549 | -2.996 | -2.706 |

Two separate variables lists were then tested for the existence of one or more cointegrating relationships, with results from the Johansen test presented in Table VI-150.¹⁵⁷² In each set of

variables, both total LDV sales and disposable income were converted to household units as a means to control for the growth in US households and the possible decision making process of

buying/consuming a new unit of LDV. The results show that 4 out of the 5 lag length selections for both variable sets conclude there being one cointegrating relationship (rank I(1)) among them.

Table VI-150 – Johansen Test for Cointegration

| Series | Lags | Max Rank | Trace Stat. | 5% Critical Value |
|--|------|----------|-------------|-------------------|
| NL LDV Sales per HH, NL PDI per HH, NL Avg. LDV Price | 2 | 1 | 9.9139 | 15.41 |
| | 3 | 0 | 28.6582 | 29.68 |
| | 4 | 1 | 8.8639 | 15.41 |
| | 5 | 1 | 7.9938 | 15.41 |
| | 6 | 1 | 12.6687 | 15.41 |
| NL LDV Sales per HH, NL PDI per HH, NL Avg. LDV Price, NL JCSM | 2 | 2 | 10.2220 | 15.41 |
| | 3 | 1 | 25.8108 | 29.68 |
| | 4 | 1 | 29.2521 | 29.68 |
| | 5 | 1 | 21.7739 | 29.68 |
| | 6 | 1 | 27.1268 | 29.68 |
| Note: NHH, PDI, and JCSM refer to households, real personal disposable income, and consumer sentiment, respectively. All tests include an unrestricted constant. Alternative tests were conducted to include restricted trend or constant terms, but are not presented here for brevity as our preferred specification only includes an unrestricted constant term in the model. | | | | |

Taken together, these tests confirm the need to address the time series properties of each variable in any modeling framework. This will become especially important when discussing the correct modeling approach, as The

pre-modeling tests provide evidence against running a simple OLS regression or VAR in first differences, because doing so would have the potential outcome of excluding important long-run information.

Furthermore, the endogeneity between vehicle sales and price is another element that needs to be considered for model specification. The IHS historical series for average price of a new light duty vehicle is defined as a

¹⁵⁷² The number of lag lengths were also tested formally, with general consensus between 2 and 6 lags as being optimal. Test results are available

upon request, however, the final lag length selection was determined on the full set of VAR and VECM output that includes satisfying time series

conditions such as no presence of autocorrelation and plausible interpretability of the estimated output.

function of business and private residential spending on light vehicles divided by total new light vehicle sales; from this identity, the average price represents the nominal price per new unit of light duty vehicle sold. This definition supports the existence of an endogenous relationship between vehicle price and sales that needs to be accounted for when developing an econometric estimation of the influence of new vehicle price on sales. This is consistent with economic theory, whereby vehicle sales and price are simultaneously determined in the market, and therefore should be included together when specifying a forecasting equation.¹⁵⁷³ This restriction holds even if nominal vehicle price is transformed into a quality adjusted real dollar series, as some commenters (EDF, Stock et al) proposed.¹⁵⁷⁴

Models

Faced with the simultaneity problem associated with price and sales, several specifications were reviewed to determine the best method for addressing this issue. An Instrumental Variable (IV) method was deemed the most direct approach, with the advantage of preserving the initial model's autoregressive distributed lag structure. In order to obtain consistent estimates of the price elasticity of demand, a suitable instrument that is correlated with average LDV price but uncorrelated with the error term is needed in the first stage. A suitable instrument must also make economic sense and have a plausible causal relationship. In theory, instruments that satisfy all three conditions (exogeneity, causality, and non-weak correlation)

should exist. In practice, however, it is often prohibitively difficult to find a viable instrument. Both Stock et al. and CARB suggested instrumenting to resolve the endogeneity issue in the NPRM model, but neither suggested specific candidates for instrumental variables.

For the purposes of modeling vehicle sales, candidate IVs would reflect the price of inputs to production that are broad enough, so that the underlying behavior of the variable is not deterministic of LDV sales. Examples of candidate variables include producer price indices (PPIs) of auto or other related manufacturing, cost of capital required for production, labor market data, energy costs, technology changes, and exogenous shocks to price, production, labor, or policy changes.

The lack of data availability and quality concerns reduced the primary list of candidate IVs to relatable PPIs such as for manufacturing and automobile primary products. Even the most "promising" candidate IVs, however, proved to be poor instruments, with counterintuitive signs, lack of statistical significance, and poor overall first stage F-statistics (even by relatively lenient weak instrument test standards).

The lack of reasonable results from the IV approach led to testing vector autoregressive (VAR) and vector error correction (VECM) models. Relaxing the strict exogeneity assumption needed under an ARDL framework is the main advantage of modeling price, sales, and macroeconomic variables as a system of equations where the feedback from previous period shocks affect both price and sales.¹⁵⁷⁵ In addition, a VAR or VECM can also adequately handle the time series and nonstationary properties discussed above. For both the VAR and VECM, a parsimonious specification

was preferred with either a three or four variable system using the variables discussed above.

We first estimated a simple VAR using a Wold causal ordering of real disposable income per household, average price of new LDV, and new total sales of LDVs per household.¹⁵⁷⁶ The alternative specification included the consumer sentiment variable in the ordering the consumer sentiment variable after income and before price. This ordering assumes that households' disposable income (and consumer sentiment) do not respond to shocks to auto prices and sales within the same quarter. It also assumes that prices are contemporaneously exogenous of sales (demand), since the MSRPs are set in advance. Lastly, sales are able to respond to unexpected changes in price in the same quarter. The alternative ordering of placing sales before average price was deemed unrealistic as it would presume sales responding independently to an unexpected change in prices.

In the first specification, all variables were transformed to first differences to ensure stationarity, while ignoring any possible long-run information (for the moment). A combination of post-estimation tests for autocorrelation and stability conditions were considered along with impulse response functions to gauge the model performance. The preferred model was estimated with five lags, and the impulse response functions (IRF) of a 1 percent shock to price on sales for the two specifications are presented in Figure VI-61.

¹⁵⁷⁶ The Wold causal ordering creates a lower triangular matrix for our shocks, so by construction these shocks are orthogonal to each other to allow for causal inference. This recursive or Wold ordering technique should be predetermined and based on economic theory as the causal interpretation of the impulse responses are dependent on the correct/plausible ordering of variables.

¹⁵⁷³ Endogeneity results in correlation between an independent variable in a regression and the error term leading to biased coefficient estimates.

¹⁵⁷⁴ For reference on how the BLS measures quality adjustments in vehicles: <https://www.bls.gov/cpi/factsheets/new-vehicles.htm>.

¹⁵⁷⁵ Strict exogeneity requires there to be past, contemporaneous, and future exogeneity between the variables of interest.

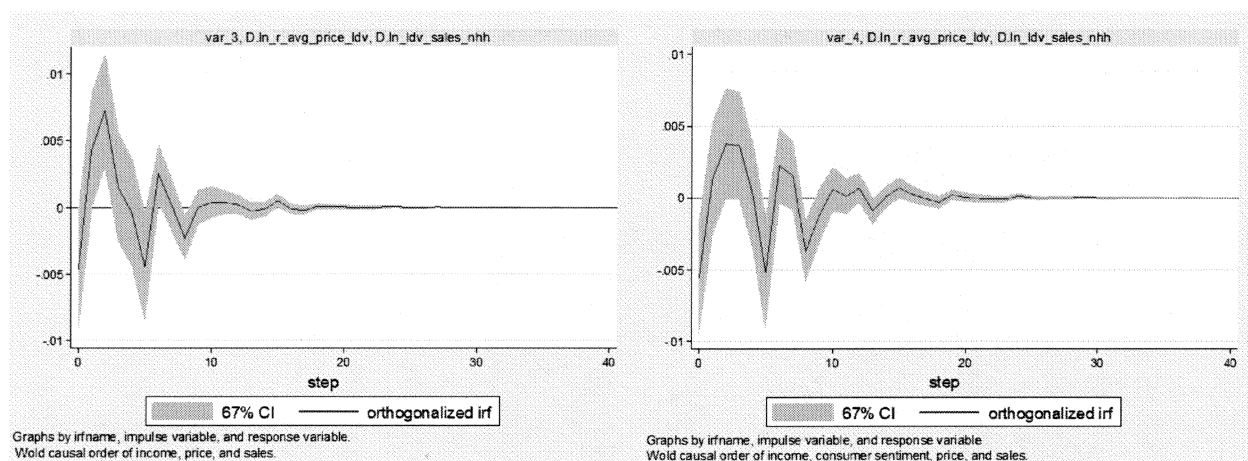

Figure VI-61 – Impulse Response Functions of Price on Sales from First Difference VARs

Both figures show a similar trend of the response in sales oscillating from negative to positive before ultimately returning to zero 12 quarters out. The three variable VAR sees a positive response in the first few periods, while the four variable VAR manages to dip below zero briefly after 4 periods out. This behavior, which by definition is short-run due to the differencing of the variables, could be representing auto dealerships' attempts to pull sales back to its equilibrium level after the price shock pushes sales negative, implying some level of over compensation during this process. Nonetheless, despite the model showing there is some evidence of an immediate and negative price elasticity, the overly simplified VAR model is missing key long run information (as identified in the cointegration tests), creating some reservations about the results. It is also worth noting that the lagged positive response in sales from an unexpected price shock is persistent regardless of the lag length selection, and in many cases even more pronounced.

A number of preliminary conclusions can be drawn from the IRF results shown in Figure VI-61. First, at least at this level of aggregation, any short-run and immediate effect of a price increase on total LDV sales is relatively small in nature. This does not suggest, however, that the price elasticity of demand is zero. Instead, what may be the case is that when faced with an unexpected change in price, consumers will choose to purchase a less expensive car with fewer features as opposed to no car at all. In other words, the level of aggregation being used, total car sales, removes important variation between the type of vehicle being sold and

consumer purchasing decisions from the data; what is left is a clouded version of the true relationship between price and sales. Second, this type of VAR ignores and throws out any long run information that may exist, which would create omitted variable bias if such a cointegrated relationship exists.

Based on the conclusions from the Johansen cointegration test, the next step involved estimating the system as a VECM. As with the VAR models, the VECM employs either a three or four variable system with five lag lengths and an unconstrained constant in the model (no trend in either the first differenced or cointegrating equations). In each model, the cointegrating vector is normalized around sales (*i.e.*, the sales' coefficient is set to 1), and the model results indicate strong evidence of a cointegrating relationship between the variables.

Aside from general agreement on a cointegrating relationship, the VECM performance was weak in nearly every specification attempted, with implausible magnitudes for the long-run coefficient estimates and insignificant short-run dynamics. Moreover, the adjustment coefficient for the sales equation is particularly weak and insignificant.¹⁵⁷⁷ The limitations of the VECM could be rooted in the system being normalized around sales, which lacks significant variation, correlation, or possibly true causation with the other variables.

¹⁵⁷⁷ The lack of a statistically significant adjustment variable could be an indication of weak exogeneity. In this case that would not be plausible given the clear endogeneity between price and sales, and is more likely an indication of poor data and the absence of reliable modelling approaches.

As with the VAR analysis, a similar focus is placed on the IRFs presented in Figure VI-62. Here a one percent shock in price on LDV sales shows a similar response between the two specifications, with an increase during the first several periods before returning to a negative and permanent long-run effect. This response is erroneous in two ways: First, the sharp positive response during the first 8 to 10 quarters defies economic logic as an increase in the price of a normal good should not induce an increase in sales. Second, the permanent and negative effect is equally as confounding because it rules out the ability for dealerships or auto manufacturers to adjust prices or supply.¹⁵⁷⁸

The updated econometric models of light duty vehicle sales (described above) thus did not provide clear, significant or robust insight into the magnitude of the price elasticity of demand. While the VAR model specification points to an immediate short-run negative price elasticity of demand (*i.e.*, sales fall in the face of an immediate price shock), this relationship is relatively small. In addition, the fact that this specification excludes the identified cointegration between the variables suggests that it is not robust or unbiased. In short, the VECM and IV approaches were unable to provide reasonable and meaningful results.

These results strongly suggest that the relationship between sales and price is

¹⁵⁷⁸ Note that error bounds cannot be generated for VECM IRFs using most statistical packages, so determining statistical significance is difficult. Given the change from positive to negative and the low magnitude of the response, it is quite possible that this effect is indistinguishable from zero.

not adequately estimated with the macro-level data used in this analysis. Recent peer reviewers of the CAFE model had similar concerns. In particular, these data are insufficient to explain the individual consumer (micro-) level decision making process of purchasing a new LDV. Aggregating the sales response to the national level

reduces the useful variation in the decision making process to levels unsuitable for estimation. Commenters generally agreed with this conclusion.

Even assuming a theoretically and econometrically correct model was possible, this relationship is impossible to evaluate at the current data aggregation level. Future research may

focus on constructing an aggregate price elasticity of demand from consumer level data utilizing discrete choice modeling or something similar.

However, constructing such models and integrating them into the simulations of the final rule are beyond the scope of this analysis.

Figure VI-62 – Impulse Response Functions of Price on Sales from VECMs

Many commenters suggested that the NPRM model was unable to find a statistically significant influence of fuel economy on sales because the model was too highly aggregated, as the agencies found with the econometric experimentation to estimate a price response. EDF, CARB, and CA et al. and Oakland et al. expressed concern that using industry averages eliminated the variation needed to detect consumer valuation of fuel economy in new vehicle purchases. The agencies noted a similar concern in the NPRM, citing the level of aggregation as the most likely reason that the average fuel economy of a new vehicle was not a statistically significant explanatory variable in the ARDL model. The approach for the final rule includes an average value of improved fuel economy in the sales response, as commenters suggested it should.

(a) How Do Car and Light Truck Buyers Value Improved Fuel Economy?

Many commenters (CARB, CA et al. and Oakland et al., NRDC, EDF, CBD, North Carolina Department of Environmental Quality, IPI, EPA Science Advisory Board, Stock et al.) stated that the agencies should explicitly consider fuel savings, and the value that consumers ascribe to it, in

addition to changes in price when estimating the response of new vehicle sales to different regulatory alternatives. NRDC stated, “The decision between new vehicle purchase alternatives must consider both differential costs and differential benefits. The CAFE model sales algorithm considers only differential costs and is, therefore, flawed.”¹⁵⁷⁹ The agencies agree that the degree to which new vehicle buyers value improvements in fuel economy is an important consideration when estimating the response of new vehicle sales to potential standards. The effect of vehicle prices on sales is difficult to detect at the aggregate level because price movements are correlated with the current strength of the economy, which can appear as a positive price elasticity when modeling sales, and there are various technical econometric difficulties in identifying the effect of price on sales (simultaneity, cointegration, etc., addressed above). The sales response model in the final rule accounts for fuel savings realized by buyers of new vehicles.

Some commenters and EPA’s Science Advisory Board noted that the sales response equation omitted any value of fuel savings to new vehicle buyers,

while other elements of the analysis—notably the technology application algorithm—assumed that buyers would demand fuel economy technologies that “pay back” within the first 2.5 years of ownership (as a result of avoided fuel costs), and manufacturers would supply fuel economy at those levels even in the absence of standards. This observation was made in comments by CARB, CBD, and IPI—the last of which stated that 2.5 year payback assumption “clashes directly with the contradictory assumption that the agencies rely on in the model’s sales module, where they implicitly assume that customers entirely disregard fuel efficiency in their purchasing decisions.”¹⁵⁸⁰ The agencies agree that this represented an internal inconsistency. The sales model used to analyze the final rule includes the estimated value of fuel savings to vehicle buyers, and is consistent with other assumptions throughout the analysis about the “pay back” period.

How potential buyers value improvements in the fuel economy of new cars and light trucks is an important issue in assessing the benefits and costs of government regulation. If buyers fully value the savings in fuel costs that result from higher fuel

¹⁵⁷⁹ NRDC, Attachment 3, NHTSA–2018–0067–11723, at 4.

¹⁵⁸⁰ IPI, Appendix, NHTSA–2018–0067–12213, at 16.

economy, manufacturers will presumably supply any improvements that buyers demand, and vehicle prices will fully reflect future fuel cost savings consumers would realize from owning—and potentially re-selling—more fuel-efficient models. If consumers internalize fuel savings this case, more stringent fuel economy standards will impose net costs on vehicle owners and can only result in social benefits through correcting externalities, because consumers would already fully incorporate private savings into their purchase decisions, as discussed further below. If instead consumers systematically undervalue some market failure such as an information asymmetry leads to an underinvestment in fuel-saving technology, the cost savings generated by improvements in fuel economy when choosing among competing models, more stringent fuel economy standards will also lead manufacturers to adopt improvements in fuel economy that buyers might not choose despite the cost savings they offer and improve consumer welfare.

The potential for car buyers voluntarily to forego improvements in fuel economy that offer savings exceeding their initial costs is one example of what is often termed the “energy-efficiency gap.” This appearance of such a gap, between the level of energy efficiency that would minimize consumers’ overall expenses and what they actually purchase, is typically based on engineering calculations that compare the initial cost for providing higher energy efficiency to the discounted present value of the resulting savings in future energy costs.

There has long been an active debate about why such a gap might arise and whether it actually exists. Economic theory predicts that individuals will purchase more energy-efficient products only if the savings in future energy costs they offer promise to offset their higher initial costs. However, the additional up-front cost of a more energy-efficient product includes more than just the cost of the technology necessary to improve its efficiency; because consumers have a scarcity of resources, it also includes the opportunity cost of any other desirable features that consumers give up when they choose the more efficient alternative. In the context of vehicles, whether the expected fuel savings outweigh the opportunity cost of purchasing a model offering higher fuel economy will depend, among other things, on how much its buyer expects to drive, his or her expectations about future fuel prices, the discount rate he or she uses to value future expenses, the

expected effect on resale value, and whether more efficient models offer equivalent attributes such as performance, carrying capacity, reliability, quality, or other characteristics.

Published literature has offered little consensus about consumers’ willingness-to-pay for greater fuel economy, and whether it implies over- or full-valuation of the expected discounted fuel savings from purchasing a model with higher fuel economy. Most studies have relied on car buyers’ purchasing behavior to estimate their willingness-to-pay for future fuel savings; a typical approach has been to use “discrete choice” models that relate individual buyers’ choices among competing vehicles to their purchase prices, fuel economy, and other attributes (such as performance, carrying capacity, and reliability), and to infer buyers’ valuation of higher fuel economy from the relative importance of purchase prices and fuel economy.¹⁵⁸¹ Empirical estimates using this approach span a wide range, extending from substantial undervaluation of fuel savings to significant overvaluation, thus making it difficult to draw solid conclusions about the influence of fuel economy on vehicle buyers’ choices.¹⁵⁸² Because a vehicle’s price is often correlated with its other attributes (both measured and unobserved), analysts have often used instrumental variables or other approaches to address endogeneity and other resulting concerns.¹⁵⁸³

Despite these efforts, more recent research has criticized these cross-sectional studies; some have questioned the effectiveness of the instruments they use,¹⁵⁸⁴ while others have observed that coefficients estimated using non-linear statistical methods can be sensitive to the optimization algorithm and starting values.¹⁵⁸⁵ Collinearity (*i.e.*, high correlations) among vehicle attributes—most notably among fuel economy, performance or power, and vehicle size—and between vehicles’ measured and unobserved features also raises questions about the reliability and interpretation of coefficients that may conflate the value of fuel economy with other attributes (Sallee, et al., 2016;

Busse, et al., 2013; Allcott & Wozny, 2014; Allcott & Greenstone, 2012; Helfand & Wolverton, 2011).

In an effort to overcome shortcomings of past analyses, three studies published fairly recently rely on panel data from sales of individual vehicle models to improve their reliability in identifying the association between vehicles’ prices and their fuel economy (Sallee, et al. 2016; Allcott & Wozny, 2014; Busse, et al., 2013). Although they differ in certain details, each of these analyses relates changes over time in individual models’ selling prices to fluctuations in fuel prices, differences in their fuel economy, and increases in their age and accumulated use, which affects their expected remaining life, and thus their market value. Because a vehicle’s future fuel costs are a function of both its fuel economy and expected gasoline prices, changes in fuel prices have different effects on the market values of vehicles with different fuel economy; comparing these effects over time and among vehicle models reveals the fraction of changes in fuel costs that is reflected in changes in their selling prices (Allcott & Wozny, 2014). Using very large samples of sales enables these studies to define vehicle models at an extremely disaggregated level, which enables their authors to isolate differences in their fuel economy from the many other attributes, including those that are difficult to observe or measure, that affect their sale prices.¹⁵⁸⁶

These studies point to a somewhat narrower range of estimates than suggested by previous cross-sectional studies; more importantly, they consistently suggest that buyers value a large proportion—and perhaps even all—of the future savings that models with higher fuel economy offer.¹⁵⁸⁷

¹⁵⁸⁶ These studies rely on individual vehicle transaction data from dealer sales and wholesale auctions, which includes actual sale prices and allows their authors to define vehicle models at a highly disaggregated level. For instance, Allcott & Wozny (2014) differentiate vehicles by manufacturer, model or nameplate, trim level, body type, fuel economy, engine displacement, number of cylinders, and “generation” (a group of successive model years during which a model’s design remains largely unchanged). All three studies include transactions only through mid-2008 to limit the effect of the recession on vehicle prices. To ensure that the vehicle choice set consists of true substitutes, Allcott & Wozny (2014) define the choice set as all gasoline-fueled light-duty cars, trucks, SUVs, and minivans that are less than 25 years old (*i.e.*, they exclude vehicles where the substitution elasticity is expected to be small). Sallee et al. (2016) exclude diesels, hybrids, and used vehicles with less than 10,000 or more than 100,000 miles.

¹⁵⁸⁷ Killian & Sims (2006) and Sawhill (2008) rely on similar longitudinal approaches to examine consumer valuation of fuel economy except that they use average values or list prices instead of actual transaction prices. Since these studies

¹⁵⁸¹ In a typical vehicle choice model, the ratio of estimated coefficients on fuel economy—or more commonly, fuel cost per mile driven—and purchase price is used to infer the dollar value buyers attach to slightly higher fuel economy.

¹⁵⁸² See Helfand & Wolverton (2011) and Green (2010) for detailed reviews of these cross-sectional studies.

¹⁵⁸³ See, *e.g.*, Barry, et al. (1995).

¹⁵⁸⁴ See Allcott & Greenstone (2012).

¹⁵⁸⁵ See Knittel & Metaxoglou (2014).

Because they rely on estimates of fuel costs over vehicles' expected remaining lifetimes, these studies' estimates of how buyers value fuel economy are sensitive to the strategies they use to isolate differences among individual models' fuel economy, as well as to their assumptions about buyers' discount rates and gasoline price expectations, among others. Since Anderson et al. (2013) found evidence that consumers expect future gasoline prices to resemble current prices, the agencies use this assumption to compare the findings of the three studies and examine how their findings vary with the discount rates buyers apply to future fuel savings.¹⁵⁸⁸

As Table VI-148 indicates, Allcott & Wozny (2014) found that consumers incorporate 55 percent of future fuel

costs into vehicle purchase decisions at a six percent discount rate, when their expectations for future gasoline prices are assumed to reflect prevailing prices at the time of their purchases. With the same expectation about future fuel prices, the authors report that consumers would fully value fuel costs only if they apply discount rates of 24 percent or higher. However, these authors' estimates are closer to full valuation when using gasoline price forecasts that mirror oil futures markets, because the petroleum market expected prices to fall during this period (this outlook reduces the discounted value of a vehicle's expected remaining lifetime fuel costs). With this expectation, Allcott & Wozny (2014) find that buyers value 76 percent of future cost savings (discounted at six percent) from

choosing a model that offers higher fuel economy, and that a discount rate of 15 percent would imply that they fully value future cost savings. Sallee et al. (2016) begin with the perspective that buyers fully internalize future fuel costs into vehicles' purchase prices and cannot reliably reject that hypothesis; their base specification suggests that changes in vehicle prices incorporate slightly more than 100 percent of changes in future fuel costs. For discount rates of five to six percent, the Busse et al. (2013) results imply that vehicle prices reflect 60 to 100 percent of future fuel costs. As Table VI-151 suggests, higher private discount rates move all of the estimates closer to full valuation or to over-valuation, while lower discount rates imply less complete valuation in all three studies.

Table VI-151 – Percent of Future Fuels Costs Internalized in Used Vehicle Purchase

Price using Current Gasoline Prices to Reflect Expectations (for Base Case Assumptions)

| Authors (Pub. Date) | Discount rate | | | |
|----------------------------|----------------------|-----------|-----------|------------|
| | 3% | 5% | 6% | 10% |
| Busse, et al. (2013)* | 54%-87% | 60%-96% | 62%-100% | 73%-117% |
| Allcott & Wozny (2014) | 48% | | 55% | 65% |
| Sallee, et al. (2016) | | 101% | | 142% |

***Note:** The ranges in the Busse et al. estimates depend on which quartiles of the fuel economy distribution are compared. With no prior on which quartile comparison to use, this analysis presents the full quartile comparison range.

The studies also explore the sensitivity of the results to other parameters that could influence their results. Busse et al. (2013) and Allcott

& Wozny (2014) find that relying on data that suggest lower annual vehicle use or survival probabilities, which imply that vehicles will not last as long,

moves their estimates closer to full valuation, an unsurprising result because both reduce the changes in expected future fuel costs caused by fuel

remain unpublished, their empirical results are subject to change, and they are excluded from this discussion.

¹⁵⁸⁸ Each of the studies makes slightly different assumptions about appropriate discount rates. Sallee et al. (2016) use five percent in their base specification, while Allcott & Wozny (2014) rely on six percent. As some authors note, a five to six percent discount rate is consistent with current interest rates on car loans, but they also acknowledge that borrowing rates could be higher

in some cases, which could be used to justify higher discount rates. Rather than assuming a specific discount rate, Busse et al. (2013) directly estimate implicit discount rates at which future fuel costs would be fully internalized; they find discount rates of six to 21 percent for used cars and one to 13 percent for new cars at assumed demand elasticities ranging from -2 to -3. Their estimates can be translated into the percent of fuel costs internalized by consumers, assuming a particular discount rate. To make these results more directly comparable to

the other two studies, we assume a range of discount rates and uses the authors' spreadsheet tool to translate their results into the percent of fuel costs internalized into the purchase price at each rate. Because Busse et al. (2013) estimate the effects of future fuel costs on vehicle prices separately by fuel economy quartile, these results depend on which quartiles of the fuel economy distribution are compared; our summary shows results using the full range of quartile comparisons.

price fluctuations. Allcott & Wozny's (2014) base results rely on an instrumental variables estimator that groups miles-per-gallon (MPG) into two quantiles to mitigate potential attenuation bias due to measurement error in fuel economy, but they find that greater disaggregation of the MPG groups implies greater undervaluation (for example, it reduces the 55 percent estimated reported in Table VI-148 to 49 percent). Busse et al. (2013) allow gasoline prices to vary across local markets in their main specification; using national average gasoline prices, an approach more directly comparable to the other studies, results in estimates that are closer to or above full valuation. Saltee et al. (2016) find modest undervaluation by vehicle fleet operators or manufacturers making large-scale purchases, compared to retail dealer sales (*i.e.*, 70 to 86 percent).

Since they rely predominantly on changes in vehicles' prices between repeat sales, most of the valuation estimates reported in these studies apply most directly to buyers of used vehicles. Only Busse et al. (2013) examine new vehicle sales; they find that consumers value between 75 to 133 percent of future fuel costs for new vehicles, a higher range than they estimate for used vehicles. Allcott & Wozny (2014) examine how their estimates vary by vehicle age and find that fluctuations in purchase prices of younger vehicles imply that buyers whose fuel price expectations mirror the petroleum futures market value a higher fraction of future fuel costs: 93 percent for one- to three-year-old vehicles, compared to their estimate of 76 percent for all used vehicles assuming the same price expectation.¹⁵⁸⁹

Accounting for differences in their data and estimation procedures, the three studies described here suggest that car buyers who use discount rates of five to six percent value at least half—and perhaps all—of the savings in future fuel costs they expect from choosing models that offer higher fuel economy. Perhaps more important in assessing the case for regulating fuel economy, one study (Busse et al., 2013) suggests that buyers of *new* cars and light trucks value three-quarters or more of the savings in future fuel costs they anticipate from purchasing higher-mpg

models, although this result is based on more limited information.

In contrast, previous regulatory analyses of fuel economy standards implicitly assumed that buyers undervalue even more of the benefits they would experience from purchasing models with higher fuel economy, so that, without increases in fuel economy standards, little improvement would occur, and the entire value of fuel savings from raising CAFE standards represented private benefits to car and light truck buyers themselves. For instance, in the EPA analysis of the 2017–2025 model year CO₂ standards, fuel savings alone added up to \$475 billion (at three percent discount rate) over the lifetime of the vehicles, far outweighing the compliance costs: \$150 billion). The assertion that buyers were unwilling to take voluntary advantage of this opportunity implies that collectively, they must have valued less than a third (\$150 billion/\$475 billion = 32 percent) of the fuel savings that would have resulted from those standards. In fact, those earlier analyses assumed that new car and light truck buyers attach relatively little value to higher fuel economy, since their baseline scenarios assumed that fuel economy levels would not increase in the absence of progressively tighter standards, despite increasing fuel prices. The evidence reviewed here makes that perspective extremely difficult to justify and would call into question any analysis that claims to show large private net benefits for vehicle buyers attributable to increases in fuel economy standards.

What analysts assume about consumers' vehicle purchasing behavior, particularly about potential buyers' perspectives on the value of increased fuel economy, clearly matters a great deal in the context of benefit-cost analysis for fuel economy regulation. In light of this recent evidence on this question, warrants a more nuanced approach that is more nuanced than merely assuming that buyers drastically undervalue benefits from higher fuel economy, (and that, as a consequence, these benefits are unlikely to be realized without stringent fuel economy standards,) seems warranted. One possible approach would be to use a baseline scenario where fuel economy levels of new cars and light trucks reflected full (or nearly so) valuation of fuel savings by potential buyers in order to reveal whether setting fuel economy standards above market-determined levels could produce net social benefits. Another might be to assume that, unlike in the agencies' previous analyses, where buyers were assumed to greatly to

undervalue higher fuel economy under the baseline but to value it fully under the proposed standards, buyers value improved fuel economy identically under both the baseline scenario and with stricter CAFE standards in place.

The agencies requested comment on the consumer valuation of fuel economy and its use in the NPRM analysis. CBD and the North Carolina Department of Environmental Quality took issue with the agencies' characterization of the literature on the value of fuel economy, citing EPA's previous determination that the estimates in the literature represented too large a range, and the degree of uncertainty made including a value of fuel economy challenging. This final rule analysis accounts for the value of fuel economy in several places, though it uses a more conservative value than is suggested by the literature summarized above. Manufacturers have consistently told the agencies that new vehicle buyers will pay for about 2 or 3 years' worth of fuel savings before the price increase associated with providing those improvements begins to impact affect sales. The agencies have assumed the same valuation, 2.5 years, in all components of the analysis that reflect consumer decisions regarding vehicle purchases and retirements.¹⁵⁹⁰ This analysis explicitly assumes that: (1) Consumers are willing to pay for fuel economy improvements that pay back within the first 2.5 years of vehicle ownership (at average usage rates); (2) manufacturers know this and will provide these improvements even in the absence of regulatory pressure; (3) potential buyers weigh these savings against increases in new vehicle prices when deciding to retire a vehicle; and (4) the amount of technology for which buyers will pay rises (or falls) with rising (or falling) fuel prices.¹⁵⁹¹ Excluding the value of fuel economy entirely from these calculations does not remove it from the analysis; it merely imposes an implausibly low value on the desired payback period of new

¹⁵⁹⁰ When accounting for social benefits and costs associated with an alternative, the full lifetime value of fuel savings is included.

¹⁵⁹¹ NADA, the Alliance of Automobile Manufacturers, and American Fuel and Petrochemical Manufacturers argued that CAFE/CO₂ standards have already reached the point where the price increases necessary to recoup manufacturers' increased costs for providing further increases in fuel economy outweigh the value of fuel savings, and requiring further increases in fuel economy will reduce new vehicle sales. The sales response in the final rule recognizes and incorporates the effect of fuel prices and fuel economy on new vehicle purchases. See NADA, NHTSA–2018–0067–12064, at 11; Auto Alliance, Full Comment Set, NHTSA–2018–0067–12073 at 163–64; AMFP, Comments, NHTSA–2018–0067–12078–29, at 3.

¹⁵⁸⁹ Allcott & Wozny (2014) and Saltee, et al. (2016) also find that future fuel costs for older vehicles are substantially undervalued (26–30%). The pattern of Allcott and Wozny's results for different vehicle ages is similar when they use retail transaction prices (adjusted for customer cash rebates and trade-in values) instead of wholesale auction prices, although the degree of valuation falls substantially in all age cohorts with the smaller, retail price based sample.

vehicle buyers and manufacturers—regardless of fuel prices or technology costs. And while the agencies acknowledge the uncertainty around the estimates in the literature, zero is far removed from the lower bounds of any study.

CARB asserted that the various market failures suggested by the agencies in past rules (lack of information about fuel savings from higher MPG, inability to calculate cost savings from higher MPG, loss aversion, first-mover disadvantage), together with advertising that only emphasizes fuel economy during periods of high fuel prices, leads buyers to undervalue fuel economy.¹⁵⁹² In contrast, CARB (and others—such as SCAQMD, Alliance to Save Energy, Save EPA, AAA, Environmental group coalition, Consumers Union, EDF, and IPI) argues elsewhere that new vehicle buyers *do* value fuel economy highly, and nearly fully once fuel prices return to “normal” levels.¹⁵⁹³ The agencies’ payback period assumption, and the matching adjustment it makes to changes in new car prices to account for accompanying changes in fuel economy, recognizes that on average potential car buyers value a significant share of lifetime cost savings resulting from higher fuel economy. The agencies considered longer payback periods along the lines suggested by Consumer Federation of America (CFA),¹⁵⁹⁴ but chose 2.5 years as a conservative approach. Our assumption is consistent with survey evidence cited by the commenters, but at odds with their assertions that this program is necessary to save buyers from their own limited ability to make decisions in their best interest.

More recently, the agencies have justified stricter CAFE and CO₂ emissions standards by asserting that buyers do not take advantage of opportunities to improve their *own* well-being, by purchasing models whose higher fuel economy would more than repay their higher initial purchase prices via future savings in fuel costs. This newer rationale is fundamentally different from asserting that some

externality—whereby buyers’ choices cause economic harm to *others*—exists to justify regulating fuel economy or CO₂ emissions, or adopting more demanding regulations. EPA and NHTSA have previously labeled this behavior an example of the “energy paradox,” whereby consumers voluntarily forego investments that conserve energy even when those initial outlays appear likely to repay themselves—in the form of savings in energy costs—over the relatively near term.¹⁵⁹⁵

However, recent research cast doubt on whether such an energy paradox exists in the case of fuel economy—that is, on whether buyers of new vehicles inadequately consider the value of future savings in fuel costs they would experience from purchasing models that feature higher fuel economy—and about how extensive it might be. Several recent studies have estimated the fraction of appropriately discounted lifetime fuel savings offered by models featuring higher fuel economy that car shoppers appear to value or willing to pay for. These estimates are typically drawn from one of three sources—(1) buyers’ choices among competing models with different purchase prices, fuel economy levels, and other features; (2) statistically “decomposing” vehicle prices into the values buyers attach to their individual features, one of which is fuel economy; or (3) analyzing how selling prices for vehicles with different fuel economy levels respond to variation in fuel prices and the changes it causes in their lifetime fuel costs.

The estimates these studies report may partly reflect variation among buyers’ preferences for different vehicle features (such as fuel economy, but also size or utility), the financial constraints they face, how much they drive, or their expectations about future fuel prices, so they should be interpreted cautiously. However, the most careful recent studies suggest that on average buyers appear to undervalue the savings from higher fuel economy at most modestly, and perhaps not at all, after accounting for the influence of vehicles’ other attributes on prices and purchasing decisions.¹⁵⁹⁶ This research suggests that the energy paradox, sometimes described as buyers’ “myopia” in

assessing the value of future fuel savings, is a much weaker rationale for regulating fuel economy than the agencies had previously asserted.

IPI commented that the agencies’ obligation to consider market failures in setting standards derives not just from Executive Order 12,866 but also from the agencies’ respective statutes, and argued that the agencies had defined market failures too narrowly in their proposal.¹⁵⁹⁷ Specifically, IPI stated that NHTSA’s task under EPCA is “not so restricted to only protecting consumers from gas price spikes,” and argued that NHTSA must also consider “externalities relating to energy security, national security, positional goods, global climate change, and air and water pollution associated with fuel production and consumption; asymmetric information, attention costs, and other information failures; internalities, including myopia; and various supply-side market failures, including first-mover disadvantage.”¹⁵⁹⁸

For EPA’s task under the CAA, IPI stated that, although while EPA must “protect the planet from unchecked climate change, [it] must not ignore other related market failures that cause harm to public health and welfare, including the issues and market failures [as described for NHTSA above].”¹⁵⁹⁹ IPI argued that the proposal was arbitrary and capricious for not “consider[ing] important aspects of the problem set before the agencies by Congress,” and also for not considering the market failures discussed in the 2012 final rule.¹⁶⁰⁰ CBD, *et al.*, asserted similarly that the agencies’ respective statutes require their actions to be more technology-forcing than what markets would otherwise achieve, in effect asserting that innovations in technology confer external benefits that vehicle manufacturers or buyers do not fully consider.¹⁶⁰¹

With regard to the specific market failures CAFE and CO₂ standards could potentially address, Global Automakers suggested that climate effects are indeed an externality that more stringent standards can address,¹⁶⁰² while CFA stated that regulating fuel economy and CO₂ emissions can address an extensive catalog of market failures, including externalities, marketing, availability of

fuel-efficient models, transaction cost friction, information asymmetry, behavioral issues, and access to capital, among others.¹⁶⁰³ CFA asserted that advances in economic theory had heavily criticized the neoclassical model, and that “a great deal of empirical evidence supports [that the] standards are seen as an important and, in many ways, preferred policy approach.”¹⁶⁰⁴ On this basis, CFA stated that attribute-based standards that “are set at a moderately aggressive level” and are “consistent with the rate of improvement that the auto industry achieved in the first decade of the fuel economy standard setting program,” among other things, would address the market failure.¹⁶⁰⁵

IPI argued that regulation of fuel economy (presumably also CO₂ emissions) is necessary because “many vehicle attributes, like horsepower and size, are positional goods—that is, they confer status on buyers of cars and light truck models that feature them prominently, so regulation of fuel economy can help correct the positional externality.”¹⁶⁰⁶ IPI also noted the externality of health effects associated with refueling. IPI cited Alcott and Sunstein (2015) to argue, like CFA, that fuel economy standards can correct market failures like informational failure, myopia, supply-side failures, positional externalities, etc., and by doing so, can provide net private welfare gains—that is, improve the utility of vehicle buyers *themselves*, not just that of *other* households or businesses.¹⁶⁰⁷

EDF and CARB both asserted that an energy paradox exists in the case of fuel economy, with EDF arguing (like CFA) that information asymmetry—that is, unequal access of vehicle manufacturers and potential buyers to information about the cost savings likely to result from owning higher-mpg models—coupled with limited availability of fuel-efficient models, leads consumers to purchase vehicles with lower fuel economy than they otherwise

would.¹⁶⁰⁸ CARB simply stated that the NPRM analysis did not account for the energy paradox.¹⁶⁰⁹

The agencies agree with these commenters that the market failures CAFE and CO₂ standards can help address are likely to exist, but note that little of the behavior in the broad catalog identified by commenters actually represents market failures, and instead simply reflects consumers’ preferences for features other than fuel economy. Even in the few cases of potential market failures that commenters identify related to the hypothetical energy paradox, the agencies question whether more stringent CAFE and CO₂ standards are necessary to address the phenomena, or are even likely to be effective in doing so. In the agencies’ view, neither the logical arguments nor the limited empirical evidence that commenters presented convincingly demonstrate the capacity of more stringent CAFE and CO₂ standards to resolve, or even mitigate, most of the various phenomena they describe as market failures.

For example, the idea that regulating fuel economy and CO₂ emissions can mitigate the consequences of inadequate access to information by placing decisions that depend on access to complete information in the hands of regulators rather than buyers has superficial appeal. Yet commenters do not establish that such a drastic step is necessary to overcome any inadequacy of information, or that requiring manufacturers to supply higher fuel economy will be more effective than less intrusive approaches such as expanding the range of information available to buyers. As OMB Circular A-4 notes, “Because information, like other goods, is costly to produce and disseminate, your evaluation will need to do more than demonstrate the possible existence of incomplete or asymmetric information.”¹⁶¹⁰

In the few cases where commenters cited empirical evidence to support their arguments that stricter fuel economy and CO₂ regulations are an appropriate response to market failures, that evidence is limited and unpersuasive. As one illustration, the frequent assertion that buyers’ widespread aversion to the prospect of financial losses makes them hesitant to purchase higher-mpg models appears to be traceable to findings from classroom experiments on small numbers of

university students, rather than to large-scale empirical evidence drawn from buyers’ observed behavior.¹⁶¹¹ Commenters’ repeated emphasis on loss aversion as a critical source of buyers’ unwillingness to choose levels of fuel economy that appear to be in their own financial interest also ignores recent research questioning whether loss aversion is a plausible motivation for such systematic or universal behavior by consumers.¹⁶¹²

¹⁶¹¹ CFA, Comments, NHTSA–2018–0067–12005, at 16 *et seq*; Consumers Union, Attachment 4, NHTSA–2018–0067–12068, at 12; Attachment 3, NHTSA–2018–0067–11741, at 5–6; CARB at 214, and States at 87 each assert that loss aversion is an important source of car buyers’ hesitance to purchase higher-mpg models, variously citing Greene, David L., John German, and Mark A. Delucchi, “Fuel Economy: The Case for Market Failure,” *Reducing Climate Impacts in the Transportation Sector*, Springer James S. Cannon and Daniel Sperling, eds., Springer, 2009, at pp. 181–205; (2009); Greene, David L. (2010). How consumers value fuel economy: A literature review (No. EPA–420–R–10–008); Greene, David L., “Uncertainty, Loss Aversion and Markets for Energy Efficiency,” *Energy Economics*, vol. 33, at pp. 608–616, (2011) and Greene, David L., “Consumers’ Willingness to Pay for Fuel Economy: Implications for Sales of New Vehicles and Scrappage of Used Vehicles,” attachment to comments by CARB, Oct. 10, 2018. However, none of these sources presents empirical evidence on how the frequency of actual common loss aversion actually is among real world vehicle buyers, instead simply asserting (or implicitly assuming) that loss aversion it is likely to be widespread. Further, their (identical) estimates of the *degree* of loss aversion are difficult to trace, and appear to be drawn from classroom exercises administered to limited numbers of university students, not from empirical research involving real world vehicle buyers. One source cited for their repeated assertion that losses of a given dollar amount are valued twice as highly as gains of the same amount is Gal, David, “A psychological law of inertia and the illusion of loss aversion,” *Judgment and Decision Making*, Vol. 1, No. 1, at pp. 23–32 (July 2006.), pp. 23–32, but this reference does not report such a value. Another source repeatedly cited by Greene and co-authors, Benartzi, Shlomo, and Richard H. Thaler, “Myopic Loss Aversion and the Equity Premium Puzzle,” *Quarterly Journal of Economics*, Vol. 110, No. 1, at pp. 73–92 (February 1995), pp. 73–92, does report this value (at p. 74), although only in passing, and cites other references as its original source. The original sources of the claim that losses are values twice as highly as equivalent gains appear to be Kahneman, Daniel, Jack L. Knetsch, and Richard H. Thaler, “Experimental Tests of the Endowment Effect and the Coase Theorem,” *Journal of Political Economy*, Vol. 98, No. 6, pp. 1325–48. (Dec., 1990) (pp. 1325–1348, specifically Section II), pp. 1329–1336; and Tversky, Amos, and Daniel Kahneman, “Loss Aversion in Riskless Choice: A Reference-Dependent Model,” *Quarterly Journal of Economics*, Vol. 106, No. 4, at pp. 1039–61 (Nov., 1991) (pp. 1039–1061, specifically pp. 1053–1054). Neither of these references, however, makes any claim about the generality of the estimate or its applicability to non-experimental settings for consumer behavior.

¹⁶¹⁰ Circular A–4, at 5.

Another example is commenters' repeated citation of the study of households' difficulties in analyzing the financial value of purchasing vehicles with higher fuel economy conducted by Turrentine and Kurani, which relies on interviews with a limited number of subjects (57 California households) to conclude that consumers are systematically unable to perform the calculations necessary to estimate the value of fuel savings.¹⁶¹³ These same

commenters consistently ignore the wealth of detailed, publicly-available information on the fuel economy of new vehicle models, and shoppers' ready access to user-friendly tools to estimate the savings they are likely to realize from purchasing higher-mpg models. These tools include the label that prominently displays how much a vehicles' fuel economy will save, or conversely, cost a purchaser in fuel costs over 5 years of use in color and

large type (see Figure VI-63), which is legally required to be prominently displayed on all new cars vehicles offered for sale.¹⁶¹⁴ Separately, new car dealers are also required to prominently display the Federal Fuel Economy Guide for each model year of new vehicles offered for sale, which provides fuel economy information for all vehicles from that model year.¹⁶¹⁵

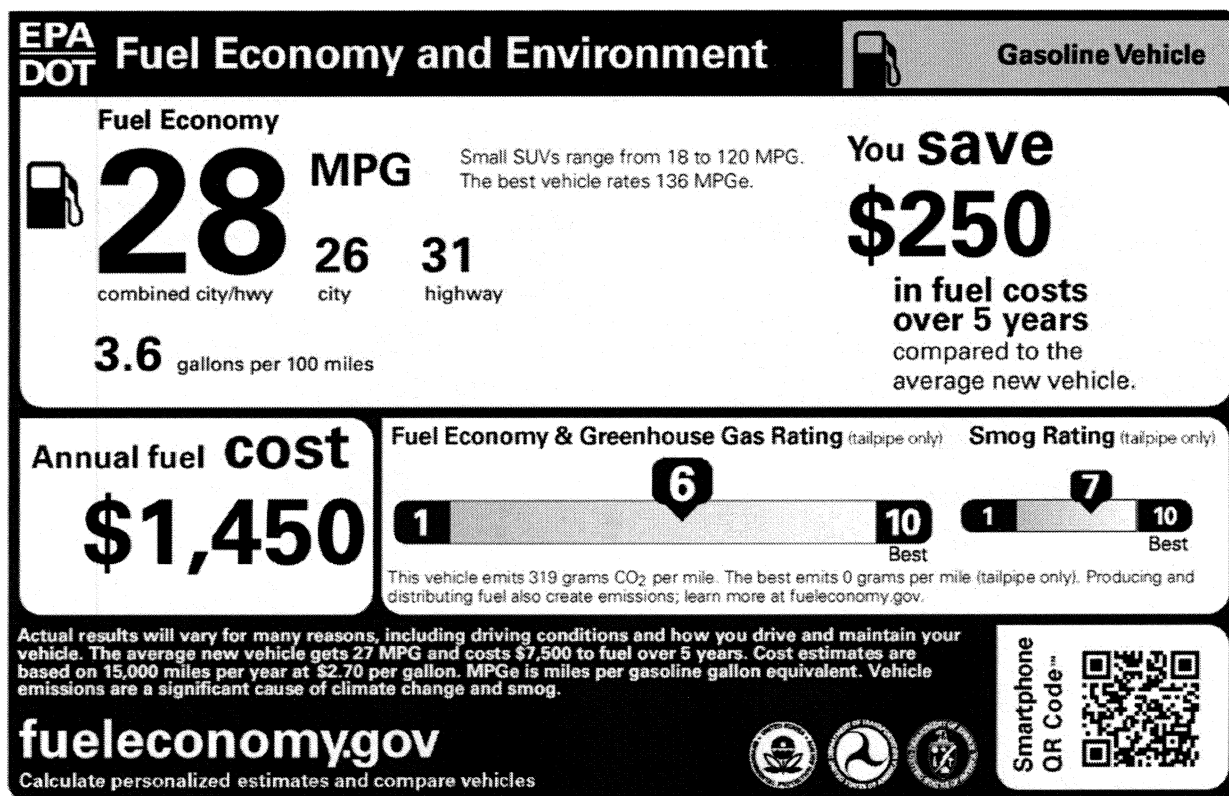

Figure VI-63 – Fuel Economy and Environment Label Example

Similarly, no commenters offered empirical evidence to support their repeated assertions that buyers or the public actually view features such as

styling, size, or performance as “positional goods” to which other potential buyers might aspire, or considered the possibility that high fuel

economy or advanced technology (such as hybrid or electric propulsion) might *themselves* represent such positional attributes.¹⁶¹⁶ Nor do commenters

575–97; (2008); Ert, E., and I. Erev, “On the descriptive value of loss aversion in decisions under risk: Six clarifications,” *Judgment and Decision Making*, Vol. 8 (2013), at pp. 214–35; (2013); Gal, David and Rucker, Derek, “The Loss of Loss Aversion: Will It Loom Larger Than Its Gain?” *Journal of Consumer Psychology*, Vol. 28 No. 3, (July 2018), at pp. 497–516 (July 2018) available at (<https://onlinelibrary.wiley.com/doi/abs/10.1002/jcpy.1047>); and Gal, David, “Why the Most Important Idea in Behavioral Decision-Making Is a Fallacy,” *Scientific American, Observations*, (July 31, 2018), available at (<https://blogs.scientificamerican.com/observations/why-the-most-important-idea-in-behavioral-decision-making-is-a-fallacy/>).

¹⁶¹³ ICCT at p. 4 and Consumers Union at p. 12 (among others), citing Turrentine, T.S., & Kurani, K.S., “Car buyers and fuel economy?,” *Energy policy*, Vol. 35 No. 2 (2007), at 1213–1223, available at <https://www.sciencedirect.com/science/article/pii/S0301421506001200>, as evidence that most or all new-car shoppers are incapable of calculating the savings they would realize from purchasing a higher-mpg model, and further misinterpret the study as evidence that buyers invariably underestimate the value of increased fuel economy. Yet this widely relied-upon analysis included only 57 households, all located in California. As an illustration, citing Turrentine and Kurani, ICCT asserts “There is substantial circumstantial evidence that most consumers in the U.S. place a

low value on fuel economy.” See ICCT at 4 (emphasis added). Similarly, Consumers Union simply asserts that “Households do not track gasoline prices over time and cannot accurately estimate future gas prices or cost savings.” See Consumers Union at 12, again citing Turrentine and Kurani as authority).

¹⁶¹⁴ See 15 U.S.C. 1531, *et seq.*, and 49 CFR 575.401.

¹⁶¹⁵ 40 CFR 600.405–08 and 600.407–08.

¹⁶¹⁶ For evidence that prestige appears to be a motivation for purchasing advanced-technology vehicles, see Hidrue, Michael K., et al., “Willingness to pay for electric vehicles and their attributes,” *Resource and Energy Economics*, Vol.

provide any empirical evidence that the various aspects of behavior they allege lead buyers to underinvest in fuel economy—ranging from unwillingness to spend time or effort estimating likely fuel savings, to inattentiveness to the economic and social importance of improved fuel economy, inability to obtain information about the savings it offers them, and incorrect “framing” of the choice among models with different levels of fuel economy—are widespread, empirically significant, or systematically likely to lead buyers to under- rather than over-invest in fuel economy.

The most frequent argument that an energy paradox or energy efficiency “gap” exists in the case of fuel economy is the observation that many U.S. vehicle buyers seem unwilling to pay higher prices for models whose increased fuel economy would appear to repay their additional investment within a relatively brief ownership period. However, this argument is unpersuasive for at least three reasons: Most obviously, it does not acknowledge the possibility that engineering studies systematically underestimate costs to produce vehicles with higher fuel economy, and thus the prices that buyers would be asked to pay for models with improved fuel economy. Nor does it account for potential sacrifices in *other* vehicle attributes that manufacturers may make in order to achieve higher fuel economy without increasing vehicles’ purchase prices beyond consumers’ willingness to

pay. Finally, claims that consumers are acting irrationally by refusing to purchase higher-mpg models usually reach this conclusion by comparing rates at which they implicitly discount future fuel costs—and thus evaluate savings from purchasing more fuel-efficient models—to interest rates in financial markets that incorporate time horizons or risk profiles that may be very different from those of consumers.

Even putting these concerns aside, comparing future fuel savings to the costs of purchasing more expensive models that offer higher fuel economy demonstrates only that buyers are not behaving as analysts *expect them to* and *believe they should* behave. These comparisons do not demonstrate that consumers are necessarily acting irrationally, and cannot diagnose the nature of information shortcomings buyers face, reasons that they might interpret such information incorrectly, or identify behavioral inconsistencies they may exhibit. In short, conjectures about why buyers *might* undervalue potential savings from investing in higher-efficiency vehicle models do not represent evidence that they actually *do so*, and as discussed above, recent research seems to show that such behavior is not widespread, if it exists at all.

Past joint rulemaking efforts by NHTSA and EPA have repeatedly sought to identify a plausible explanation for car buyers’ perceived undervaluation of improved fuel economy. The agencies have occasionally relied on explanations such as consumers’ insufficient appreciation of the importance of fuel economy, the difficulty of obtaining adequate information about the fuel economy of competing models or of converting competing models’ fuel economy ratings to future fuel costs and savings, or consumers’ misunderstanding or mistrust of such information when it is provided to them. At other times, the agencies have pointed to consumers’ “myopia” about the future—asserting that for some reason, they appear to underestimate future fuel costs and savings—or argued that shoppers are insufficiently attentive to fuel costs when comparing competing models, that the value of improved fuel economy is obscured (“shrouded”) by vehicles’ other, more visible attributes, or that uncertainty about the savings in fuel costs owners will actually realize causes them to undervalue those savings when comparing the upfront costs of models with different fuel economy.

Despite the frequency with which the agencies have cited these hypotheses, clear support for any of them remains

elusive. Consumers have long had ready access to detailed information about individual models’ fuel economy, which appears prominently on the labels displayed by new cars,¹⁶¹⁷ and is published online and in printed outlets that shoppers use routinely rely widely on to compare models.¹⁶¹⁸ In addition, the fuel economy actually experienced by previous buyers of individual models is increasingly reported in readily accessible on-line databases.¹⁶¹⁹

Similarly, consumers appear to be well aware of the prices they pay for gasoline and how those vary among retail outlets, and are reminded clearly and frequently of the financial consequences of their fuel economy choices each time they purchase fuel. Increasingly, consumers also have ready online access to comparisons of fuel prices at competing locations near their homes or along routes they travel.¹⁶²⁰ There is also considerable evidence that drivers’ forecasts of future fuel prices are more accurate than those issued by government agencies or private forecasting services.¹⁶²¹ Evidence exists

¹⁶¹⁷ Fuel economy labels have been displayed on the window sticker of all new light duty cars and trucks since the mid-1970s, as required by the Energy Policy and Conservation Act. See <https://www.epa.gov/fueleconomy/history-fuel-economy-labeling>. Among the information currently required to be posted on the fuel economy label is both an estimated annual fuel cost for the vehicle, as well as an estimate of how that cost compares to the fuel cost over five years for an average new vehicle, so it is unclear what information consumers lack that prevents them from making an informed decision in this regard.

¹⁶¹⁸ See, e.g., <http://www.fueleconomy.gov>, where consumers can find and compare the fuel economy (and greenhouse gas CO₂ and smog emissions) of different vehicle models across model years, as well as upload information about their own real-world fuel economy and compare it to other drivers.

¹⁶¹⁹ See *id.*

¹⁶²⁰ See, e.g., Gas Buddy, available at www.gasbuddy.com.

¹⁶²¹ Anderson *et al.* report evidence that consumers believe fuel prices are likely to remain constant in inflation-adjusted terms; see Anderson, Soren T., Ryan Kellogg, and James M. Sallee, “What do consumers believe about future gasoline prices?” *Journal of Environmental Economics and Management*, vol. 66 no. 3 (2013), at pp. 383–403. (2013). Other evidence generally supporting this view is reported by Allcott, Hunt, “Consumers’ Perceptions and Misperceptions of Energy Costs,” *American Economic Review: Papers & Proceedings*, Vol. 101 No. 3 (2011), at pp. 98–104, (2011), although Allcott finds that some fraction of consumers consistently believes that gasoline prices will rise in the future. In related research, Anderson *et al.* demonstrate that consumers’ expectations that gasoline prices will return to their current levels, even after sudden and significant variation, is generally accurate; see Anderson, Soren T., Ryan Kellogg, James M. Sallee, and Richard T. Curtin, “Forecasting Gasoline Prices Using Consumer Surveys,” *American Economic Review: Papers & Proceedings*, Vol. 101 No. 3 (2011), at pp. 110–14. (2011). In contrast to many consumers’ expectation that fuel prices may vary over the future but will generally return to current levels, the U.S. Energy Information Administration predicted that gasoline

33, Issue 3 (September 2011), at pp. 686–705; Chua, Wan Ying, Lee, Alvin and Sadeque, Saalem 2010, “Why do people buy hybrid cars?,” *Proceedings of Social Marketing Forum*, University of Western Australia, Perth, Western Australia, Edith Cowan University, Churchlands, W.A., at pp. 1–13; Liu, Yizao, “Household demand and willingness to pay for hybrid vehicles,” *Energy Economics*, Volume 44, 2014, at pp. 191–197; Hur, Won-Moo, Jeong Woo, and Yeonshim Kim, “The Role of Consumer Values and Socio-Demographics in Green Product Satisfaction: The Case of Hybrid Cars,” *Psychological Reports*, Volume 117, issue 2, October 2015, at pp. 406–427. A useful summary of many studies appears in Table 1 (p. 196) of Makoto Tanaka, Takanori Ida, Kayo Murakami, Lee Friedman, “Consumers’ willingness to pay for alternative fuel vehicles: A comparative discrete choice analysis between the US and Japan,” *Transportation Research Part A: Policy and Practice*, Volume 70, 2014, at pp. 194–209 (Table 1 at p. 196). Some of these studies find that buyers are apparently willing to pay significant price premiums for the prestige or status value of hybrids or battery-electric vehicles—which their authors speculate may derive from their “greenness”—because their purchases cannot be explained on the basis of economic or financial considerations. Others find that average or typical shoppers’ willingness to pay advanced-technology vehicles is below the price premiums they command, suggesting that their purchasers must derive some status or prestige value from owning and driving them.

that car buyers and owners anticipate extreme volatility in fuel prices, recognize that there is considerable uncertainty about future fuel prices and potential savings from driving a higher-mpg model, and respond cautiously to these uncertainties when evaluating competing vehicle models,¹⁶²² none of which suggests a market failure as much as it suggests that consumers balance multiple, often competing objectives, and make choices based on the outcome of such balancing.

In past rulemakings, the agencies have also hypothesized that consumers may “satisfice”—that is, select some minimum acceptable level of fuel economy, and then evaluate models that achieve that minimum on the basis of their other attributes. This explanation for buyers’ reluctance to purchase more fuel-efficient vehicles ignores the possibility that they do account fully for the value of higher fuel economy in their decision-making, but simply value differences in vehicles’ other attributes more highly than they do fuel economy, which would not reveal irrational or myopic behavior.

A related argument has been that calculating future savings attributable to fuel economy is complicated, so car shoppers resort to simplified decision rules to choose among models with

different fuel economies, and relying on these rules-of-thumb causes them to choose models with lower fuel economy.¹⁶²³ However, it is unclear why buyers’ reliance on simplified procedures or approximations for estimating the value of fuel savings would necessarily lead them to systematically choose models with lower fuel economies rather than leading some to underinvest in fuel economy while others overinvest.

The agencies have also frequently described consumers as “loss averse,” making them reluctant to pay the upfront and certain higher prices for models offering better fuel economy when the future savings they expect to realize are more distant and less certain.¹⁶²⁴ The agencies’ past assumption that loss aversion is universal (and equally strong) among new-car shoppers appears to be a simplification that is largely unsupported by empirical evidence, and in any case has been challenged both as a widespread feature of consumer behavior and more specifically as an explanation for vehicle shoppers’ reluctance to purchase more costly models that offer higher fuel economy.¹⁶²⁵ Further, the extremely wide variety of competing models among which car buyers can choose enables many of those searching for a model with better fuel economy at a comparable price to do so simply by choosing a version with fewer other features, which might partly offset the effect of their aversion to the prospect of losses from paying a higher purchase price. Lastly, the agencies note that *both* increased fuel costs and increased upfront car prices will appear as “losses,” so it is not obvious why potential buyers would react to the prospects of these different forms of losses in different ways.

OMB Circular A–4 does acknowledge that “[e]ven when adequate information is available, people can make mistakes by processing it poorly.” It goes on to say that people may rely on “mental rules-of-thumb” that produce errors, or cognitive “availability” may lead to consumers overstating the likelihood of an event. However, Circular A–4 also cautions that “the mere possibility of poor information processing is not enough to justify regulation,” and that potential problems with information processing “should be carefully documented.” Some of the above examples of potential market failures

may fall into this category, but lack evidentiary support. As with claims of asymmetric information, it is very difficult to distinguish between information processing errors and behavior consistent with consumer preferences for time and other vehicle attributes that differ from what government agency analysts *believe* they should be.

Similarly, the agencies have occasionally noted (and seemingly been critical of) some consumers’ apparent preferences for vehicle attributes that convey social status, such as size or styling, and suggested that they may give inadequate attention to fuel economy because it does not provide similar status. The agencies have also suggested that consumers may be reluctant to purchase more fuel-efficient models because they associate higher fuel economy with inexpensive, less well-designed vehicles. These might be plausible explanations, were they not contradicted by concurrent arguments that potential buyers are inattentive to or uninformed about fuel economy, or have difficulty isolating it from vehicles’ other attributes. Moreover, the market currently offers a wide range of highly fuel efficient (and advanced technology) vehicles at many different price points, including in the luxury and performance segments, which belies the assumption that fuel economy is inconsistent with positional attributes. In any case, consumers’ hesitance to choose models offering higher fuel economy because they are reluctant to sacrifice improvements in other vehicle attributes on which they place higher values cannot reasonably be characterized as a market failure.

Although past rulemakings have raised the possibility that car buyers’ apparent tendency to underinvest in fuel economy could plausibly be explained by their use of discount rates exceeding those the agencies employ to assess the present value of fuel savings, the agencies have generally dismissed that possibility. In combination with factors such as their valuation of vehicles’ attributes other than fuel economy, differences in driving habits that affect fuel economy and in how much they expect to drive newly-purchased cars, and variation in their expectations about future fuel prices, differing attitudes about the importance of future costs relative to more immediate ones could readily explain buyers’ apparent reluctance to purchase models offering fuel economy levels that the agencies interpret as privately “optimal.”

As with consumption of any good or service, the agencies believe consumers’

prices would rise significantly over the future, at the time the two previous rules establishing CAFE standards for model years 2012–16 and 2017–21 were adopted, in 2010 and 2012; see Energy Information Administration (EIA), Annual Energy Outlook 2010, Table A12, p. 131, available at [https://www.eia.gov/outlooks/archive/aeo10/pdf/0383\(2010\).pdf](https://www.eia.gov/outlooks/archive/aeo10/pdf/0383(2010).pdf), Table A12, p. 131; and Annual Energy Outlook 2012, Appendix A, Table A12, at p. 155, available at <https://www.eia.gov/outlooks/archive/aeo12/pdf/appa.pdf>, Table A12, p. 155. As of those same dates, forecasts of future petroleum prices issued by other government agencies and most private forecasting services (with the notable exception of HIS-Global Insight, which projected little or no increase in future prices) agreed closely with EIA’s forecasts that prices would increase significantly over both the near- and longer-term futures; see EIA, Annual Energy Outlook 2010, Table 10, at p. 86; and Annual Energy Outlook 2012, Table 23, available at https://www.eia.gov/outlooks/archive/aeo12/table_23.php. Expressed in constant-dollar terms, U.S. gasoline prices in 2019 are essentially unchanged from those in 2010, although prices have varied significantly above and below that level during the intervening period. See https://www.eia.gov/dnav/pet/hist/LeafHandler.ashx?n=pet&s=emm-epm0_pte_nus_dpg&f=m.

choice in vehicles represents what economists call “constrained optimization.” That is, consumers select a bundle of vehicle features—within their budget constraint—that optimizes the value to them. The agencies also believe, as is the case in every constrained consumer choice, that each of these attributes provide what economists call diminishing marginal returns (or value) to consumers. For instance, the agencies believe that consumers value vehicle size, comfort, performance, trim-level, appearance, etc. As such, fuel-saving technologies that increase the cost of the car are just one of many vehicle attributes that consumers balance against each other. And instead of using their entire budget on a single vehicle attribute, consumers tend to sacrifice some degree of many or all attributes in a degree that varies according to their preferences so that they can consume some degree of most or all attributes they value. This means that many consumers may not maximize fuel-saving technologies in their vehicle selection, but instead may choose some other bundle of attributes. The agencies’ use of a 30 month pay-back period in this analysis—as opposed to fuel-savings over the life of the vehicle—is consistent with the constrained optimization consumers perform when selecting a vehicle. It is a reasonable representation of consumers’ valuation of fuel-saving technologies, given the diminishing marginal returns of additional fuel economy. If the agencies had used the entire undiscounted fuel-savings over the entire life of the vehicle, the agencies would be effectively modeling a scenario where consumers maximize fuel economy to the detriment of all other vehicle attributes—an assumption that is evidently wrong. As such, it is not necessary that purchasers do not value lifetime fuel savings—and, in all likelihood, purchasers would prefer vehicles with better fuel efficiency and all of their preferred attributes—but rather consumers are forced to choose between fuel economy and other vehicle attributes while weighing how much each attribute contributes to the total cost of the vehicle.

Finally, the agencies have also previously speculated that vehicle producers may be reluctant to offer models featuring the higher levels of fuel economy that buyers are willing to pay for, and that buyers’ apparent underinvestment in fuel economy reflects this lack of choice. The agencies have speculated that such behavior by manufacturers could arise from their collective underestimation of the value

that buyers attach to fuel economy, or failing this, from limitations on competition among them to supply improved fuel economy, whether voluntarily or as a consequence of the industry’s structure.¹⁶²⁶ The agencies have also raised the seemingly contradictory argument that producers have more complete knowledge about fuel economy than potential buyers (“asymmetric information”) causing them to provide *lower* levels than buyers demand, and speculated that deliberate decisions by manufacturers may limit the range of fuel economy they offer in potential market segments.¹⁶²⁷

The overarching theme of these arguments seems to be that vehicle manufacturers cannot identify—or can, but voluntarily forego—opportunities to increase sales and profits at the expense of their rivals by offering models that feature higher fuel economy. The agencies have sometimes ascribed this behavior to the risk that producers might incur large investments to produce the more fuel-efficient models that would enable them to seize these opportunities, but subsequently lose sales and profits to competitors who simply followed suit after their rivals were successful. This explanation is at odds with the customary view that innovative producers can be rewarded—substantially, even if only temporarily—with commensurate profits that justify taking such risks, when they correctly assess consumer demand for innovative features or products.

In any case, behavior on the part of individual businesses that leaves obvious opportunities to increase profits unexploited *by an entire industry* seems extremely implausible, particularly in light of the fact that auto manufacturers are profit-seeking businesses whose ownership shares are publicly traded and subject to regular market valuation. This notion also seems to ignore the range of choices already available in the current automobile market, where extraordinarily efficient models are available in nearly every vehicle class or market segment, including plug-in hybrid and fully electric versions of a rapidly increasing number of models. Automobile manufacturers can, and in fact are, competing on the basis of fuel economy.

The central analysis presented in this final regulatory impact analysis does not account for the possibility that imposing stricter standards may require

manufacturers to make sacrifices in other vehicle features that compete with fuel economy, and that some buyers may value more highly. If this proved to be the case, more stringent alternatives could impose offsetting losses on buyers well beyond the increases in vehicle prices that are necessary for manufacturers to recover their outlays for adding new technology (or changing design features) to improve fuel economy. By doing so, it could significantly reduce the estimates of total and net benefits the agencies report. To further illustrate this issue, the agencies have conducted a sensitivity analysis that incorporates a conservative estimate of consumers’ valuation of other vehicle attributes, as further discussed in Chapter VII of the FRIA accompanying today’s notice.¹⁶²⁸ The agencies also recognize that buyers may have time preferences that cause them to discount the future at higher rates than the agencies are directed to consider in their regulatory evaluations.

If either case is true—that the analysis is incomplete regarding consumer valuation of other vehicle attributes or discount rates used in regulatory analysis inaccurately represent consumers’ time preferences—no market failure would exist to support the hypothesis of a fuel efficiency gap. In either case, the agencies’ central analysis would overstate both the net private and social benefits from adopting more stringent fuel economy and CO₂ emissions standards. For instance, Table VII–93 (Combined LDV Societal Net Benefits for MYs 1975–2029, CAFE Program, 7% Discount Rate) shows that the CAFE final rule would generate \$16.1 billion in total social net benefits using a 7% discount rate, but without the large net private loss of \$26.1 billion, the net social benefits would equal the external net benefits, or \$42.2 billion. Because government action cannot improve net social benefits in the absence of a market failure, if no market failure exists to motivate the \$26.1 billion in private losses to consumers, the net benefits of these final standards would be \$42.2 billion.

In sum, the agencies do not take a position in this rule on whether a fuel

¹⁶²⁸ This sensitivity analysis assumes that consumer’s value of other vehicle attributes is *at least as great as a portion* of the fuel savings that consumers supposedly “leave on the table.” In this analysis, the private net benefits of the final rule are a positive \$15 billion using a 7% discount rate—which is consistent with the theory that providing consumers with greater choices will enhance their private welfare. The net external benefits are identical to the primary analysis, or \$34 billion, so the sensitivity results show the final rule improves net social benefits by \$49 billion.

¹⁶²⁶ See 75 FR at 25653–64 (May 7, 2010); and 77 FR at 63115 (Oct. 15, 2012).

¹⁶²⁷ See, e.g. 75 FR 25510–13; 76 FR 57315–19; 77 FR 62914.

efficiency gap exists or constitutes a failure of private markets. Accordingly, the final regulatory impact analysis is not constrained in any manner that ensures the private net benefits of more stringent standards will necessarily be either positive or negative. In fact, however, the analysis supporting this final rule *does* present a situation where adopting more stringent CAFE and CO₂ emission standards aligns consumers' decisions with a simplified representation of *their own economic interests*, and by doing so improves their well-being from what they would experience under less stringent standards. In other words, our final modelling results reflect the case where some fuel efficiency gap persists (albeit of smaller magnitude than the agencies found in previous analyses), despite our expressed reservations about its likelihood.

(b) Representing Sales Responses in CAFE/CO₂ Analysis

The approach used in the NPRM relied on a single model to produce the total number of new vehicle sales in each calendar year for a given regulatory scenario. Many commenters expressed reservations about the predictive capabilities of the model (CARB, North Carolina Department of Environmental Quality, EDF, Aluminum Association). As the Aluminum Association commented, “[D]eveloping a model to predict consumer reaction to changes in prices is complicated and highly sensitive to macroeconomic conditions, consumer confidence and employment levels.”¹⁶²⁹ As discussed above, the agencies agree that development of such a model is complicated, and the agencies have elected to simplify the approach for the final rule. For the purposes of regulatory evaluation, the relevant sales metric is the difference between alternatives rather than the absolute number of sales in any of the alternatives. As such and in response to these comments and others previously addressed, the agencies divided the sales response model for the final rule into two parts: A nominal forecast that provides the level of sales in the baseline (based primarily upon macroeconomic inputs), and a price

elasticity that creates sales differences relative to that baseline in each year. The nominal forecast does not include price, and is merely a (continuous) function of several macroeconomic variables that are provided to the model as inputs. While the statistical model used in the NPRM attempted to account for the influence of these other factors in estimating the price elasticity, the forecast in this analysis separates the two completely (as described further below). The price elasticity is also specified as an input, but this analysis assumes a unit elastic response of 1.0—meaning that a one percent increase in the average price of a new vehicle produces a one percent decrease in total sales.¹⁶³⁰

The revised sales model features three broad changes: (1) It uses the change in average vehicle price net of fuel costs instead of vehicle prices on their own, (2) it uses macroeconomic factors to project baseline sales without considering vehicle prices, and (3) it assesses the change in sales across the various regulatory alternatives considered using an own-price elasticity from the literature. These changes were made in response to comments that consumers are willing to pay for some level of fuel economy and vehicle prices and sales are simultaneously and jointly determined (*e.g.* endogenous). This section discusses these three broad changes, as well as other more technical and minor changes.

The first component of the new sales response model is the nominal forecast, which is a function (with a small set of inputs) that determines the size of the new vehicle market in each calendar year in the analysis for the baseline. It leverages some of the same structure of the statistical model used in the NPRM, though the dependent variable and some of the explanatory variables have changed. It is of some relevance that this statistical model is intended only as a means to project a baseline sales series. Some commenters raised econometric objections about the NPRM specification's ability to isolate the causal effect of new vehicle prices on new vehicle sales. The agencies note that the nominal forecast model does

not include prices and is not intended for statistical inference.

The forecast is derived from a statistical model that accounts for a similar set of exogenous factors related to new light-duty vehicle sales. In particular, the model accounts for the number of households in the U.S., recent number of new vehicles sold, GDP, and consumer confidence. The structure of the forecast model is similar to the NPRM model, which also used a ARDL specification, but even the variables that are common between the two models have different structural forms in the final rule version. In particular, the dependent variable has been transformed to reflect the fact that, as some commenters suggested, households are an important component of demand for new vehicles. As such, the dependent variable is defined as new vehicles sold per household.¹⁶³¹ While this variable still exhibits the cyclic behavior that new vehicle sales exhibit over time, the trend shows the number of new vehicles sold per household declining since the 1970's, as shown in Figure VI–64, where the dotted line is the trend over time. As this time series is non-stationary,¹⁶³² a lagged variable (the value in the previous year) is included on the right-hand side of the regression equation. In addition, the model includes a lagged variable that represents the three-year running sum of new vehicle sales, divided by the number of households in the previous year. This variable represents the saturation effect, where the existing number of households can only buy so many new vehicles before a significant number of households already have one (and do not need to buy another). As vehicle durability and cost has increased over time, and average length of initial ownership has increased similarly, this variable acts to put downward pressure on sales after successive years of high sales (particularly during extrapolation).

BILLING CODE 4910–59–P

¹⁶³¹ Number of U.S. households is taken from Federal Reserve Economic data, <https://fred.stlouisfed.org/series/TTLHH>.

¹⁶³² Stationary refers to whether a time series statistical properties are constant over time. Since car sales are increasing over time, the time series non-stationary.

¹⁶³⁰ The “price increase” in this case represents the new vehicle price net of a portion of fuel savings, described further in this section.

BILLING CODE 4910–59–C

Similar to the NPRM model, the forecast model includes real U.S. GDP,¹⁶³³ but in natural logarithm form (as some commenters suggested was more appropriate).¹⁶³⁴ The final variable is consumer sentiment, as measured by the University of Michigan survey of consumers.¹⁶³⁵ As both of these series are non-stationary (determined by applying augmented Dickey-Fuller unit root tests to the time series), lagged

versions of the variables are included to ensure stationarity in the residuals. The functional form appears below in Equation 2.

Equation 2—Statistical Model Used to Generate Nominal Forecast

The model fit is described in Table VI-152. The included lag term of the dependent variable and both GDP variables are statistically significant at nearly zero, while both the lagged three

year sum term and consumer sentiment are both marginally significant. Being a time series model, the agencies also computed the Durbin-Watson test statistic for autocorrelation (1.77) and the Breusch-Godfrey test for serial correlation (0.65) at order 1. The signs of the coefficients are all correct, in the sense that they are consistent with our expectations.

BILLING CODE 4910–59–C

Because the dependent variable is the number of new vehicles sold per household, it is necessary to multiply by the number of households to produce an estimate of new vehicle sales. This model is used to produce a forecast of new vehicle sales out to 2050, so it is necessary to have projections of each variable used in Equation 2 through calendar year 2050. In an effort to be consistent with other inputs to the analysis, the projection of U.S. GDP is taken from the 2019 AEO. The forecast of households in this analysis comes from the Harvard Joint Center for Housing Studies 2018 Household projections.¹⁶³⁶ The consumer confidence forecast is taken directly from the University of Michigan index for 2017 and 2018, and from the Global Insight forecast of consumer confidence for all subsequent years.

While the analysis could have relied on a forecast of new vehicle sales taken from a published source (the 2019 AEO, for example), using a function is an attractive option because it allows the CAFE Model dynamically to adjust the forecast in response to input changes. If

a sensitivity case requires a forecast that is consistent with a set of specific, possibly unlikely, assumptions, a forecast of new vehicle sales that is consistent with those assumptions may not exist in the public domain, for example low GDP growth sensitivity cases. As implemented in this rulemaking, using a functional form allows the user to vary some of the assumptions to the analysis without creating inconsistencies with other elements of the analysis. However, it is incumbent upon the analyst to ensure that any set of assumptions that deviate from the central analysis are logically consistent.

This function, and the set of assumptions contained in the central analysis, produces a projection that is comparable in magnitude to the forecast in the 2019 AEO reference case, though there are differences. The two forecasts, and the percentage difference relative to the AEO 2019, appear in Table VI–153, as does a recent forecast published by the Center for Automotive Research.¹⁶³⁷ The reader will notice that even 2017 shows a discrepancy of nearly 7 percent between the final rule forecast and the

Annual Energy Outlook, one of the larger differences between annual forecasts. However, the final rule analysis is based upon the certified production volumes of MY2017, which exceed 17 million units. So, while the difference may seem significant, the final rule volumes in 2017 represent the ground truth for model year production.¹⁶³⁸ The CAR forecast, while shorter in length, is consistently higher than both the AEO and final rule forecasts—though likely also includes class 2b (and possibly class 3) pickup trucks in its light vehicle forecast. Finding a public forecast that explicitly excludes light-duty vehicles exempt from these regulations is challenging. However, all three forecasts exhibit similar trends—decreases in sales starting in 2019 that last for a few years before ticking up again slowly. As commenters observed, all forecasts are almost guaranteed to have some errors, and projections out to 2050 should be taken as potential future projections limited by our knowledge at the time, rather than an ironclad prediction of the future.

BILLING CODE 4910-59-C

Although the forecast produces the total number of new vehicle sales in the baseline, an elasticity is imposed on price differences to produce sales changes between alternatives. The

NPRM version of the model considered only differences in average new vehicle prices between alternatives, and the agencies received a number of comments (from CBD, IPI, EDF, CARB, CA et al., and Oakland et al., as well as

recent peer reviewers) encouraging the agencies to account for some component of fuel savings associated with those price changes. In their comment, California et al. and Oakland et al. stated the model failed “to consider

how consumers will respond to the reduced cost of operating the vehicle from better gas mileage and therefore inaccurately predicts a decline in vehicle sales under the existing standards.”¹⁶³⁹ The agencies agree that price is not the only consideration, and that the value of fuel savings to new vehicle buyers is also relevant to the purchase decision.

In previous rules, while the agencies produced analyses that qualitatively considered sales and employment impacts, the agencies acknowledged that fuel economy and CO₂ standards were likely to increase vehicle prices, while simultaneously reducing operating costs, and that estimating how consumers would choose to balance those two factors in the new vehicle market was challenging.¹⁶⁴⁰ Furthermore, the agencies recognized that there is a broad consensus in the economic literature that the price

elasticity of demand for automobiles is approximately -1.0 .¹⁶⁴¹ The agencies feel that a unit elasticity of -1.0 is still a reasonable estimate.¹⁶⁴²

Because the elasticity assumes no perceived change in the quality of the product, and the vehicles produced under different regulatory scenarios have inherently different operating costs, the price metric must account for this difference. As commenters suggested is appropriate, the price to which the unit elasticity is applied in this analysis represents the residual price change *between scenarios* after accounting for 2.5 years’ worth of fuel savings to the new vehicle buyer. This approach is consistent with the 2012 FRIA analysis of sales impacts, that which considered several payback periods over which the value of fuel savings was subtracted from the change in average new vehicle price.

Similar to the NPRM, the price elasticity is applied to the percentage change in average price (in each year). However, the average price to which the elasticity is applied is calculated differently in the final rule in response to comments. As discussed below the price change does not represent an increase/decrease over the last observed year, but rather the percentage change relative to the baseline. In the baseline, the average price is defined as the observed new vehicle price in 2017 plus the average regulatory cost associated with the alternative. In the case of CO₂ standards, the regulatory cost is equivalent to the retail equivalent price of technology improvements. In the case of CAFE standards, the regulatory cost includes both technology costs and civil penalties paid for non-compliance in a model year. So the change in sales for alternative *a* in year *y* is:

$$\Delta Sales_{y,a} = \frac{(\Delta RegCost_{y,a-0} - \Delta FuelCosts_{t,a-0})}{34449 + RegCost_{y,0}} \cdot PriceElasticity \cdot NominalSales_y$$

$\Delta RegCost$ is the difference in average regulatory cost between alternative *a* and the baseline scenario in year *y* to make a vehicle compliant with the

standards, \$34,449 is the average transaction price of a new vehicle in 2016, *NominalSales* is the forecasted sales (in the baseline) in year *y*,

$\Delta FuelCosts$ is the change in average fuel costs over 2.5 years relative to the baseline in year *y* and *PriceElasticity* is -1.0 :

$$\Delta FuelCosts_{t,a-0} = \left(\frac{FuelPrice_t}{NewVehFE_{t,a}} - \frac{FuelPrice_t}{NewVehFE_{t,0}} \right) * 35000$$

Where 35,000 miles is assumed to be equivalent to 2.5 years of vehicle usage.¹⁶⁴³ The agencies assume that consumers behave as if the fuel price faced at the time of purchase is the fuel price that they will face over the first 2.5 years of ownership and usage. Essentially, they behave as if fuel prices follow a random walk, where the best prediction of (near) future prices is the price today. Scrappage rates in the first few years of ownership are close to zero, so buyers can reasonably expect to travel the full annual

mileage in each of the first three years of ownership. Total sales in each alternative (that is not the baseline) will equal $NominalSales_y + \Delta Sales_{a,y}$ for alternative *a* in year *y*.

This implementation produces a range of differences in total sales, both between alternatives and over time. Table VI–154 shows the range of differences in the final rule at the industry level for CO₂, and Table VI–

155 shows the sales changes under CAFE. While cost decreases between the baseline and alternatives differ by program, one can see that removing the value of fuel savings from the price limits the sales increases in the alternatives to under 300,000 units in a single year under the preferred alternative, and about one percent of total sales between 2017 and 2050.

¹⁶⁴¹ See, e.g., Kleit, A.N., “The Effect of Annual Changes in Automobile Fuel Economy Standards,” *Journal of Regulatory Economics*, Vol. 2 (1990), at pp 151–72; Bordley, R., “An Overlapping Choice Set Model of Automotive Price Elasticities,” *Transportation Research B*, Vol. 28B no. 6 (1994), at pp 401–408; and McCarthy, P.S., “Market Price and Income Elasticities of New Vehicle Demands,”

The Review of Economics and Statistics, Vol. LXXVII no. 3 (1996), at pp. 543–547.

¹⁶⁴² For example, a recent review of 12 studies examining vehicle price elasticities conducted by the Center of Automotive Research (“CAR”) found an “average short-run elasticity of -1.09” and focusing “only those models which also employ time series methods, the average short-run own-price elasticity is higher yet, at -1.25.” CAR’s own analysis found a -.79 short-run elasticity. Appendix II of the CAR report shows that the long-run elasticities ranged from -.46 and -1.2 with an average of -.72. In sum, a -1.0 elasticity is well-aligned with the totality of research. Ph.D., Sean P., Chen, Yen, Schultz, Michael, Andrea, David J., The Potential Effects of the 2017–2025 EPA/NHTSA GHG/Fuel Economy Mandates of the US Economy, Center for Automotive Research, Ann Arbor, MI (Sept. 2016), available at https://www.cargroup.org/wp-content/uploads/2017/02/The-Potential-Effects-of-the-2017_2025-EPANHTSA-GHG-Fuel-Economy-Mandates-on-the-US-Economy.pdf.

¹⁶⁴³ Based on odometer data, 35,000 miles is a good representation of typical new vehicle usage in the first 2.5 years of ownership and use—though the distribution of usage is large.

Table VI-154 and Table VI-155 show sales under the baseline (augural standards), and differences under the

proposal (0 percent increase in stringency) and final rule (1.5 percent increase in stringency) of MYs 2017–2050.

c) Dynamic Fleet Share (DFS)

The first module described above (the forecast function and applied elasticity)

determine the total industry sales in each model year from 2018 (in this analysis, 2017 is based on certified compliance data) to 2050. A second module, the dynamic fleet share, acts to distribute the total industry sales across two different body-types: “cars” and “light trucks.” While there are specific definitions of “passenger cars” and “light trucks” that determine a vehicle’s regulatory class, the distinction used in this phase of the analysis is more simplistic. All body-styles that are obviously cars—sedans, coupes, convertibles, hatchbacks, and station wagons—are defined as “cars” for the purpose of determining fleet share. Everything else—SUVs, smaller SUVs (crossovers), vans, and pickup trucks—are defined as “light trucks”—even though they may not be treated as such for compliance purposes. In the case of SUVs, in particular, many models may have sales volumes that reside in both the passenger car and light fleets for regulatory purposes, but the dynamic fleet share does not make this distinction. The fleet share model was applied at the same level in the NPRM—namely, at the level of body-style rather than regulatory class. EDF expressed concern that any simulated increase in the light truck share represented consumers shifting from sedans to either 4WD drive crossovers, SUVs or pickup trucks.¹⁶⁴⁴ However, this was not the

case. All crossovers are considered light trucks for the purposes of fleet share, even though they may be 2WD crossovers treated as passenger cars for compliance purposes. So, while the number may increase overall for a given scenario, the proportion of crossovers sold as 4WD, rather than 2WD, does not.

EDF was also concerned that the sales implementation in the NPRM, which relied on the absolute average price to determine differences between alternatives, was unduly influenced by fleet share—as differences in the share of light-trucks had the potential to skew differences in average price because light-trucks are generally more expensive than sedans and hatchbacks. The final rule implementation, which starts from an observed average transaction price and evolves the average price in the alternatives based on average regulatory cost, is less vulnerable to this potential distortion. Even if the fleet share model (described in greater detail below) increases the share of light trucks (for example), the inherent price difference between passenger cars and light trucks does not pass through to the average price—only the relative difference in compliance costs associated with the vehicle types. Despite the fact that light trucks have generally higher transaction prices than passenger cars, there is no guarantee that regulatory costs will be higher for light-trucks than for cars (which depend upon the mix of footprints, their

distance from the relevant curve, and the technology cost needed to bring each fleet into compliance). Thus, the average price differences used in the sales calculations are relatively unaffected by the fleet share model.

As in the NPRM, the dynamic fleet share represents two difference equations that independently estimate the share of passenger cars and light trucks, respectively, given average new market attributes (fuel economy, horsepower, and curb weight) for each group and current fuel prices, as well as the prior year’s market share and prior year’s attributes. The two independently estimated shares are then normalized to ensure that they sum to one. As with the Sales Response model, the DFS utilizes values from one and two years preceding the analysis year when estimating the share of the fleet during the model year being evaluated. For the horsepower, curb weight, and fuel economy values occurring in the model years before the start of analysis, the DFS model uses the observed values from prior model years. After the first model year is evaluated, the DFS model relies on values calculated during analysis by the CAFE model. The DFS model begins by calculating the natural log of the new shares during each model year, independently for each vehicle class, as specified by the following equation:

¹⁶⁴⁴ EDF, Appendix B, NHTSA–2018–0067–12108, at 40–41.

Equation 5 – Dynamic Fleet Share Equation

$$\ln(\text{Share}_{VC,MY}) = \left(\begin{array}{l} \beta_C \times (1 - \beta_{Rho}) + \beta_{Rho} \times \ln(\text{Share}_{VC,MY-1}) \\ + \beta_{FP} \times (\ln(\text{Price}_{Gas,MY}) - \beta_{Rho} \times \ln(\text{Price}_{Gas,MY-1})) \\ + \beta_{HP} \times (\ln(\text{HP}_{VC,MY-1}) - \beta_{Rho} \times \ln(\text{HP}_{VC,MY-2})) \\ + \beta_{CW} \times (\ln(\text{CW}_{VC,MY-1}) - \beta_{Rho} \times \ln(\text{CW}_{VC,MY-2})) \\ + \beta_{MPG} \times (\ln(\text{FE}_{VC,MY-1}) - \beta_{Rho} \times \ln(\text{FE}_{VC,MY-2})) \\ + \beta_{Dummy} \times (\ln(0.423453) - \beta_{Rho} \times \ln(0.423453)) \end{array} \right)$$

Where:

- $\beta_C - \beta_{Dummy}$: set of beta coefficients, as defined by Table VI-156 below, used for tuning the Dynamic Fleet Share model,
- $\text{Share}_{VC,MY-1}$: the share of the total industry new sales classified as vehicle class VC , in the year immediately preceding model year MY ,
- $\text{Price}_{Gas,MY}$: the fuel price of gasoline fuel, in cents per gallon, in model year MY ,¹⁶⁴⁵,
- $\text{Price}_{Gas,MY-1}$: the fuel price of gasoline fuel, in cents per gallon, in the year immediately preceding model year MY ,

$\text{HP}_{VC,MY-1}$: The average horsepower of all vehicle models belonging to vehicle class VC , in the year immediately preceding model year MY ,

$\text{HP}_{VC,MY-2}$: The average horsepower of all vehicle models belonging to vehicle class VC , in the year preceding model year MY by two years,

$\text{CW}_{VC,MY-1}$: The average curb weight of all vehicle models belonging to vehicle class VC , in the year immediately preceding model year MY ,

$\text{CW}_{VC,MY-2}$: The average curb weight of all vehicle models belonging to vehicle class

VC , in the year preceding model year MY by two years,

$\text{FE}_{VC,MY-1}$: The average on-road fuel economy rating of all vehicle models (excluding credits, adjustments, and petroleum equivalency factors) belonging to vehicle class VC , in the year immediately preceding model year MY ,

$\text{FE}_{VC,MY-2}$: The average on-road fuel economy rating of all vehicle models (excluding credits, adjustments, and petroleum equivalency factors) belonging to vehicle class VC , in the year preceding model year MY by two years,

0.423453 : a dummy coefficient, and $\ln(\text{Share}_{VC,MY})$: The natural log of the calculated share of the total industry fleet classified as vehicle class VC , in model year MY .

In the equation above, the beta coefficients, β_C through β_{Dummy} , are provided in the following table. The beta coefficients differ depending on the vehicle class for which the fleet share is being calculated.

¹⁶⁴⁵ As discussed elsewhere in this final rule, model year and calendar year are assumed to be

equivalent in the simulation—as they always have been in all prior rulemaking analyses.

Table VI-156 – DFS Coefficients

| Coefficient | Car Value | Light Truck Value |
|---------------|-----------|-------------------|
| β_C | 3.4468 | 7.8932 |
| β_{Rho} | 0.8903 | 0.3482 |
| BFP | 0.1441 | 0.4690 |
| BHW | -0.4436 | 1.3607 |
| BCW | -0.0994 | 1.5664 |
| BMPG | -0.5452 | 0.0813 |
| BDummy | -0.1174 | 0.6192 |

Once the initial car and light truck fleet shares are calculated (as a natural log), obtaining the final shares for a

specific vehicle class is simply a matter of taking the exponent of the initial value, and normalizing the result at one

(or 100%). This calculation is demonstrated by the following:

Equation 6 – Normalizing individual fleet shares

$$Share_{VC,MY} = \frac{e^{\ln(Share_{VC,MY})}}{e^{\ln(Share_{LDV,MY})} + e^{\ln(Share_{LDT1/2a,MY})}}$$

Where:

- $\ln(Share_{VC,MY})$: the natural log of the calculated share of the total industry fleet classified as vehicle class *VC*, in model year *MY*,
- $\ln(Share_{LDV,MY})$: the natural log of the calculated share of the total industry fleet classified as light duty passenger vehicles (LDV), in model year *MY*,
- $\ln(Share_{LDT1/2a,MY})$: the natural log of the calculated share of the total industry fleet classified as class 1/2a light duty truck (LDT1/2a), in model year *MY*, and
- $Share_{VC,MY}$: the calculated share of the total industry fleet classified as vehicle class *VC*, in model year *MY*.

These shares are applied to the total industry sales derived in the first stage of the sales response. This produces total industry volumes of car and light truck body styles. Individual model sales are then determined from there based on the following sequence: (1) individual manufacturer shares of each body style (either car or light truck) times the total industry sales of that body style, then (2) each vehicle within a manufacturer's volume of that body-style is given the same percentage of sales as appear in the 2017 fleet. This implicitly assumes that consumer preferences for particular styles of vehicles are determined in the aggregate (at the industry level), but that

manufacturers' sales shares of those body styles are consistent with MY2017 sales. Within a given body style, a manufacturer's sales shares of individual models are also assumed to be constant over time. The agencies assume that manufacturers are currently pricing individual vehicle models within market segments in a way that maximizes their profit. Without more information about each OEM's true cost of production and operation, fixed and variable costs, and both desired and achievable profit margins on individual vehicle models, the agencies have no reason to assume that strategic shifts within a manufacturer's portfolio will occur in response to standards.

The Global Automakers noted in their comments that the market share of SUVs continues to grow, while conventional passenger car body-styles continue to lose market share.¹⁶⁴⁶ The agencies are aware of this, and include the DFS model in an attempt to address these market realities. In the 2012 final rule, the agencies projected fleet shares based on the continuation of the baseline standards (MY2012–2016) and a fuel price forecast that was much higher than the realized prices since that time. As a result, that analysis showed passenger car body-styles comprising

¹⁶⁴⁶ Global Automakers, Attachment A, NHTSA–2018–0067–12032, at 13.

about 70 percent of the new vehicle market by 2025. The reality, as Global Automakers note, has been quite different.

The coefficients of the DFS model show passenger car styles gaining share with higher fuel prices and losing them when prices are lower. Similarly, as fuel economy increases in light truck models, which offer consumers other desirable attributes beyond fuel economy (ride height or interior volume, for example) their relative share increases. NRDC, in particular, found this counterintuitive.¹⁶⁴⁷ However, this approach does not suggest that consumers *dislike* fuel economy in passenger cars, but merely recognizes the fact that fuel economy has diminishing returns. As the fuel economy of light trucks increases, the tradeoff between passenger car and light truck purchases increasingly involves a consideration of other attributes. Similarly, the coefficients show a relatively stronger preference for power improvements in cars than light trucks because that is an attribute where trucks have outperformed cars, like cars have outperformed trucks for fuel economy.

Rather than estimate new functions to determine relative market shares of cars and light trucks, the agencies applied existing functions from the transportation module of the National Energy Modeling System (NEMS) that was used to produce the 2017 Annual Energy Outlook. The functions above appear in the “tran.f” input file to that version of NEMS, and were embedded (in their entirety) in the CAFE model in the NPRM (and this final rule). NEMS uses the functions to estimate the percent of total light vehicles less 8,500

GVW that are cars/trucks. While NRDC asserted that the agencies must demonstrate the propriety of the fleet share model before relying on its estimates,¹⁶⁴⁸ they ignore the fact that, by using the AEO to develop a static fleet in prior rulemakings, the agencies have always relied on NEMS estimates. The primary difference between those analyses and the NPRM (and this final rule), is that prior analyses applied the fleet share that was simulated for the baseline to all regulatory scenarios considered. Based on the fleet share functions in NEMS, NPRM corrected this internal inconsistency found in previous analyses. This approach also enables consistent sensitivity cases—where higher fuel prices produce fleets with more transitional passenger car body styles, for example—and ensures that the starting point (MY 2017) evolves in response to both fuel economy improvements and fuel prices in a way that is internally consistent.

The agencies are making one change to the DFS function, which is the level of application. While NEMS intended the fleet shares to be defined by regulatory classes, vehicles are defined much more coarsely in NEMS than in the CAFE model, and manufacturers are not differentiated at all. In order to produce well-behaved fleet share projections with this model, the agencies applied the share functions to body-styles rather than regulatory classes. For many years, there was little overlap between nameplates in a manufacturer’s passenger car regulatory class and its light truck regulatory class. However, with the recent emergence of smaller FWD SUVs and crossovers, it is increasingly common to have nameplates with model variants in both

the passenger car and light truck regulatory classes, and it is also common for there to be only minor differences (like the presence of 4WD or AWD) between versions regulated as cars and versions regulated as light trucks. The agencies have modified the application of the fleet share equations to focus on body-style, rather than regulatory class, in recognition of the increased ambiguity between the regulatory class distinction for popular models like the Honda CR-V and Toyota RAV4, that sell more than 100K units in each regulatory class (typically using the same powertrain configuration). The Nissan Rogue sold more than 400K units in MY2017, and almost exactly half of them were in the light truck (LT) regulatory class. Applying the fleet share at the body-style level preserves the existing regulatory class splits for nameplates that straddle the class definitions. It also serves to minimize the deviation from the observed MY2017 regulatory class shares over time. Had the agencies applied the share equations at the regulatory class level, as some commenters incorrectly claimed the agencies were doing in the proposal, the passenger car regulatory class would have eroded much faster than we’ve seen in the real world and ceased to resemble the composition of the MY2017 fleet. Our implementation allows the passenger car (PC) regulatory class to continue evolving toward crossover-type cars, if that is what economic and policy conditions favor.¹⁶⁴⁹

¹⁶⁴⁹ The “passenger car” fleet for CAFE represents the combination of both imported passenger cars (IC) and domestic cars (DC). While Table VI–157 illustrates shares for the CAFE program, resulting shares under the tailpipe CO₂ emissions standards are comparable.

| 2025 | 0.53 | 0.47 | 0.55 | 0.45 | 0.55 | 0.45 |
| 2026 | 0.53 | 0.47 | 0.55 | 0.45 | 0.55 | 0.45 |
| 2027 | 0.53 | 0.47 | 0.55 | 0.45 | 0.55 | 0.45 |
| 2028 | 0.54 | 0.46 | 0.55 | 0.45 | 0.55 | 0.45 |
| 2029 | 0.54 | 0.46 | 0.56 | 0.44 | 0.55 | 0.45 |
| 2030 | 0.54 | 0.46 | 0.56 | 0.44 | 0.56 | 0.44 |

Table VI-157 shows the regulatory class shares under the baseline (augural standards), proposal (0 percent increase in stringency), and final rule (1.5 percent increase in stringency) between 2017 and 2030. The shares move relatively little between the classes in the baseline, with larger (but still small) deviations occurring in the least stringent alternative (0 percent increase) and the final rule. As the sensitivity cases show, the changes in shares (both over time and between regulatory classes) respond to the fuel price case, but remain internally consistent due to the inclusion of the DFS.

Some commenters encouraged the agencies to consider vehicle attributes beyond price and fuel economy when estimating a sales response to fuel economy/CO₂ standards, and suggested that a more detailed representation of the new vehicle market would allow the agencies to simulate strategic mix shifting responses from manufacturers and diverse attribute preferences among consumers. Doing so would have required a discrete choice model (at some level), and below the reasons why the agencies have not chosen to employ that approach in this final rule.

d) Using Vehicle Choice Models in Rulemaking Analysis

Some commenters argued that the NPRM's statistical model used to estimate changes in sales between alternatives was too highly aggregated

and missed consumers' valuation of other vehicle attributes. CARB, Cities and States, and EDF all made some version of the argument that the sales model in the NPRM operated at too high a level of aggregation to estimate the real sales response, which primarily occurs at the model level where consumers are making decisions based on the comprehensive set of attributes and body styles available in the market. They also argued that a model must operate at the same level, such as a discrete choice model, in order to capture consumer response accurately. EPA's Science Advisory Board, Bento, Toyota, Automobile Alliance, RFF, and Bunch (writing on behalf of CARB) insisted that the best approach to estimating the change in sales across alternatives is to use a discrete choice model and embed it in the simulation.

Other commenters expressed different views on the importance of a consumer choice model. For example, while the Aluminum Association supported a consumer choice model, they suggested that total new vehicle sales may not change due to increases in price, but rather the attributes of new vehicles would shift, as consumers would likely shift their purchases toward lower content vehicles (in terms of safety, luxury, or other option content) when faced with generally higher prices. Other commenters, including UCS and CBD, strongly encouraged the agencies to avoid using consumer choice models;

commenters asserted that consumer choice models have historically lacked reliability and predictive power.¹⁶⁵⁰

In general, these various comments present the agencies with considerably different suggestions on how to address these issues, and certain suggestions are in direct opposition to each other. That is, while some commenters argue that only micro-level consumer responses are relevant to the analysis, and that a consumer choice model is required to estimate these responses, others argue that it is inappropriate to use a discrete choice model—the method by which those responses are econometrically estimated—in a regulatory analysis. Adding to the confusion, some of the same commenters who argued against a consumer choice model,¹⁶⁵¹ also argued that it was necessary for the analysis to account for the influence of other vehicle attributes in purchasing decisions, which would require incorporating a discrete choice model.

CARB argued that “accurately capturing the relative impact of sales shifts versus no-buy decisions would require a more detailed consumer choice model, as recommended by the CAFE Model peer reviewers. The current new vehicle sales model has no

¹⁶⁵⁰ UCS, Technical Appendix, NHTSA-2018-0067-12039 at 50.

¹⁶⁵¹ For example, see EDF, NRDC, RFF, NCAT, and CBD comments.

way of capturing these types of effects.”¹⁶⁵²

David Bunch, writing for CARB, said, “In fact, in previous versions of the CAFE model there were no attempts to directly simulate consumer response from *within* the CAFE model at all. Instead, NHTSA relied on fixed projections of future vehicle market behavior from multiple sources for the purpose of performing the required economic cost and benefit calculations. While this might possibly be less than ideal, this approach is only a problem if, in the real world, there [are] notable *differences* in future market behavior [that] occur under different regulation scenarios, and, moreover, that these differences would be large enough to compromise the validity of the net benefit comparisons.” Bunch essentially argues that the old approach, asserting that standards can have no impact on sales, even at the individual model level, is more appropriate than trying to capture the general idea that when all new vehicles get more expensive, consumers are likely to buy fewer of them, all else being equal. The agencies disagree with that perspective.

There are a number of practical challenges to using estimates of consumer attribute preferences to simulate market responses. Discrete choice models typically rely on fixed effects (or alternative-specific constant terms) to account for the unobserved characteristics of a given model that influence purchasing decisions, such as styling,¹⁶⁵³ but are not captured by independent variables that represent specific vehicle attributes (horsepower, interior volume, or safety rating, for example). Ideally, these constant terms would contribute relatively little to the fit and performance of the model, assuming that the most salient characteristics are accounted for explicitly. In practice, this is seldom the case. While the fixed effects at the model level are statistically sound

estimates of consumer preferences for the unobserved vehicle characteristics of the individual models, the estimates are inherently historical—based on observed versions of the specific vehicle models to which they belong. However, once the simulation starts, and new technologies are added to each manufacturer’s product portfolio over successive generations, it is no longer obvious that those constant terms would still be valid in the context of those changes.

Another complication is that discrete choice models are highly dependent on their inputs and are unable to account for future market changes. For example, the Draft TAR relied on a MY 2014 market (for EPA’s analysis) and a MY 2015 market (for NHTSA’s analysis), while the NPRM used a MY 2016 fleet, and this final rule has updated the market characterization to a MY 2017 fleet. A discrete choice model estimated on any of those model years would probably produce different fixed effects estimates for each model variant in the fleet. Even assuming that no new variants of a given model are offered over time, new nameplates emerge as others are retired—and for those new nameplates and all of their model variants, no constant terms would exist. They would have to be imputed (either from comparable vehicles in the market, some combination of their attributes, or both). Some studies have attempted to estimate fixed effects for a single new entrant to the market,¹⁶⁵⁴ but none have attempted to do so at the scale required to migrate a discrete choice model fit on an earlier model year to a newer model year for simulation.

Figure VI–65 shows the cumulative percentage of nameplates in the 2017 new vehicle market by year of introduction. About ten percent of nameplates in 2017 have been around since the 1970s, but another ten percent have only existed since about 2010. This fact illustrates the likely necessity of

constructing vehicle model fixed effects for the inevitable new entrants between the estimating fleet and the rulemaking fleet. But it also suggests another challenge. New model entrants are driven by the dynamics of the market, where some vehicle models succeed and others fail, but a simulated market with a discrete choice model can only simulate failure—where consumer demand for specific nameplates erode to the point that the nameplate volumes trend toward zero. It has no mechanism to generate new nameplates to replace those nameplates whose sales it estimates will erode beyond some minimal practical level of production.

Consumer choice models are typically fit on a single year of data (a cross-section of vehicles and buyers), but this approach misses relevant trends that build over time, such as rising GDP or shifting consumer sentiment toward emerging technologies. If such a model is used to estimate total sales, but lacks trends in GDP growth or employment, etc., it will have the wrong set (likely a smaller set) of new vehicle buyers and exaggerate price responses and attribute preferences. Consumer preferences change over time in response to any number of factors—given manufacturers’ recent investments in electric powertrains, they are counting on this fact. But a choice model estimated on observed consumer preferences for EVs—or other vehicle attributes with comparatively little experience in the market—would necessarily disadvantage a technology that is currently (or only recently) unpopular, but gaining popularity. While these are problems that may not matter in the estimation process, where a researcher is attempting to measure revealed consumer preference for given attributes at a single point in time, they become material once that model is integrated into the simulation and dynamically carried forward for three decades. The agencies note that models that examine aggregate trends, such as the one utilized in this analysis, are able to side-step this issue by not placing a value on unique vehicle attributes.

¹⁶⁵² CARB, Detailed Comments, NHTSA–2018–0067–11873, at 192.

¹⁶⁵³ Aesthetics such as styling are difficult, if it not impossible, to define in a manner that allows meaningful comparison between choices.

Figure VI-65 – Nameplate Introduction and Attrition

The agencies' compliance simulation model estimates the additional cost of technology required to achieve compliance, or to satisfy market demand for additional fuel economy. While it necessarily calculates these costs on a per-vehicle basis, estimating the cost of additional technologies as they are applied to each specific model in order to bring an entire fleet into compliance, it is agnostic about how these costs are distributed to buyers. Manufacturers have strategic, complex pricing models that rely on extensive market research and reflect each company's strategic interests in each segment. Automobile companies attempt to maximize profit from the sale of their vehicles, rather than solely focusing on minimizing the cost of compliance, as this rulemaking simulates. Lacking reliable data for each manufacturer on production costs and profit margins for each vehicle model in their portfolios, the most reasonable course of action is to simulate compliance as if OEMs are attempting to minimize costs, and, worth noting, this approach is also the one NHTSA takes in its rulemakings related to the FMVSS. However, it is obvious that some market segments and individual models are much less elastic than others.¹⁶⁵⁵ As reflected in the prices of those models,

consumers are able to bear a greater share of the total cost of compliance before negatively affecting sales and manufacturer profits.

Several commenters (CARB, CBD, IPI, and Bento et al.) suggested that the agencies should employ a pricing model that allows manufacturers to vary prices in response to heterogeneous consumer preferences and different levels of willingness to pay for fuel economy, and other attributes, in the new vehicle market. Fundamentally, this would require the agencies to model strategic pricing for each manufacturer individually—no single pricing model would be appropriate for every manufacturer. Bento et al. stated that the agencies should simulate the market by allowing manufacturers to dynamically adjust vehicle prices to ensure compliance with the standards.¹⁶⁵⁶ There is no reasonable expectation that the agencies could embed and utilize each manufacturer's pricing strategy, as this is an essential feature of competitive corporate behavior and that automakers closely hold pricing strategy information and the agencies have insufficient information to model manufacturer pricing strategies. Furthermore, models in the academic literature that commenters have suggested are superior because they allow prices to adjust, merely

demonstrate that the mechanics of those adjustments work; they do not imply that the resulting prices are reasonable or realistic. Given the burden to estimate each manufacturer's standard under the attribute-based system, where the mix of vehicles sold defines not only the achieved fuel economy of each fleet but also the standard to which it is compared, the agencies are understandably reluctant to implement models that might shift a manufacturer's mix of vehicles sold within a market segment.

Bunch suggested the agencies use a joint model of household vehicle holdings and sales that encompasses decisions to purchase new vehicles, retain existing ones, or reduce or augment current holdings of vehicles of all types and vintages in each period. Manufacturers would modify either new vehicle content, prices, or both to produce a supply of new vehicles that allowed them each to comply with standards. And, subsequently, households and manufacturers would iteratively interact until the market reached equilibrium. The model described by Bunch would face many of the same issues outlined above. There are significant econometric challenges associated with estimating a household's decision to buy a new vehicle instead of a used vehicle (of some vintage), or to maintain its current set. And integrating such a model would

¹⁶⁵⁵ See, for example, Kleit, A.N. (2004), Impacts of Long-Range Increases in the Fuel Economy (CAFE) Standard. *Economic Inquiry*, 42: 279–294. doi:10.1093/ei/cbh060.

¹⁶⁵⁶ NHTSA–2018–0067–12326 at 10.

require the agencies to simulate the dynamics of the used vehicle market—hundreds of unique nameplates for each of dozens of vintages—in order to provide the correct choice set in each simulated year. Such a model is beyond the scope of the current analysis.

While the agencies believe that these challenges provide a reasonable basis for not employing a discrete choice model in today's final rule analysis, the agencies also believe they are not insurmountable, and that some suitable variant of such models may yet be developed for use in future fuel economy and CO₂ emissions rulemakings. The agencies have not abandoned the idea and plan to continue experimenting with econometric specifications that address heterogeneous consumer preferences in the new vehicle market as they further refine the analytical tools used for regulatory analysis.

Operating at the level of individual auto and light truck model variants—the same level at which compliance is, necessarily, simulated—may not be tractable for rulemaking analyses. However, market shares for brands and manufacturers within market segments are more stable over time—even if the volumes of segments across the industry fluctuate. In the 2012 final rule, the agencies' analysis showed a new vehicle market where the share of passenger car body styles—sedans, coupes, hatchbacks—reached almost 70 percent of the new vehicle market by 2025, while light trucks, including many crossovers, accounted for the remaining 30 percent. Those results were consistent with the assumptions made in 2012, but the combination of low fuel prices and decreasing differences in fuel consumption between body styles has instead reduced the market share of those body styles significantly (only 40% in the MY 2017 fleet), and, thus eroded the value of the 2012 analysis to inform current decisions. Including a choice model that operated on existing market shares, albeit at a higher level of aggregation than specific nameplates, such as brand/segment/powertrain, may be able to improve internal consistency with the interaction of assumptions about fuel prices and regulatory alternatives. The agencies will continue to engage with the academic community and other stakeholders to ensure that future work on this question improves our analysis of regulatory alternatives.

3) Scrappage

a) The Impacts of New Vehicle Fuel Economy Standards on Fleet Turnover

Economic literature and theory indicate that the retirement (or scrappage) rates of existing vehicles slows when new vehicle fuel economy standards increase and cause new vehicle price increases. Slower retirement rates result in an older distribution of the on-road fleet. Today's on-road fleet is the oldest it has ever been, approaching an average of 12 years old.¹⁶⁵⁷ Since older vehicles are, on average, less safe and less fuel efficient, modeling this reduction in the scrappage rates of existing vehicles has important implications. As mentioned in the sales section above, past quantitative analyses of CO₂ and CAFE standards excluded the scrappage effect (though the agencies discussed the scrappage effect qualitatively), which could have resulted in an overestimate of the benefits of increasing standards.

For the NPRM, the agencies chose for the first time to model the change in existing vehicle retirement rates across regulatory alternatives. The agencies used a logistic function to estimate the instantaneous scrappage rate for vehicles of different body styles and model year vintages using registration data from Polk, the estimated durability of specific model year vintages, the prices of new vehicles, a measure of the cost of travel for the model year cohort versus new vehicles in any given calendar year, and other cyclical macroeconomic indicators.¹⁶⁵⁸

The agencies received many comments about the NPRM's scrappage model. While some commenters objected to the inclusion of a scrappage model, most commenters supported the inclusion of a dynamic scrappage model as an improvement in the agencies' analysis; these comments are discussed in Section VI.C.1.b(3)(a)(ii). Other commenters raised concerns about the specific scrappage models used in the NPRM analysis; these are discussed in Section VI.C.1.b(3)(b). Specifically, commenters raised concerns about overfitting in the models, the identification strategy, the modeling of new and used vehicle fuel economy in general, the exclusion of certain variables, about how the agencies captured macroeconomic effects, and

about the lack of integration with the sales model.

The agencies contemplated all of the comments and suggestions made by commenters and, in response, have made several changes to final rule's model. First, the agencies changed the time-series strategy used in the model, as discussed in Section VI.C.1.b(3)(c)(iii)(a). This change allows the agencies to simplify the models significantly, addressing commenters' concerns about potential overfitting of the model and difficulty of interpreting individual coefficient values (discussed in Section VI.C.1.b(3)(b)(i)). Second, the agencies changed the modeling of the durability effect as discussed in Section VI.C.1.b(3)(c)(iii)(c); this change reduces the reliance on the decay function and has the added benefit of addressing concerns about overfitting and out-of-sample projections discussed in Section VI.C.1.b(3)(b)(i). Third, a portion of anticipated fuel savings from increased fuel economy are netted from new vehicle prices—meaning consumers are now assumed to value fuel economy at the time of purchase to a certain extent—as discussed in Section VI.C.1.b. This change is in response to comments discussed in Section VI.C.1.b(3)(c)(iii)(d) and addresses inconsistent treatment of consumer valuation within the NPRM's analysis. Finally, the agencies consider the inclusion of additional or alternative variables in the scrappage model in response to comments discussed in Section VI.C.1.b(3)(b)(ii). After extensive testing, the agencies concluded that these additional variables do not improve the model fits or would introduce autocorrelation in the error structures (see Sections VI.C.1.b(3)(c)(iii)(e) and VI.C.1.b(3)(c)(iii)(f) for further discussion). As such, the agencies rejected the additional terms suggested by commenters. Input from commenters was used to simplify the scrappage model, make it more consistent with modeling of new vehicle prices elsewhere in the analysis, and improve its predictions for the instantaneous scrappage rates of vehicles beyond age 20.

i) Basis for 'The Gruenspecht Effect'

Gruenspecht (1981) and (1982) recognized that since fuel economy standards affect only new vehicles, any increase in price (net of the portion of reduced fuel savings valued by consumers) will increase the expected life of used vehicles and reduce the number of new vehicles entering the fleet. The effects of differentiated regulation in the context of fuel

¹⁶⁵⁷ Bureau of Transportation Statistics (BTS). "Average Age of Automobiles and Trucks in Operation in the United States." Available at <https://www.bts.gov/content/average-age-automobiles-and-trucks-operation-united-states>.

¹⁶⁵⁸ For a more detailed explanation of the NPRM model, see PRIA Chapter 8.10.

economy is often deemed the *Gruenspecht Effect*.¹⁶⁵⁹ Jacobsen and van Benthem (2015) first quantified the Gruenspecht Effect, or the share of new vehicle fuel savings lost to the used vehicle fleet due to delayed scrappage, to be between 13 and 16 percent.¹⁶⁶⁰

As discussed in the write up of the sales model, fuel economy standards increase the cost of acquiring new vehicles, but also improve the quality of those vehicles by increasing their fuel economy. The CAFE analysis assumes that consumers value 30 months of fuel savings, so that the quality-adjusted change in new vehicle prices is the increase in regulatory costs less 30 months of fuel savings. As long as the quality-adjusted price is positive,¹⁶⁶¹ it becomes more expensive for manufacturers to produce vehicles and, as a result, prices of new vehicles increase. From a supply and demand perspective, this equates to the supply curve for new vehicles moving inwards or to the left and a corresponding increase in the equilibrium price and decrease in the equilibrium quantity of new vehicles purchased.

New and used vehicles are substitutes. When the price of a good's substitute increases, the demand curve for that good shifts upwards and the equilibrium price and quantity supplied also increases. Thus, increasing the quality-adjusted price of new vehicles will result in an increase in equilibrium price and quantity of used vehicles. Since, by definition, used vehicles are not being "produced" but rather "supplied" from the existing fleet, the increase in quantity must come via a reduction in their scrappage rates. Practically, when new vehicles become more expensive, demand for used vehicles increases (and they become more expensive). Because used vehicles are more valuable in such circumstances, they are scrapped at a lower rate, and just as rising new vehicle prices push marginal prospective buyers into the used vehicle market, rising used vehicle prices force marginal prospective buyers of used vehicles to acquire older vehicles or vehicles with fewer desired attributes.

ii) Commenter Response to the Inclusion of the Gruenspecht Effect

(a) Many Commenters Support the Inclusion of the Effect

Academic researchers and automakers widely agree with the existence and direction of the Gruenspecht Effect. For example, RFF commented, "There's good evidence supporting the scrappage effect."¹⁶⁶² The Auto Alliance stated that the agencies "made significant strides toward improving their modeling of consumer behavior by adding new modules to estimate new vehicle sales and in-use vehicle scrappage in response to changes to new vehicle prices."¹⁶⁶³ FCA agreed "that an outcome of the current augural stringency of the CAFE/[CO₂] emission regulations may be a decreasing trend in vehicle scrappage rates as consumers delay purchases [. . .] forc[ing] consumers to hold their current vehicles for additional time."¹⁶⁶⁴

Other commenters agreed with the existence of the effect, but took issue with the implications of the combination of the sales and scrappage models. Mark Jacobsen stated "while we agree that the scrappage effects we study will mitigate changes in the used fleet, we do not believe they could be strong enough to reverse completely the direction of change in the used fleet."¹⁶⁶⁵ Jacobsen's contention was echoed by many commenters; the main point was that they believed that the prices of both new and used vehicles should be less expensive in the NPRM's preferred alternative than the augural standards, and that this should, if anything, result in a larger fleet in the NPRM's preferred alternative. This issue is further discussed in Section (b)(iv) with other comments about integrating the sales and scrappage models and the incremental fleet size across alternatives. Here it is important to note that this concern does not suggest that a scrappage model *should not exist*, but takes issue with the *specific modeling* of scrappage and/or sales implemented in the NPRM analysis.

b) Some Commenters Worry About the Shift in Agency Perspective

Some commenters argued that the agencies modeling of sales and scrappage in the NPRM analysis

contradicted previous positions that these effects were too uncertain to model. For example, the Center for Biological Diversity (CBD) commented:

In the 2012 rulemaking for fuel economy and [CO₂] standards, both NHTSA and EPA stated that analysis of the standards' impact on new vehicles sales and on the "scrappage" of used vehicles was too uncertain to be used in the rulemaking. The agencies reiterated this position in their 2016 technical assessment of the standards.¹⁶⁶⁶

They further stated:

The agencies have not provided a meaningful rationale or justification for the change in position regarding their ability to present quantified estimates of the impact of the standards on new vehicle sales and the scrappage of used vehicles.¹⁶⁶⁷

To respond to these comments, it is useful to look at the reasons the agencies gave for not considering fleet turnover effects on pages 845–46 of the 2012 rulemaking:

If the value of fuel savings resulting from improved fuel efficiency to the typical potential buyer of a new vehicle outweighs the average increase in new models' prices, sales of new vehicles will rise, while scrappage rates of used vehicles will increase slightly. This will cause the "turnover" of the vehicle fleet—that is, the retirement of used vehicles and their replacement by new models—to accelerate slightly, thus accentuating the anticipated effect of the rule on fleet-wide fuel consumption and CO₂ emissions. However, if potential buyers value future fuel savings resulting from the increased fuel efficiency of new models at less than the increase in their average selling price, sales of new vehicles will decline, as will the rate at which used vehicles are retired from service. This effect will slow the replacement of used vehicles by new models, and thus partly offset the anticipated effects of the final rules on fuel use and emissions.

*Because the agencies are uncertain about how the value of projected fuel savings from the final rules to potential buyers will compare to their estimates of increases in new vehicle prices, we have not attempted to estimate explicitly the effects of the rule on scrappage of older vehicles and the turnover of the vehicle fleet.*¹⁶⁶⁸

The agencies' reason for not modeling the fleet turnover effects in prior rulemakings was not uncertainty about the direction or impact of vehicle prices on sales or scrappage rates, but rather uncertainty about how consumers value fuel savings. The agencies now have sufficient knowledge regarding the amount of fuel savings consumers are assumed to value at the time they purchase new vehicles and make these

assumptions in the technology application simulation. With this assumption, it becomes possible to model the fleet turnover effects, including the scrappage effect.

c) Some Commenters Think the Effects Are Uncertain

Other commenters argue that the sales and scrappage effects are too uncertain to include in a rulemaking analysis. For example, CBD argued that “the models are attempting to evaluate the small and uncertain effects of changes in vehicle standards on certain dynamics—vehicle sales, scrappage rates, and vehicle usage—which are largely determined by much stronger forces, such as the state of the economy.”¹⁶⁶⁹

The agencies agree that there is uncertainty around the magnitude of the sales and scrappage response, but do not agree that sign of either effect is uncertain. Importantly, excluding modeling of the sales and scrappage effects would only make sense if there was a legitimate existential concern—the sales and scrappage effects are founded in very basic economic theory, as noted above, in Section VI.C.1.b)(3)(a)(i). Furthermore, the agencies believe that assessing the magnitudes of the sales and scrappage effects is a tractable task for researchers and sufficient data exists to quantify these effects. Thus, excluding these effects would be a serious omission that limits accurate accounting of the costs and benefits of fuel economy standards. Other stakeholders commented that the NPRM analysis did not thoroughly consider the uncertainty around the magnitudes of the sales and scrappage responses. These comments and the agencies response is discussed in Section VI.C.1.b)(3)(b)(i), below. The agencies believe it is better to consider a range of the scrappage and sales response to address concerns about uncertainty, and that excluding them would be inappropriate.¹⁶⁷⁰ The agencies did just that with the proposal through sensitivity analyses—including seeking comment and having the scrappage modeling peer reviewed—and continue to do so for the final rule.

b) Summary of Notice, Request for Comments, and the Agencies’ Response

The comments related to the scrappage model are summarized here

into five major categories: Overfitting and identification strategies, modeling fuel economy and new vehicle prices, consideration of other additional variables, integration with sales or VMT, and evaluations of associated costs and benefits due to changes in scrappage rates within the CAFE model. Specific modeling decisions the agencies have made or considered in response to the public comments summarized in this section are discussed in Sections VI.C.1.b)(3)(c)(ii)(d) and VI.C.1.b)(3)(c)(iii).

i) Overfitting and Identification Strategy

Several commenters argued that the NPRM scrappage model did not have a clear identification strategy, or that the model *over-fit* the data. These commenters suggest that the NPRM model may not capture a causal relationship, but picks up other correlation or noise within the data. This section outlines the specific claims made by commenters.

a) Overfitting and the Use of Lagged and Interactions Terms

Several commenters argued that the results presented in the NPRM could be driven by the specific structure of the price effect used in the scrappage models that were implemented into the CAFE Model. IPI, California States et. al., CARB, and other commenters suggested that the NPRM model is overfit. CARB outlined its argument that the agencies overfit the data in the following passage:
